In pregnant women, the important caveat is that normal findings with venous ultrasonography results do not always exclude a pulmonary embolism. This is because the thrombosis may have already embolized or because it arose from iliac or other deep-pelvic veins, which are less accessible to ultrasound evaluation (Goldhaber, 2004). Thrombosis associated with pulmonary embolism during pregnancy frequently originates in the iliac veins. Although serial investigations are recommended by many, Le Gal and colleagues (2012) recently studied the use of nonserial proximal and distal compression ultrasonography in 226 pregnant and postpartum women with suspected deep-vein thrombosis. Deep-vein thrombosis was diagnosed in 10 percent. Of the 177 women without a deep-vein thrombosis and who were not anticoagulated, two had an objectively confirmed thrombosis diagnosed within three months. Thus, these preliminary data suggest that a negative single complete compression ultrasonography study may safely exclude the diagnosis of deep-vein thrombosis in most pregnant women.

Magnetic Resonance Imaging

This imaging technique allows excellent delineation of anatomical detail above the inguinal ligament. Thus, in many cases, magnetic resonance (MR) imaging is immensely useful for diagnosis of iliofemoral and pelvic vein thrombosis. The venous system can also be reconstructed using MR venography as discussed in Chapter 46 (Fig. 46-5, p. 936). Erdman and associates (1990) reported that MR imaging was 100-percent sensitive and 90-percent specific for detection of venographically proven deep-vein thrombosis in nonpregnant patients. Importantly, almost half of those without deep-vein thrombosis were found to have nonthrombotic conditions that included cellulitis, myositis, edema, hematomas, and superficial phlebitis.

Khalil and coworkers (2012) used magnetic resonance venography to study the natural history of pelvic vein thrombosis after vaginal delivery. Among the 30 asymptomatic patients who were all within four days of delivery, 30 percent had a definitive thrombosis in either the iliac or ovarian veins, and another 37 percent had a suspected thrombosis. Our experience with hundreds of postpartum MR scans does not support these findings. Thus, although the clinical significance of their findings is uncertain, it seems clear that some degree of pelvic vein intraluminal filling defect may be a normal finding.

D-Dimer Screening Tests

These specific fibrin degradation products are generated when fibrinolysin degrades fibrin, as occurs in thromboembolism (Chap. 41, p. 809). Their measurement is frequently incorporated into diagnostic algorithms for venous thromboembolism in nonpregnant patients (Kelly, 2002; Wells, 2003). Screening with the D-dimer test in pregnancy, however, is problematic for a number of
reasons. As shown in the Appendix (p. 1288), depending on assay sensitivity, D-dimer serum levels increase with gestational age along with substantially elevated plasma fibrinogen concentrations (McCrae, 2014). Levels are also affected by multifetal gestation and cesarean delivery (Morikawa, 2011). In a serial study of 50 healthy women, Kline and colleagues (2005) found that D-dimer levels increased progressively during pregnancy. Also, 22 percent of women in midpregnancy and no women in the third trimester had a D-dimer concentration below 0.50 mg/L—a conventional threshold used to exclude thromboembolism. D-Dimer concentrations can also be elevated in certain pregnancy complications such as placental abruption, preeclampsia, and sepsis syndrome. For these reasons, their use during pregnancy remains uncertain, but a negative D-dimer test should be considered reassuring (Lockwood, 2012; Marik, 2008).

Venography
Invasive contrast venography is the gold standard to exclude lower extremity deep-vein thrombosis (Chunilal, 2001). It has a negative-predictive value of 98 percent, and as discussed in Chapter 46 (p. 932), fetal radiation exposure without shielding is approximately 3 mGy (Nijkeuter, 2006). That said, venography is associated with significant complications, including thrombosis, and it is time consuming and cumbersome. Because of this, noninvasive methods are used primarily to confirm the diagnosis, and venography is seldom used today.

Management
Optimal management of venous thromboembolism during pregnancy has not undergone major clinical study to provide evidence-based practices. There is, however, consensus for treatment with anticoagulation and limited activity. If thrombophilia testing is performed, it is done before anticoagulation because heparin induces a decline in antithrombin levels, and warfarin decreases protein C and S concentrations (Lockwood, 2002).

Anticoagulation is initiated with either unfractionated or low-molecular-weight heparin. Although either type is acceptable, most recommend one of the low-molecular-weight heparins. In its recently revised guidelines, for example, the American College of Chest Physicians suggests preferential use of low-molecular-weight heparin during pregnancy because of better bioavailability, longer plasma half-life, more predictable dose response, reduced risks of osteoporosis and thrombocytopenia, and less frequent dosing (Bates, 2012).

During pregnancy, heparin therapy is continued, and for postpartum women, anticoagulation is begun simultaneously with warfarin. Recall that pulmonary embolism develops in as many as 60 percent of patients with untreated venous thrombosis, and anticoagulation decreases this risk to less than 5 percent. In nonpregnant patients, the mortality rate is approximately 1 percent (Douketis, 1998; Pollack, 2011).

Over several days, leg pain dissipates. After symptoms have abated, graded ambulation should be started. Elastic stockings are fitted, and anticoagulation is continued. Recovery to this stage usually takes 7 to 10 days. Graduated compression stockings should be continued for 2 years after the diagnosis to reduce the incidence of postthrombotic syndrome (Brandjes, 1997). This syndrome can include chronic leg paresthesias or pain, intractable edema, skin changes, and leg ulcers.

Unfractionated Heparin
This agent should be considered for the initial treatment of thromboembolism and in situations in
which delivery, surgery, or thrombolysis may be necessary (p. 1039) (American College of Obstetricians and Gynecologists, 2011). Unfractionated heparin (UFH) can be administered by one of two alternatives: (1) initial intravenous therapy followed by adjusted-dose subcutaneous UFH given every 12 hours; or (2) twice-daily, adjusted dose subcutaneous UFH with doses adjusted to prolong the activated partial thromboplastin time (aPTT) into the therapeutic range 6 hours postinjection (Bates, 2012). As shown in Table 52-5, the therapeutic dose for subcutaneous UFH is usually 10,000 units or more every 12 hours.

Abbreviations: aPTT, activated partial thromboplastin time; INR, international normalized ratio; LMWH, low molecular weight heparin; SC, subcutaneously; UFH, unfractionated heparin.

*Although at extremes of body weight, modification of dose may be required.
† Also referred to as weight adjusted, full treatment dose.

For intravenous therapy, there are a number of acceptable protocols. In general, UFH is initiated with a bolus intravenous dose of 70 to 100 U/kg, about 5000 to 10,000 U, followed by continuous intravenous infusions beginning at 1000 U/hr or 15 to 20 U/kg/hr, titrated to achieve an aPTT of 1.5 to 2.5 times control values (Brown, 2010). Intravenous anticoagulation should be maintained for at least 5 to 7 days, after which treatment is converted to subcutaneous heparin to maintain the aPTT to at least 1.5 to 2.5 times control throughout the dosing interval. For women with antiphospholipid syndrome, aPTT does not accurately assess heparin anticoagulation, and thus anti-factor Xa levels are preferred.
The duration of full anticoagulation varies, and there are no studies that have defined the optimal duration for pregnancy-related thromboembolism. In nonpregnant patients with venous thromboembolism, evidence supports a minimum treatment duration of 3 months (Kearon, 2012). For pregnant patients, the American College of Chest Physicians recommends anticoagulation throughout pregnancy and postpartum for a minimum total duration of 3 months (Bates, 2012). Lockwood (2012) recommends that full anticoagulation be continued for at least 20 weeks followed by prophylactic doses if the woman is still pregnant. Prophylactic doses of subcutaneous unfractionated heparin can range from 5000 to 10,000 units every 12 hours titrated to maintain an anti-factor Xa level of 0.1 to 0.2 units, measured 6 hours after the last injection. If the venous thromboembolism occurs during the postpartum period, Lockwood (2012) recommends a minimum of 6 months of anticoagulation treatment.

**Low-Molecular-Weight Heparin**

This is a family of derivatives of unfractionated heparin, and their molecular weights average 4000 to 5000 daltons compared with 12,000 to 16,000 daltons for conventional heparin. None of these heparins cross the placenta, and all exert their anticoagulant activity by activating antithrombin. The primary difference is their relative inhibitory activity against factor Xa and thrombin (Garcia, 2008). Specifically, unfractionated heparin has equivalent activity against factor Xa and thrombin, but low-molecular-weight heparins (LMWH) have greater activity against factor Xa than thrombin. They also have a more predictable anticoagulant response and fewer bleeding complications than unfractionated heparin because of their better bioavailability, longer half-life, dose-independent clearance, and decreased interference with platelets (Tapson, 2008). These LMWH compounds are cleared by the kidneys and must be used cautiously when there is renal dysfunction.

A number of studies have shown that venous thromboembolism is treated effectively with LMWH (Quinlan, 2004; Tapson, 2008). Using serial venograms, Breddin and associates (2001) observed that these compounds were more effective than UFH in reducing thrombus size without increasing mortality rates or major bleeding complications. Several different treatment regimens using adjusted-dose LMWH for treatment of acute venous thromboembolism are recommended by the American College of Obstetricians and Gynecologists (2011) and are listed in Table 52-5.

**Pharmacokinetics in Pregnancy**

Low-molecular-weight heparins available for use in pregnancy include enoxaparin, tinzaparin, and dalteparin. Enoxaparin (Lovenox) pharmacokinetics were studied by Rodie and coworkers (2002) in 36 women with venous thromboembolism during pregnancy or immediately postpartum. The dose was approximately 1 mg/kg given twice daily based on early pregnancy weight. Treatment was monitored by peak anti-factor Xa activity 3 hours postinjection, with a target therapeutic range of 0.4–1.0 U/mL. In 33 women, enoxaparin provided satisfactory anticoagulation. In the other three women, dose reduction was necessary. None developed recurrent thromboembolism or bleeding complications. Smith and colleagues (2004) reported similar results with tinzaparin (Innohep) given as a once-daily 50 U/kg dose. They found that a dosage of 75 to 175 U/kg/day was necessary to achieve peak anti-factor Xa levels of 0.1 to 1.0 U/mL.

Dalteparin (Fragmin) pharmacokinetics were studied by Barbour (2004) and Jacobsen (2003) and their associates in longitudinal studies of 13 and 20 pregnant women, respectively. Both groups of investigators concluded that conventional starting doses of dalteparin—100 U/kg every 12 hours—were likely insufficient to maintain full anticoagulation and that slightly higher doses
than that shown in Table 52-5 may be required. As an aside, several groups of investigators have found in preliminary studies that dalteparin use is associated with shorter labors (Ekman-Ordeberg, 2010; Isma, 2010). If these observations are verified, then the mechanism of action may involve increased cytokine secretion as in vitro studies suggest.

Dosing and Monitoring

Standard prophylactic and therapeutic dosages recommended by the American College of Obstetricians and Gynecologists (2011) for various LMWHs are listed in Table 52-5. Whether such dosages require adjustments during the course of pregnancy is controversial (Cutts, 2013). Some suggest periodic measurement of anti-factor Xa levels 4 to 6 hours after an injection with dose adjustment to maintain a therapeutic level. According to Bates and coworkers (2012), large studies using clinical end points that demonstrate an optimal therapeutic range or that show dose adjustments increase therapy safety or efficacy are lacking. Moreover, assay measurement accuracy and reliability are uncertain; correlations with bleeding and recurrence risks are lacking; and assay costs are high. Accordingly, the American College of Chest Physicians has concluded that routine monitoring with anti-Xa levels is difficult to justify.

Safety in Pregnancy

Early reviews by Sanson (1999) and Lepercq (2001), each with their colleagues, concluded that low-molecular-weight heparins were safe and effective. Despite this, in 2002, the manufacturer of Lovenox warned that its use in pregnancy had been associated with congenital anomalies and an increased risk of hemorrhage. After its own extensive review, the American College of Obstetricians and Gynecologists (2002) concluded that these risks were rare, that their incidence was not higher than expected, and that no cause-and-effect relationship had been established. It further concluded that enoxaparin and dalteparin could be given safely during pregnancy, and subsequent reports have continued to confirm their safety (Andersen, 2010; Bates, 2012; Deruelle, 2007; Galambosi, 2012).

Nelson-Piercy and coworkers (2011) assessed the safety profile of tinzaparin through a comprehensive study of 1267 pregnant women treated at 28 participating hospitals in North America and Europe. There were no maternal deaths or complications from regional analgesia. Although thrombocytopenia developed in 1.8 percent, there were no cases of heparin-induced thrombocytopenia (p. 1040). The allergy incidence was 1.3 percent. Osteoporotic fractures in three women (0.2 percent) were judged to be related to tinzaparin (p. 1038). A total of 43 women (3.4 percent) required medical intervention for bleeding. Of the 15 stillbirths, four were judged as possibly being related to tinzaparin use. But, none of the neonatal deaths or congenital abnormalities was attributed to tinzaparin. The authors concluded that tinzaparin during pregnancy was safe for mother and fetus.

Like unfractionated heparin, LMWHs are safe during breast feeding. Although there may be detectable levels of these drugs in breast milk, the bioavailability when ingested orally is poor, and there is no anticoagulant effect in the infant (Lim, 2010).

Caveats are that LMWHs should be avoided in women with renal failure (Krivak, 2007). Moreover, when given within 2 hours of cesarean delivery, these agents increase the risk of wound hematoma (van Wijk, 2002). Lee and Goodwin (2006) described development of a massive subchorionic hematoma associated with enoxaparin use. Forsnes and associates (2009) reported a woman who developed a spontaneous thoracolumbar epidural hematoma that required surgical drainage.
Labor and Delivery

Women receiving either therapeutic or prophylactic anticoagulation should be converted from LMWH to the shorter half-life UFH in the last month of pregnancy or sooner if delivery appears imminent. The purpose of conversion to UFH has less to do with any risk of maternal bleeding at the time of delivery, but rather with neuraxial blockade complicated by an epidural or spinal hematoma (Chap. 25, p. 516). The American College of Chest Physicians recommends that women scheduled for a planned delivery who are receiving twice-daily adjusted-dose subcutaneous UFH or LMWH discontinue their heparin 24 hours before labor induction or cesarean delivery. Patients receiving once-daily LMWH should take only 50 percent of their normal dose on the morning of the day before delivery (Bates, 2012). The American College of Obstetricians and Gynecologists (2013) advises that adjusted-dose subcutaneous LMWH or UFH can be discontinued 24 to 36 hours before an induction of labor or scheduled cesarean delivery. The American Society of Regional Anesthesia and Pain Medicine advises withholding neuraxial blockade for 10 to 12 hours after the last prophylactic dose of LMWH or 24 hours after the last therapeutic dose (Horlocker, 2010).

If a woman begins labor while taking UFH, clearance can be verified by an aPTT. Reversal of heparin with protamine sulfate is rarely required and is not indicated with a prophylactic dose of heparin (p. 1044). For women in whom anticoagulation therapy has temporarily been discontinued, pneumatic compression devices are recommended (American College of Obstetricians and Gynecologists, 2011).

Anticoagulation with Warfarin Compounds

Warfarin derivatives are generally contraindicated because they readily cross the placenta and may cause fetal death and malformations from hemorrhages (Chap. 12, p. 252). Like UFH and LMWH, however, they do not accumulate in breast milk and do not induce an anticoagulant effect in the infant and are thus safe during breast feeding.

Postpartum venous thrombosis is usually treated with intravenous heparin and oral warfarin initiated simultaneously. The initial dose of warfarin is usually 5 to 10 mg for the first 2 days. Subsequent doses are titrated to achieve an international normalized ratio (INR) of 2 to 3. To avoid paradoxical thrombosis and skin necrosis from the early anti-protein C effect of warfarin, these women are maintained on therapeutic doses of UFH or LMWH for 5 days and until the INR is in a therapeutic range (2.0–3.0) for 2 consecutive days (American College of Obstetricians and Gynecologists, 2013; Stewart, 2010). Warfarin skin necrosis has been described in a postpartum patient with protein S deficiency (Cheng, 1997).

Treatment in the puerperium may require larger doses of anticoagulant. Brooks and colleagues (2002) compared anticoagulation in postpartum women with that of age-matched nonpregnant controls. The former required a significantly larger median total dose of warfarin—45 versus 24 mg—and a longer time—7 versus 4 days—to achieve the target INR. Moreover, the mean maintenance dose was slightly higher in postpartum women compared with that in the control group—4.9 versus 4.3 mg.

Newer Agents

Several oral anticoagulants have recently become available. These inhibit thrombin—dabigatran, or factor Xa—rivaroxaban and apixaban. Preliminary studies in nonpregnant patients have been
very promising (Cohen, 2013; Schulman, 2013). In one study of nearly 2500 nonpregnant subjects, anticoagulation with apixaban significantly reduced the risk of recurrent venous thromboembolism without increasing major bleeding complications (Agnelli, 2013). Currently, there are no studies of these newer agents during pregnancy, and thus the human reproductive risks are unknown (Bates, 2012).

Complications of Anticoagulation

Three significant complications associated with anticoagulation are hemorrhage, thrombocytopenia, and osteoporosis. The latter two are unique to heparin, and their risk may be reduced with low-molecular-weight heparins. The most serious complication is hemorrhage, which is more likely if there has been recent surgery or lacerations. Troublesome bleeding also is more likely if the heparin dosage is excessive. Unfortunately, management schemes using laboratory testing to identify when a heparin dosage is sufficient to inhibit further thrombosis, yet not cause serious hemorrhage, have been discouraging.

Heparin-Induced Thrombocytopenia

There are two types—the most common is a nonimmune, benign, reversible thrombocytopenia that develops within the first few days of therapy and resolves in approximately 5 days without therapy cessation. The second is the severe form of heparin-induced thrombocytopenia (HIT), which results from an immune reaction involving IgG antibodies directed against complexes of platelet factor 4 and heparin. When severe, HIT paradoxically causes thrombosis, which is the most common presentation.

The incidence of HIT is approximately 3 to 5 percent in nonpregnant individuals. Interestingly, however, Fausett and coworkers (2001) reported no cases among 244 heparin-treated pregnant women compared with 10 among 244 nonpregnant patients. Accordingly, the American College of Chest Physicians estimates that the incidence of HIT in obstetrical patients is less than 0.1 percent (Linkins, 2012). In the latest guidelines, moreover, the American College of Chest Physicians recommends against platelet count monitoring when the risk of HIT is considered to be less than 1 percent. In others, they suggest monitoring every 2 or 3 days from day 4 until day 14 (Linkins, 2012). Kelton and colleagues (2013) have recently provided a scholarly review of HIT.

Management

When HIT is diagnosed, heparin therapy is stopped and alternative anticoagulation initiated. LMWH may not be entirely safe because it has some cross reactivity with unfractionated heparin. The American College of Chest Physicians recommends danaparoid—a sulfated glycosaminoglycan heparinoid (Bates, 2012; Linkins, 2012). In a review of nearly 50 pregnant women with either HIT or a skin rash, Lindhoff-Last and associates (2005) concluded that danaparoid—available only from Canada—was a reasonable alternative. However, they reported two fatal maternal hemorrhages and three fetal deaths. Magnani (2010) reviewed 30 case reports of pregnant women treated with danaparoid. Although it was effective, two patients died related to bleeding, three patients suffered nonfatal major bleeds, and three women developed thromboembolic events unresponsive to danaparoid.

Other agents are fondaparinux and argatroban (Kelton, 2013; Linkins, 2012). Argatroban is a direct thrombin inhibitor available in this country to treat HIT (Chapman, 2008; Tapson, 2008). Fondaparinux is a pentasaccharide factor Xa inhibitor that is also used for HIT (Kelton, 2013). Successful use in pregnancy has been reported (Knol, 2010; Mazzolai, 2006). Tanimura and
coworkers (2012) successfully used argatroban, and later fondaparinux, to manage HIT in a pregnant woman with hereditary antithrombin deficiency. Interestingly, heparin-dependent antibodies do not invariably reappear with subsequent heparin use (Warkentin, 2001).

**Heparin-Induced Osteoporosis**

Bone loss may develop with long-term heparin administration—usually 6 months or longer—and is more prevalent in cigarette smokers (Chap. 58, p. 1159). UFH can cause osteopenia, and this is less likely with LMWH (Deruelle, 2007). Women treated with any heparin should be encouraged to take a daily 1500-mg calcium supplement (Cunningham, 2005; Lockwood, 2012). In one study, Rodger and colleagues (2007) found that long-term use for a mean of 212 days with dalteparin was not associated with a significant decrease in bone mineral density.

**Anticoagulation and Abortion**

The treatment of deep-vein thrombosis with heparin does not preclude pregnancy termination by careful curettage. After the products are removed without trauma to the reproductive tract, full-dose heparin can be restarted in several hours.

**Anticoagulation and Delivery**

The effects of heparin on blood loss at delivery depend on several variables: (1) dose, route, and timing of administration; (2) number and depth of incisions and lacerations; (3) intensity of postpartum myometrial contractions; and (4) presence of other coagulation defects. Blood loss should not be greatly increased with vaginal delivery if the episiotomy—if any—is modest in depth, there are no lacerations, and the uterus promptly contracts. Unfortunately, such ideal circumstances do not always prevail. For example, Mueller and Lebherz (1969) described 10 women with antepartum thrombophlebitis treated with heparin. Three women who continued to receive heparin during labor and delivery bled remarkably and developed large hematomas. Thus, heparin therapy generally is stopped during labor and delivery. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend restarting UFH or LMWH no sooner than 4 to 6 hours after vaginal delivery or 6 to 12 hours after cesarean delivery. It is our practice, however, to wait at least 24 hours if there are significant lacerations or following a major surgical procedure.

Slow intravenous administration of protamine sulfate generally reverses the effect of heparin promptly and effectively. It should not be given in excess of the amount needed to neutralize the heparin, because it also has an anticoagulant effect. Serious bleeding may occur when heparin in usual therapeutic doses is administered to a woman who has undergone cesarean delivery within the previous 24 to 48 hours.

**SUPERFICIAL VENOUS THROMBOPHLEBITIS**

Thrombosis limited strictly to the superficial veins of the saphenous system is treated with analgesia, elastic support, heat, and rest. If it does not soon subside or if deep-vein involvement is suspected, appropriate diagnostic measures are performed. Heparin is given if deep-vein involvement is confirmed. Superficial thrombophlebitis is typically seen in association with
varicosities or as a sequela to an indwelling intravenous catheter.

**PULMONARY EMBOLISM**

Although it causes approximately 10 percent of maternal deaths, pulmonary embolism is relatively uncommon during pregnancy and the puerperium. The incidence averages 1 in 7000 pregnancies. There is an almost equal prevalence for antepartum and postpartum embolism, but those developing postpartum have a higher mortality rate. According to Marik and Plante (2008), 70 percent of women presenting with a pulmonary embolism have associated clinical evidence of deep-vein thrombosis. And recall that between 30 and 60 percent of women with a deep-vein thrombosis will have a coexisting silent pulmonary embolism.

**Clinical Presentation**

Findings from the international cooperative pulmonary embolism registry were reported by Goldhaber and colleagues (1999). During a 2-year period, almost 2500 nonpregnant patients with a proven pulmonary embolism were enrolled. Symptoms included dyspnea in 82 percent, chest pain in 49 percent, cough in 20 percent, syncope in 14 percent, and hemoptysis in 7 percent. Pollack and coworkers (2011) presented results from a similar study of 1880 nonpregnant patients who presented to an emergency room and were found to have a proven pulmonary embolism. Half had dyspnea at rest, 40 percent had pleuritic chest pain, 27 percent had dyspnea with exertion, and 25 percent had coughing. Other predominant clinical findings typically included tachypnea, apprehension, and tachycardia. In some cases, there was an accentuated pulmonic closure sound, rales, and/or friction rub.

Right axis deviation and T-wave inversion in the anterior chest leads may be evident on the electrocardiogram. In at least half, chest radiography is normal. But, there is atelectasis, an infiltrate, or an effusion each in 14 percent of nonpregnant patients (Pollack, 2011). There also may be loss of vascular markings in the lung region supplied by the obstructed artery. Although most women are hypoxemic, a normal arterial blood gas analysis does not exclude pulmonary embolism. Approximately a third of young patients have $p_{O_2}$ values $> 80$ mm Hg. In contrast, the alveolar-arterial oxygen tension difference is a more useful indicator of disease. More than 86 percent of patients with acute pulmonary embolism will have an alveolar-arterial difference of $> 20$ mm Hg (Lockwood, 2012). Even with massive pulmonary embolism, signs, symptoms, and laboratory data to support the diagnosis may be deceptively nonspecific.

**Massive Pulmonary Embolism**

This is defined as embolism causing hemodynamic instability (Tapson, 2008). Acute mechanical obstruction of the pulmonary vasculature causes increased vascular resistance and pulmonary hypertension followed by acute right ventricular dilatation. In otherwise healthy patients, significant pulmonary hypertension does not develop until 60 to 75 percent of the pulmonary vascular tree is occluded (Guyton, 1954). Moreover, circulatory collapse requires 75- to 80-percent obstruction. This is depicted schematically in Figure 52-3 and emphasizes that most acutely symptomatic emboli are large and likely a saddle embolism. These are suspected when the pulmonary artery pressure is substantively increased as estimated by echocardiography.
FIGURE 52-3  Schematic of pulmonary arterial circulation. Note that the cross-sectional area of the pulmonary trunk and the combined pulmonary arteries is 9 cm$^2$. A large saddle embolism could occlude 50 to 90 percent of the pulmonary tree, causing hemodynamic instability. As the arteries give off distal branches, the total surface area rapidly increases, that is, 13 cm$^2$ for the combined five lobar arteries, 36 cm$^2$ for the combined 19 segmental arteries, and more than 800 cm$^2$ for the total 65 subsegmental arterial branches. Thus, hemodynamic instability is less likely with emboli past the lobar arteries. (Data from Singhal, 1973.)

If there is evidence of right ventricular dysfunction, the mortality rate approaches 25 percent, compared with 1 percent without such dysfunction (Kinane, 2008). It is important in these cases to infuse crystalloids carefully and to support blood pressure with vasopressors. Oxygen treatment, endotracheal intubation, and mechanical ventilation are completed preparatory to thrombolysis, filter placement, or embolectomy (Tapson, 2008).

**Diagnosis**

In most cases, recognition of a pulmonary embolism requires a high index of suspicion that prompts objective evaluation. In 2011, the American Thoracic Society and the Society of Thoracic Radiology developed an algorithm—shown in Figure 52-4—for the diagnosis of pulmonary
embolism during pregnancy (Leung, 2011). In addition to compression ultrasonography, which was previously discussed (p. 1036), the algorithm includes computed-tomographic pulmonary angiography (CTPA) and ventilation-perfusion scintigraphy.
FIGURE 52-4 The American Thoracic Society and Society of Thoracic Radiology diagnostic algorithm for suspected pulmonary embolism during pregnancy. CTPA = computed tomographic pulmonary angiography; CUS = compression ultrasonography; CXR = chest x-ray; PE = pulmonary embolism; V/Q = ventilation/perfusion scintigraphy. (Redrawn from Leung, 2011, with permission.)

**Computed-Tomographic Pulmonary Angiography**

Multidetector computed tomography with pulmonary angiography is currently the most commonly employed technique used for pulmonary embolism diagnosis in nonpregnant patients (Bourjeily, 2012; Pollack, 2011). The technique is described further in Chapter 46 (p. 934), and an imaging example is shown in Figure 52-5.

![Figure 52-5](image)

There is some controversy regarding the best imaging method to be used in pregnancy. The American College of Radiology has concluded CTPA to be the most accurate. With a normal chest radiograph, however, the perfusion scan alone with radioisotopes is similarly accurate, and the ventilation scan can be omitted. And because pregnant women frequently have an accompanying normal chest radiograph, the British Society of Haemostasis and Thrombosis recommends the perfusion scan as the initial preferred procedure (Cutts, 2013). Finally, the estimated breast dose of 10 to 70 mGy attributable to CTPA far exceeds that of approximately 0.5 mGy with lung...
In a prospective study of 102 consecutive nonpregnant patients with suspected pulmonary embolism who underwent CTPA, Kavanagh and coworkers (2004) found that during a mean surveillance period of 9 months, only one patient had a false-negative scan. Bourjeily and colleagues (2012) performed a similar follow-up study of 318 pregnant women who had a negative CTPA performed for a suspected pulmonary embolism. All were seen 3 months following their initial presentation or at 6 weeks postpartum. None of these women were subsequently diagnosed with a venous thromboembolism.

Although CTPA has many advantages, we have found that the better resolution allows detection of previously inaccessible smaller distal emboli that have uncertain clinical significance. Similar observations have been reported by Anderson (2007) and Hall (2009) and all their associates. Others have found that the hyperdynamic circulation and increased plasma volume associated with pregnancy lead to a higher number of nondiagnostic studies compared with nonpregnant patients (Ridge, 2011; Scarsbrook, 2006).

### Ventilation–Perfusion Scintigraphy—Lung Scan

This technique is used less commonly in the United States. It involves a small dose of radiotracer such as intravenously administered technetium-99m–macroaggregated albumin. As shown in Table 52-6, there is negligible fetal radiation exposure. The scan may not provide a definite diagnosis because many other conditions—for example, pneumonia or local bronchospasm—can cause perfusion defects. Ventilation scans with inhaled xenon-133 or technetium-99m were added to perfusion scans to detect abnormal areas of ventilation in areas with normal perfusion such as with pneumonia or hypoventilation. The method is not precise, and although ventilation scanning increased the probability of an accurate diagnosis with large perfusion defects and ventilation mismatches, normal V/Q scan findings do not exclude pulmonary embolism. Chan and coworkers (2002) found that a fourth of V/Q scans in pregnant women were nondiagnostic. In these instances, CTPA is preferred.

**TABLE 52-6. Estimated Mean Fetal Radiation Dosimetry from Ventilation-Perfusion (V/Q) Lung Scanning Compared with 4-Channel Multidetector Spiral Computed Tomography (CT) Scanning**
Revel and colleagues (2011) retrospectively compared the performance of lung scintigraphy and CTPA in 137 pregnant women with suspected pulmonary embolism. They found that the two modalities had comparable performance, and no significant differences between the proportions of positive, negative, or indeterminate results were found. Specifically, the proportion of indeterminate results for both was approximately 20 percent. By way of comparison, about a fourth of the nonpregnant population has indeterminate studies. The investigators attributed this difference to the younger age of the pregnant patients.

**Magnetic Resonance Angiography**

Although this technique has a high sensitivity for detection of central pulmonary emboli, the sensitivity for detection of subsegmental emboli is less precise (Scarsbrook, 2006). In a study of 141 nonpregnant patients with suspected pulmonary embolism, Oudkerk and associates (2002) performed magnetic resonance angiography (MRA) before conventional angiography. Approximately a third of patients were found to have an embolus. And, the sensitivity of MRA for isolated subsegmental, segmental, and central or lobar pulmonary embolism was 40, 84, and 100 percent, respectively. There are no reports specifically involving MRA during pregnancy.

**Intravascular Pulmonary Angiography**

This requires catheterization of the right side of the heart and is considered the reference test for pulmonary embolism. With newer generation multidetector CT scanners, however, the role of invasive pulmonary angiography has been questioned (Kuriakose, 2010). Other detractions are that it is time consuming, uncomfortable, and associated with dye-induced allergy and renal failure. Indeed, the procedure-related mortality rate is approximately 1 in 200 (Stein, 1992). It is reserved for confirmation when less invasive tests are equivocal.

**Management**

Immediate treatment for pulmonary embolism is full anticoagulation similar to that for deep-vein thrombosis as discussed on page 1036. A number of complementary procedures may be indicated.

**Vena Caval Filters**

The woman who has very recently suffered a pulmonary embolism and who must undergo cesarean delivery presents a particularly serious problem. Reversal of anticoagulation may be followed by another embolus, and surgery while fully anticoagulated frequently results in life-threatening hemorrhage or troublesome hematomas. In these, placement of a vena caval filter should be considered before surgery (Marik, 2008). Although an uncommon occurrence, we have had good outcomes at Parkland Hospital with placement of a short-term filter. Routine filter placement has no added advantage to heparin given alone (Decousus, 1998). In the very infrequent circumstances in which heparin therapy fails to prevent recurrent pulmonary embolism from the pelvis or legs, or when embolism develops from these sites despite heparin treatment, a vena caval filter may be indicated. Such filters can also be used with massive emboli in patients who are not candidates for thrombolysis (Deshpande, 2002). The device may be inserted through either the jugular or femoral vein and can be inserted during labor (Jamjute, 2006).

Retrievable filters may be used as short-term protection against embolism. These may be removed before they become endothelialized, or they can be left in place permanently (Tapson, 2008). Liu and colleagues (2012) describe the successful use of retrievable filters placed on the
day of cesarean delivery in 15 women with deep-vein thrombosis and then removed 1 to 2 weeks later.

**Thrombolysis**

Compared with heparin, thrombolytic agents provide more rapid lysis of pulmonary clots and improvement of pulmonary hypertension (Tapson, 2008). Konstantinides and coworkers (2002) studied 256 nonpregnant patients receiving heparin for an acute submassive pulmonary embolism. They also were assigned randomly to a placebo or the recombinant tissue plasminogen activator alteplase. Those given the placebo had a threefold increased risk of death or treatment escalation compared with those given alteplase. Agnelli and associates (2002) performed a metaanalysis of nine randomized trials involving 461 nonpregnant patients. They reported that the risk of recurrence or death was significantly lower in patients given thrombolytic agents and heparin compared with those given heparin alone—10 versus 17 percent. Importantly, however, there were five—2 percent—fatal bleeding episodes in the thrombolysis group and none in the heparin-only group.

There are a few cases reports of thrombolysis during pregnancy. In their review, Leonhardt and colleagues (2006) identified 28 reports of thrombolytic therapy using tissue plasminogen activator during pregnancy. Ten of these cases were for thromboembolism. Complication rates were similar compared with reports from nonpregnant patients, and the authors concluded that such therapy should not be withheld during pregnancy if indicated. More recent reports of the successful use of thrombolysis for massive pulmonary embolism in five pregnant patients support this conclusion (Fasullo, 2011; Holden, 2011; Lonjaret, 2011). Our anecdotal experiences with these drugs also have been favorable. Tissue plasminogen activator does not cross the placenta.

**Embolectomy**

Surgical embolectomy is uncommonly indicated with use of thrombolysis and filters. Published experience with emergency embolectomy during pregnancy is limited to case reports such as those by Funakoshi (2004) and Taniguchi (2008) and their coworkers. Based on their review, Ahearn and associates (2002) found that although the operative risk to the mother is reasonable, the stillbirth rate is 20 to 40 percent.

**THROMBOPROPHYLAXIS**

Most recommendations regarding thromboprophylaxis during pregnancy stem from consensus guidelines, and thus not are all congruent. Okoroh and colleagues (2012) performed a systematic review of evidence-based guidelines for thromboprophylaxis published between 2000 and 2011. From the nine separate guidelines, they concluded that “there is a lack of overall agreement about which groups of women should be offered thromboprophylaxis during or after pregnancy or offered testing for thrombophilies.” The confusion that has ensued has provided fertile ground for the plaintiff bar to plow. Cleary-Goldman and associates (2007) surveyed 151 fellows of the American College of Obstetricians and Gynecologists and reported that intervention without a firm indication is common. Table 52-7 and 52-8 list several consensus recommendations for thromboprophylaxis. In some cases, more than one option is listed, thus illustrating the confusion that currently reigns.

If no risk factors, recommend early mobilization.

If one major or two minor risk factors, recommend prophylactic low-molecular-weight heparin or mechanical prophylaxis (elastic stockings or intermittent pneumatic compression) in those with contraindications to anticoagulants while in the hospital.

If at higher risk, recommend low-molecular weight heparin plus mechanical prophylaxis.

If significant risk factors persist following delivery, prophylaxis should be extended for up to 6 weeks postpartum.

In general, and as shown in Table 52-8, either antepartum surveillance or heparin prophylaxis is recommended for women without a recurrent risk factor, including no known thrombophilia. The study by Tengborn and coworkers (1989), however, suggested that such management may not be effective. They reported outcomes in 87 pregnant Swedish women who had prior thromboembolic disease and were not tested for thrombophilias. Despite heparin prophylaxis, which was usually 5000 U twice daily, three of 20—or 15 percent—of women developed antepartum recurrence compared with eight of 67—or 12 percent—of women not given heparin.

Brill-Edwards and colleagues (2000) prospectively studied 125 pregnant women with a single prior venous thromboembolism. Antepartum heparin was not given, but anticoagulant therapy was given for 4 to 6 weeks postpartum. A total of six women had a recurrent venous thrombosis—three antepartum and three postpartum. There were no recurrences in the 44 women without a known thrombophilia or whose prior thrombosis was associated with a temporary risk factor. These findings imply that prophylactic heparin may not be required for these two groups of women. In contrast, women with a prior thrombosis in association with a thrombophilia or in the absence of a temporary risk factor generally should be given both antepartum and postpartum prophylaxis (see Table 52-8).

De Stefano and coworkers (2006) studied 1104 women who had a first-episode venous thromboembolism before the age of 40 years. After excluding those with antiphospholipid antibodies, 88 women were identified who subsequently had a total of 155 pregnancies and who were not given antithrombotic prophylaxis. There were 19 women—22 percent—who had a subsequent pregnancy- or puerperium-related venous thromboembolism. Of 20 women whose

Prophylactic, intermediate-, and adjusted-dose regimens are listed in Table 52-5 (p. 1037).
original thrombosis was associated with a transient risk factor—not including pregnancy or oral contraceptive use—there were no recurrences during pregnancy, but two during the puerperium. Like the findings by Brill-Edwards and associates (2000), these data suggest that for women with a prior venous thromboembolism, antithrombotic prophylaxis during pregnancy could be tailored according to the circumstances of the original event. It is emphasized that more data are needed.

Our practice at Parkland Hospital for many years for women with a history of prior thromboembolism was to administer subcutaneous unfractionated heparin, 5000 to 7500 units two to three times daily. With this regimen, the recurrence of documented deep-vein thrombosis embolization was rare. Beginning approximately 10 years ago, we have successfully used 40 mg enoxaparin given subcutaneously daily.

## Cesarean Delivery

For many years in the United States, thromboprophylaxis for women undergoing cesarean delivery was not widely employed. In a survey of 157 members of the Society for Maternal-Fetal Medicine, for example, Casele and Grobman (2007) found that only 8 percent of respondents routinely used thromboprophylaxis—defined as compression boots, stockings, or heparin—for women undergoing cesarean delivery. Friedman and colleagues (2013) found that the rate of postcesarean prophylaxis increased from 8 percent in 2003 to 41 percent in 2010. The risk for deep-vein thrombosis and especially for fatal thromboembolism is increased manyfold in women following cesarean compared with vaginal delivery. When considering that a third of women giving birth in the United States yearly undergo cesarean delivery, it is easily understandable that pulmonary embolism is a major cause of maternal mortality (Chap. 1, p. 5).

For these reasons, the American College of Obstetricians and Gynecologists (2011) recently has recommended placement of pneumatic compression devices before cesarean delivery for all women not already receiving thromboprophylaxis. For patients undergoing cesarean delivery with additional risk factors for thromboembolism, both pneumatic compression devices and unfractionated or low-molecular-weight heparin may be recommended. Cesarean delivery in an emergency setting should not be delayed because of the time necessary to implement thromboprophylaxis. The American College of Chest Physicians recommends the risk-adjusted approach to thromboprophylaxis shown in Table 52-7 (Bates, 2012).

## Prolonged Antepartum Bed Rest

There are no recommendations concerning thromboprophylaxis for women placed on bed rest for a number of obstetrical indications. This danger is possibly mitigated because strict bed rest is seldom indicated or enforced. In the survey cited above by Casele and Grobman (2007), 25 percent of maternal-fetal medicine specialists routinely use some form of thromboprophylaxis for women on bed rest > 72 hours. It seems reasonable to consider such measures if additional risk factors are identified, for example, obesity or diabetes.

Renal and urinary tract disorders are commonly encountered in pregnancy. Some precede pregnancy—one example being nephrolithiasis. In some women, pregnancy-induced changes may predispose to development or worsening of urinary tract disorders—an example is the markedly increased risk for pyelonephritis. Finally, there may be renal pathology unique to pregnancy such as preeclampsia. With good prenatal care, however, most women with these disorders will likely have no long-term sequelae.

**PREGNANCY-INDUCED URINARY TRACT CHANGES**

Significant changes in both structure and function that take place in the urinary tract during normal pregnancy are discussed in Chapter 4 (p. 63). The kidneys become larger, and as shown in Figure 53-1, dilatation of the renal calyces and ureters can be striking. Some dilatation develops before 14 weeks and likely is due to progesterone-induced relaxation of the muscularis. More marked dilatation is apparent beginning in midpregnancy because of ureteral compression, especially on the right side (Faúndes, 1998). There is also some vesicoureteral reflux during pregnancy. An important consequence of these physiological changes is an increased risk of upper urinary
Evidence of functional renal hypertrophy becomes apparent very soon after conception. Glomeruli are larger, although cell numbers do not increase (Strevens, 2003). Pregnancy-induced intrarenal vasodilatation—both afferent and efferent resistance decreases—leads to increased effective renal plasma flow and glomerular filtration (Helal, 2012; Hussein, 2014). By 12 weeks’ gestation, the glomerular filtration rate is already increased 20 percent above nonpregnant values (Hladunewich, 2004). Ultimately, plasma flow and glomerular filtration increase by 40 and 65 percent, respectively. Consequently, serum concentrations of creatinine and urea decrease substantively across pregnancy, and values within a nonpregnant normal range may be abnormal for pregnancy (Appendix, p. 1289). Other alterations include those related to maintaining normal acid-base homeostasis, osmoregulation, and fluid and electrolyte retention.

Assessment of Renal Function During Pregnancy

The urinalysis is essentially unchanged during pregnancy, except for occasional glucosuria. Although protein excretion normally is increased, it seldom reaches levels that are detected by usual screening methods. As discussed in Chapter 4 (p. 65), Higby and colleagues (1994) reported...
24-hour protein excretion to be 115 mg with a 95-percent confidence level of 260 mg/day. There were no significant differences by trimester. Albumin constitutes only a small part of total protein excretion and ranges from 5 to 30 mg/day. From their review, Airoldi and Weinstein (2007) concluded that proteinuria must exceed 300 mg/day to be considered abnormal. Many consider 500 mg/day to be important with gestational hypertension. Quantification of urinary albumin-to-creatinine ratio (ACR) in a spot urine sample—ideally from a first-morning void—is helpful in estimating a 24-hour albumin excretion rate (AER), in which ACR (mg/g) approximates AEF (mg/24 h). Some laboratories measure total proteins instead of albumin.

Stehman-Breen and associates (2002) found that 3 percent of 4589 nulliparas had idiopathic hematuria, defined as 1+ or greater blood on urine dipstick when screened before 20 weeks. They also reported that these women had a twofold risk of developing preeclampsia. In another study of 1000 women screened during pregnancy, Brown and coworkers (2005) reported a 15-percent incidence of dipstick hematuria. Most women had trace levels of hematuria, and the false-positive rate was 40 percent.

If the serum creatinine level in pregnancy persistently exceeds 0.9 mg/dL (75 μmol/L), then intrinsic renal disease should be suspected. In these cases, some determine the creatinine clearance as an estimate of the glomerular filtration rate. Sonography provides imaging of renal size, relative consistency, and elements of obstruction (see Fig. 53-1). Full-sequence intravenous pyelography is not done routinely, but injection of contrast media with one or two abdominal radiographs may be indicated by the clinical situation (Chap. 46, p. 931). The usual clinical indications for cystoscopy are followed. There is an approximate 5-percent complication rate of ureteroscopy done for stone removal during pregnancy (Johnson, 2012; Semins, 2009). Magnetic resonance (MR) imaging of renal masses has been shown to have excellent results (Putra, 2009).

Although renal biopsy is relatively safely performed during pregnancy, it usually is postponed unless results may change therapy. From a review of 243 biopsies in pregnant women, the incidence of complications was 7 percent—this compares with 1 percent in postpartum women (Piccoli, 2013). Lindheimer and colleagues (2007a) recommend its consideration for rapid deterioration of renal function with no obvious cause or for symptomatic nephrotic syndrome. We and others have found biopsy helpful in selected cases to direct management (Chen, 2001; Piccoli, 2013). Strevens and associates (2003) performed renal biopsy in 12 normal pregnant volunteers and reported that five had slight to moderate glomerular endotheliosis. In contrast, all 27 women with proteinuric hypertension had endotheliosis, and in all but one, it was moderate to severe.

### Pregnancy after Unilateral Nephrectomy

After removal of one kidney, and if the remaining kidney is normal, there is hypertrophy of renal function. In addition, with pregnancy, the surviving kidney undergoes further hypertrophy of function (Fig. 53-2). Because of this, women with one normal kidney most often have no difficulty in pregnancy (Baylis, 1991). Thorough functional evaluation of the remaining kidney is essential. Finally, there are no long-term adverse consequences of kidney donation done before pregnancy (Ibrahim, 2009).
FIGURE 53-2 Increased glomerular filtration rate in early pregnancy in normal women, those stable after unilateral nephrectomy, and those with a successful renal transplant. (Data from Newcastle-upon-Tyne, 1974–2006, courtesy of Dr. John Davison.)

URINARY TRACT INFECTIONS

These are the most common bacterial infections during pregnancy. Although asymptomatic bacteriuria is the most common, symptomatic infection includes cystitis, or it may involve the renal calyces, pelvis, and parenchyma—pyelonephritis.

Organisms that cause urinary infections are those from the normal perineal flora. Approximately 90 percent of Escherichia coli strains that cause nonobstructive pyelonephritis have adhesins such as P- and S-fimbriae. These are cell-surface protein structures that enhance bacterial adherence and thereby, virulence (Foxman, 2010; Hooton, 2012). These adhesins promote binding to vaginal and uroepithelial cells through expression of the PapG gene that encodes the P-fimbriae tip and by production of toxins and other virulence factors (Spurbeck, 2011).

Data suggest that pregnant women have more severe sequelae from urosepsis. The T-helper cell—Th1/Th2 ratio—reversal of normal pregnancy is discussed in Chapter 4 (p. 56). There are also various perturbations of cytokine expression that have been reported (Chaemsaiithong, 2013). And maternal deaths have been attributed to E coli bearing Dr+ and P adhesins (Sledzińska, 2011). But even if pregnancy itself does not enhance these virulence factors, urinary stasis, vesicoureteral reflux, and diabetes predispose to symptomatic upper urinary infections (Czaja, 2009; Twickler, 1994).

In the puerperium, there are several risk factors that predispose a woman to urinary infections. Bladder sensitivity to intravesical fluid tension is often decreased as a consequence of labor trauma or conduction analgesia (Chap. 36, p. 676). Sensation of bladder distention can also be
diminished by discomfort caused by an episiotomy, periurethral lacerations, or vaginal wall hematomas. Normal postpartum diuresis may worsen bladder overdistention, and catheterization to relieve retention commonly leads to urinary infection. Postpartum pyelonephritis is treated in the same manner as antepartum renal infections (McDonnold, 2012).

Asymptomatic Bacteriuria

This refers to persistent, actively multiplying bacteria within the urinary tract in asymptomatic women. Its prevalence in nonpregnant women is 5 to 6 percent and depends on parity, race, and socioeconomic status (Hooton, 2000). The highest incidence is in African-American multiparas with sickle-cell trait, and the lowest incidence is in affluent white women of low parity. Asymptomatic infection is also more common in diabetics (Schneeberger, 2014). Because in most women there is recurrent or persistent bacteriuria, it frequently is discovered during prenatal care. The incidence during pregnancy is similar to that in nonpregnant women and varies from 2 to 7 percent.

Bacteriuria is typically present at the first prenatal visit. An initial positive urine culture result prompts treatment, after which, fewer than 1 percent of women develop a urinary tract infection (Whalley, 1967). A clean-voided specimen containing more than 100,000 organisms/mL is diagnostic. It may be prudent to treat when lower concentrations are identified, because pyelonephritis develops in some women despite colony counts of only 20,000 to 50,000 organisms/mL (Lucas, 1993).

Significance

If asymptomatic bacteriuria is not treated, approximately 25 percent of infected women will develop symptomatic infection during pregnancy. Eradication of bacteriuria with antimicrobial agents prevents most of these. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012), as well as a U.S. Preventive Services Task Force (2008) recommend screening for bacteriuria at the first prenatal visit (Chap. 9, p. 174). Standard urine cultures may not be cost effective when the prevalence is low. However, less expensive screening tests such as the leukocyte esterase-nitrite dipstick are when the prevalence is 2 percent or less (Rouse, 1995). Because of a high prevalence—5 to 8 percent—at Parkland Hospital, culture screening is done in most women. Susceptibility determination is not necessary because initial treatment is empirical (Hooton, 2012). Also, a dipstick culture technique has excellent positive- and negative-predictive values (Mignini, 2009). With this, a special agar-coated dipstick is first placed into urine and then also serves as the culture plate.

In some, but not all studies, covert bacteriuria has been associated with preterm or low-birthweight infants (Kass, 1962). It is even more controversial whether eradication of bacteriuria decreases these complications. Evaluating a cohort of 25,746 mother-infant pairs, Schieve and coworkers (1994) reported urinary tract infection to be associated with increased risks for low-birthweight infants, preterm delivery, pregnancy-associated hypertension, and anemia. These findings vary from those of Gilstrap and colleagues (1981b) and Whalley (1967). In most studies, asymptomatic infection is not evaluated separately from acute renal infection (Banhidy, 2007). A Cochrane database review by Vasquez and Abalos (2011) found that benefits of treatment for asymptomatic bacteria are limited to the reduction of the incidence of pyelonephritis.

Treatment

Bacteriuria responds to empirical treatment with any of several antimicrobial regimens listed in
Although selection can be based on in vitro susceptibilities, in our extensive experience, empirical oral treatment for 10 days with nitrofurantoin macrocrystals, 100 mg at bedtime, is usually effective. Lumbiganon and associates (2009) reported satisfactory results with a 7-day oral course of nitrofurantoin, 100 mg given twice daily. Single-dose antimicrobial therapy has also been used with success for bacteriuria. The important caveat is that, regardless of regimen given, the recurrence rate is approximately 30 percent. This may indicate covert upper tract infection and the need for longer therapy.

Periodic surveillance is necessary to prevent recurrent urinary infections (Schneeberger, 2012). For recurrent bacteriuria, we have had success with nitrofurantoin, 100 mg orally at bedtime for 21 days (Lucas, 1994). For women with persistent or frequent bacteriuria recurrences, suppressive therapy for the remainder of pregnancy can be given. We routinely use nitrofurantoin, 100 mg orally at bedtime. This drug may rarely cause an acute pulmonary reaction that dissipates on its withdrawal (Boggess, 1996).

### Cystitis and Urethritis

Lower urinary infection during pregnancy may develop without antecedent covert bacteriuria.
Cystitis is characterized by dysuria, urgency, and frequency, but with few associated systemic findings. Pyuria and bacteriuria are usually found. Microscopic hematuria is common, and occasionally there is gross hematuria from hemorrhagic cystitis (Fakhoury, 1994). Although cystitis is usually uncomplicated, the upper urinary tract may become involved by ascending infection. Almost 40 percent of pregnant women with acute pyelonephritis have preceding symptoms of lower tract infection (Gilstrap, 1981a).

Women with cystitis respond readily to any of several regimens. Most of the three-day regimens listed in Table 53-1 are usually 90-percent effective (Fihn, 2003). Single-dose therapy is less effective, and if it is used, concomitant pyelonephritis must be confidently excluded.

Lower urinary tract symptoms with pyuria accompanied by a sterile urine culture may be from urethritis caused by *Chlamydia trachomatis*. Mucopurulent cervicitis usually coexists, and azithromycin therapy is effective. (Chap. 65, p. 1270)

### Acute Pyelonephritis

Renal infection is the most common serious medical complication of pregnancy. In a study of the 2006 Nationwide Inpatient Sample by Jolley and coworkers (2012), there were nearly 29,000 hospitalizations for acute pyelonephritis. Rates were highest for adolescents at 17.5 per 1000 and for Hispanic women at 10.1 per 1000. In another study of more than 70,000 pregnancies in a managed care organization, Gazmararian and colleagues (2002) reported that 3.5 percent of antepartum admissions were for urinary infections. The potential seriousness is underscored by the observations of Snyder and associates (2013) that pyelonephritis was the leading cause of septic shock during pregnancy. And in a 2-year audit of admissions to the Parkland Hospital Obstetrical Intensive Care Unit, 12 percent of antepartum admissions were for sepsis syndrome caused by pyelonephritis (Zeeman, 2003). There is also concern that urosepsis may be related to an increased incidence of cerebral palsy in preterm infants (Jacobsson, 2002). Fortunately, there appear to be no serious long-term maternal sequelae (Raz, 2003).

#### Clinical Findings

Renal infection develops more frequently in the second trimester, and nulliparity and young age are associated risk factors (Hill, 2005). Pyelonephritis is unilateral and right-sided in more than half of cases, and it is bilateral in a fourth. There is usually a rather abrupt onset with fever, shaking chills, and aching pain in one or both lumbar regions. Anorexia, nausea, and vomiting may worsen dehydration. Tenderness usually can be elicited by percussion in one or both costovertebral angles. The urinary sediment contains many leukocytes, frequently in clumps, and numerous bacteria. Bacteremia is demonstrated in 15 to 20 percent of these women. *E coli* is isolated from urine or blood in 70 to 80 percent of infections, *Klebsiella pneumoniae* in 3 to 5 percent, *Enterobacter* or *Proteus* species in 3 to 5 percent, and gram-positive organisms, including group B *Streptococcus* and *S aureus*, in up to 10 percent of cases (Hill, 2005; Wing, 2000). The differential diagnosis includes, among others, labor, chorioamnionitis, appendicitis, placental abruption, or infarcted leiomyoma. Evidence of the sepsis syndrome is common, and this is discussed in detail in Chapter 47 (p. 946).

Plasma creatinine is monitored because early studies reported that 20 percent of pregnant women developed renal dysfunction. More recent findings, however, show this to be only 5 percent if aggressive fluid resuscitation is provided (Hill, 2005). Follow-up studies have demonstrated that this endotoxin-induced damage is reversible in the long term. Varying degrees of respiratory insufficiency from endotoxin-induced alveolar injury are manifest in up to 10 percent
of women and may result in frank pulmonary edema (Cunningham, 1987; Sheffield, 2005; Snyder, 2013). In some cases, pulmonary injury may be so severe that it causes acute respiratory distress syndrome (ARDS) (Fig. 53-3).

![Figure 53-3](image)

**FIGURE 53-3** A series of anterior-posterior projection chest radiographs of improving acute respiratory distress syndrome (ARDS) in a second-trimester pregnant woman with severe pyelonephritis. **A.** An extensive infiltrative process and complete obliteration of the diaphragm (white arrows) is seen. **B.** Improved aeration of lung fields bilaterally is noted as pleural disease resolves (arrows). **C.** Markedly improved visualization of the lungs fields with residual platelike atelectasis and normal appearance of the diaphragm.

Uterine activity from endotoxin is common and is related to fever severity (Graham, 1993). In the study by Millar and coworkers (2003), women with pyelonephritis averaged 5 contractions per hour at admission, and this decreased to 2 per hour within 6 hours of intravenous fluid and antimicrobial administration. As discussed in Chapter 47 (p. 942), -agonist therapy for tocolysis increases the likelihood of respiratory insufficiency from permeability edema because of the sodium- and fluid-retaining properties of those agents (Lamont, 2000). The incidence of pulmonary edema in women with pyelonephritis who were given -agonists was reported to be 8 percent—a fourfold increase over that expected (Towers, 1991).

Endotoxin-induced hemolysis is common, and approximately a third of patients with pyelonephritis develop anemia (Cox, 1991). With recovery, hemoglobin regeneration is normal because acute infection does not affect erythropoietin production (Cavenee, 1994).

**Management**

One scheme for management of acute pyelonephritis is shown in Table 53-2. Although we routinely obtain urine and blood cultures, prospective trials show them to be of limited clinical utility (Wing, 2000). *Intravenous hydration to ensure adequate urinary output is the cornerstone of treatment.* Antimicrobials are also begun promptly with the caveat that they may initially worsen endotoxemia from bacterial lysis. Ongoing surveillance for worsening of sepsis syndrome is monitored by serial determinations of urinary output, blood pressure, pulse,
temperature, and oxygen saturation. High fever should be lowered with a cooling blanket or acetaminophen. This is especially important in early pregnancy because of possible teratogenic effects of hyperthermia (Chap. 14, p. 284).

Modified from Lucas, 1994; Sheffield, 2005.

Antimicrobial therapy usually is empirical, and ampicillin plus gentamicin; cefazolin or ceftriaxone; or an extended-spectrum antibiotic were all 95-percent effective in randomized trials (Sanchez-Ramos, 1995; Wing, 1998, 2000). Fewer than half of *E coli* strains are sensitive to ampicillin in vitro, but cephalosporins and gentamicin generally have excellent activity. Serum creatinine is monitored if nephrotoxic drugs are given. Initial treatment at Parkland Hospital is ampicillin plus gentamicin. Some recommend suitable substitutes if bacterial studies show in vitro resistance. With any of the regimens discussed, response is usually prompt, and 95 percent of women are afebrile by 72 hours (Hill, 2005; Sheffield, 2005; Wing, 2000). After discharge, most recommend oral therapy for a total of 7 to 14 days (Hooton, 2012).

**Persistent Infection.** Generally, intravenous hydration and antimicrobial therapy are followed by stepwise defervescence of approximately 1°F per day. With persistent spiking fever or lack of clinical improvement by 48 to 72 hours, urinary tract obstruction or another complication or both are considered. Renal sonography is recommended to search for obstruction manifest by abnormal ureteral or pyelocaliceal dilatation (Seidman, 1998). Although most women with continuing infection have no evidence of obstruction, some are found to have calculi. Although renal sonography will detect hydronephrosis, stones are not always seen in pregnancy (Butler, 2000; Maikranz, 1987). If stones are strongly suspected despite a nondiagnostic sonographic examination, a plain abdominal radiograph will identify nearly 90 percent. Another option is the modified one-shot intravenous pyelogram—a single radiograph obtained 30 minutes after contrast injection—which usually provides adequate imaging (Butler, 2000).

In some women, MR imaging may disclose the cause of persistent infection (Spencer, 2004). Even without urinary obstruction, persistent infection can be due to an intrarenal or perinephric abscess or phlegmon (Cox, 1988; Rafi, 2012). Obstruction relief is important, and one method is cystoscopic placement of a double-J ureteral stent (Rodriguez, 1988). Because these stents are
usually left in place until after delivery, they frequently become encrusted and require replacement. We have found that percutaneous nephrostomy is preferable because the stents are more easily replaced. Finally, surgical removal of stones may be required in some women (p. 1057).

**Outpatient Management of Pyelonephritis.** Outpatient management is an option for nonpregnant women with uncomplicated pyelonephritis (Hooton, 2012). Wing and associates (1999) have described outpatient management in 92 pregnant women who were first given in-hospital intramuscular ceftriaxone, two 1-g doses 24 hours apart. At this point, one third of the group was considered suitable for outpatient therapy, and these women were randomized either to discharge and oral antimicrobials or to continued hospitalization with intravenous therapy. A third of the outpatient management group was unable to adhere to the treatment regimen and was admitted. These findings suggest that outpatient management is applicable to very few pregnant women.

**Surveillance**

Recurrence of infection—either covert or symptomatic—is common and develops in 30 to 40 percent of women following completion of treatment for pyelonephritis (Cunningham, 1973). Unless other measures are taken to ensure urine sterility, nitrofurantoin, 100 mg orally at bedtime given for the remainder of the pregnancy, reduces bacteriuria recurrence (Van Dorsten, 1987).

---

**Reflux Nephropathy**

Vesicoureteral reflux in early childhood can cause recurrent urinary tract infections, and thus, subsequent chronic interstitial nephritis was attributed to chronic pyelonephritis. Moreover, it was also found that high-pressure sterile reflux impaired normal renal growth. Combined, this leads to patchy interstitial scarring, tubular atrophy, and loss of nephron mass and is termed reflux nephropathy. In adults, long-term complications include hypertension, which may be severe if there is demonstrable renal damage (Diamond, 2012; Köhler, 2003).

Perhaps half of women with reflux nephropathy were treated during childhood for renal infections. Of these, many also had surgical correction of reflux as children, and these commonly have bacteriuria when pregnant (Mor, 2003). In the other half of women with reflux nephropathy, there is no clear history of recurrent cystitis, acute pyelonephritis, or obstructive disease (Diamond, 2012). Reports describing 939 pregnancies in 379 women with reflux nephropathy indicate that impaired renal function and bilateral renal scarring were associated with increased maternal complications (El-Khatib, 1994; Jungers, 1996; Köhler, 2003). Chronic renal disease and pregnancy outcome is discussed further on page 1061.

---

**Nephrolithiasis**

Kidney stones develop in 7 percent of women during their lifetime with an average age of onset in the third decade (Asplin, 2012). Calcium salts make up approximately 80 percent of stones, and up to half of affected women have polygenic familial idiopathic hypercalciuria (Worcester, 2010). Hyperparathyroidism should be excluded. Although calcium oxalate stones in young nonpregnant women are most common, most stones in pregnancy—65 to 75 percent—are calcium phosphate or hydroxyapatite (Ross, 2008; Tan, 2013). Patients who have a stone typically form another stone every 2 to 3 years.
Contrary to past teachings, a low-calcium diet promotes stone formation. Prevention of recurrences with hydration and a diet low in sodium and protein is currently recommended (Asplin, 2012). Thiazide diuretics also diminish stone formation. In general, obstruction, infection, intractable pain, and heavy bleeding are indications for stone removal. Removal by a flexible basket via cystoscopy, although used less often than in the past, is still a reasonable consideration for pregnant women. In nonpregnant patients, stone destruction by lithotripsy is preferred to surgical therapy in most cases. There is limited information on the use of these procedures during pregnancy, and they are not generally recommended.

Stone Disease During Pregnancy

The incidence of stone disease complicating pregnancy has been reported with widespread variability. At the low end, Butler and colleagues (2000) found the incidence to be 0.3 admissions per 1000 pregnancies in more than 186,000 deliveries at Parkland Hospital. In an Israel population-based study, the incidence in nearly 220,000 pregnancies was 0.8 per 1000 (Rosenberg, 2011). In a population-based study from Washington state, Swartz and coworkers (2007) reported an incidence of 1.7 per 1000 pregnancies. Bladder stones are rare, but recurrent infection and labor obstructed by stones have been reported (Ait Benkaddour, 2006; Ruan, 2011).

Data are conflicting whether women with kidney stones have an increased risk for low-birthweight and preterm infants. The case-control study by Swartz and colleagues (2007) of 2239 women with nephrolithiasis reported excessive preterm delivery—10.6 versus 6.4 percent—compared with normal controls. The more recent nationwide population-based case-control study from Taiwan also reported 20- to 40-percent increases in low-birthweight and preterm births (Chung, 2013). To the contrary, a case-control study from Hungary reported that pregnancy outcomes, including preterm delivery, were similar in women with stones and normal controls (Banhidy, 2007). Comparable conclusions were drawn from the Israeli population-based study noted earlier (Rosenberg, 2011).

Diagnosis

There is some evidence that pregnant women may have fewer symptoms with stone passage because of urinary tract dilatation (Hendricks, 1991; Tan, 2013). That said, more than 90 percent of pregnant women with nephrolithiasis present with pain. Gross hematuria is less common than in nonpregnant women and was reported to be a presenting symptom in 23 percent of women described by Butler and associates (2000). In another study, however, Lewis and coworkers (2003) found that only 2 percent had hematuria. Sonography is usually selected to visualize stones, but as discussed above, many are not detected because hydronephrosis may obscure findings (McAleer, 2004). If there is abnormal dilatation without stone visualization, then the one-shot pyelogram may be useful. Transabdominal color Doppler sonography to detect presence or absence of ureteral “jets” of urine into the bladder has been used to exclude obstruction (Asrat, 1998).

Helical computed tomography (CT) scanning is the imaging method of choice for nonpregnant individuals, however, it is avoided during pregnancy if possible (Brown, 2010). If it is used, the slices can be tailored as needed (Chap. 46, p. 934). For pregnant women, White and colleagues (2007) recommend unenhanced helical CT and cite an average fetal radiation dose to be 7 mGy. These exigencies have led some to recommend MR imaging as the second-line test following nondiagnostic sonography (Masselli, 2013).
Management

Treatment depends on symptoms and gestational age (Semins, 2013). Intravenous hydration and analgesics are given. In half of women with symptomatic stones, infection will be identified, and this is treated vigorously. Although calculi infrequently cause symptomatic obstruction during pregnancy, persistent pyelonephritis should prompt a search for obstruction due to nephrolithiasis.

Approximately 65 to 80 percent of symptomatic women will have improvement with conservative therapy, and the stone usually passes spontaneously (Tan, 2013). Others require an invasive procedure such as ureteral stenting, ureteroscopy, percutaneous nephrostomy, transurethral laser lithotripsy, or basket extraction (Butler, 2000; Semins, 2010). The need for fluoroscopy limits the utility of percutaneous nephrolithotomy (Toth, 2005). In the case-control study cited above by Swartz and associates (2007), there were 623 procedures performed in 2239 symptomatic pregnant women, but less than 2 percent required surgical exploration.

As noted earlier, extracorporeal shock-wave lithotripsy is contraindicated in pregnancy. Watterson and coworkers (2002) described successful transurethral holmium:YAG laser lithotripsy in nine of 10 women. Semins and Matlaga (2010) found that ureteroscopic removal is also safe in pregnancy.

PREGNANCY AFTER RENAL TRANSPLANTATION

In 2013, there were approximately 97,000 registrants on the waiting list for renal transplantations through the Organ Procurement and Transplantation Network—OPTN (2013). The 1-year graft survival rate is 95 percent for grafts from living donors and 89 percent from deceased donors (Carpenter, 2008). Survival rates approximately doubled between 1988 and 1996, due in large part to the introduction of cyclosporine and muromonab-CD3 (OKT3 monoclonal antibody) to prevent and treat organ rejection. Since then, mycophenolate mofetil and tacrolimus have further reduced acute rejection episodes, however, the former is considered teratogenic (Briggs, 2011). In the report from the National Transplant Pregnancy Registry, 23 percent of fetuses exposed to mycophenolate had birth defects (Coscia, 2010). Importantly, resumption of renal function after transplantation promptly restores fertility in reproductive-aged women (Hladunewich, 2011; Lessan-Pezeshki, 2004). More than half of transplant recipients reported that they were not counseled regarding contraception (French, 2013).

Pregnancy Outcomes

Coscia and coworkers (2010) reviewed the outcomes of 2000 pregnancies in transplant recipients as reported to the National Transplantation Pregnancy Registry. Most were treated with cyclosporine and tacrolimus, and approximately 75 percent of pregnancies resulted in a live birth. Similar outcomes were described for the Australian and New Zealand Transplant Registry by Wyld and associates (2013). Bramham and colleagues (2013) identified 105 pregnancies in renal transplant recipients and the United Kingdom Obstetric Surveillance System (UKOSS). Excluding nine abortions, there was only one perinatal death and 97 living children. Half were delivered before 37 weeks’ gestation, but only 9 percent before 32 weeks. Half were born weighing < 2500 g, and a fourth were growth restricted. Importantly, the incidence of fetal malformations was not increased, except in those who took mycophenolate mofetil (Coscia, 2010). Twin pregnancy has also been described following renal transplantation (Gizzo, 2014).
The incidence of preeclampsia is high in all transplant recipients (Brosens, 2013). In the UK National Cohort Study reported by Bramham and associates (2013), the incidence of preeclampsia was 22 percent. From their review, Josephson and McKay (2011) cite an incidence of a third of pregnancies but question the validity of this frequency. Importantly, in some cases, rejection is difficult to distinguish from preeclampsia. That said, the incidence of rejection episodes approximates only 2 percent (Bramham, 2013). Viral infections—especially polyomavirus hominis 1, also called BK virus, infections—are frequent. Also, gestational diabetes is found in approximately 5 percent. Both are likely related to immunosuppression therapy. Similar outcomes have been reported by several other investigators (Al Duraihimh, 2008; Cruz Lemini, 2007; Ghafari, 2008; Gutierrez, 2005).

Lindheimer (2007a) and Josephson (2011) and their coworkers recommend that women who have undergone transplantation satisfy several requisites before attempting pregnancy. First, women should be in good general health for at least 1 to 2 years after transplantation. Also, there should be stable renal function without severe renal insufficiency—serum creatinine < 2 mg/dL and preferably < 1.5 mg/dL—and < 500 mg/day proteinuria. Evidence for graft rejection should be absent for 6 months, and pyelocalyceal distention by urography should not be apparent. Moreover, hypertension should be absent or well controlled. And last, no teratogenic drugs are being given, and drug therapy is reduced to maintenance levels.

Cyclosporine or tacrolimus is given routinely to renal transplantation recipients (Jain, 2004). Cyclosporine blood levels decline during pregnancy, although this was not reported to be associated with rejection episodes (Thomas, 1997). Unfortunately, these agents are nephrotoxic and also may cause renal hypertension. In fact, they likely contribute substantively to chronic renal disease that develops in 10 to 20 percent of patients with nonrenal solid-organ transplantation (Goes, 2007).

Concern persists regarding the possible late effects in offspring subjected to immunosuppressive therapy in utero. These include malignancy, germ cell dysfunction, and malformations in the children of the offspring. In addition, cyclosporine is secreted in breast milk, and in at least one instance, it produced therapeutic serum levels in the nursing child (Moretti, 2003).

Finally, although pregnancy-induced renal hyperfiltration theoretically may impair long-term graft survival, Sturgiss and Davison (1995) found no evidence for this in a case-control study of 34 allograft recipients followed for a mean of 15 years.

**Management**

Close surveillance is necessary. Covert bacteriuria is treated, and if it is recurrent, suppressive treatment is given for the remainder of the pregnancy. Serial hepatic enzyme concentrations and blood counts are monitored for toxic effects of azathioprine and cyclosporine. Some recommend measurement of serum cyclosporine levels. Gestational diabetes is more common if corticosteroids are taken, and overt diabetes must be excluded with glucose tolerance testing done at approximately 26 weeks’ gestation. Surveillance for opportunistic infections from herpesvirus, cytomegalovirus, and toxoplasmosis is important because these infections are common. Some recommend surveillance for BK virus in women known to be infected (Josephson, 2011). Treatment is problematic.

Renal function is monitored, and as shown in Figure 53-2, the glomerular filtration rate usually increases 20 to 25 percent. If a significant rise in the serum creatinine level is detected, then its cause must be determined. Possibilities include acute rejection, cyclosporine toxicity,
preeclampsia, infection, and urinary tract obstruction. Evidence of pyelonephritis or graft rejection should prompt admission for aggressive management. Imaging studies and kidney biopsy may be indicated. The woman is carefully monitored for development or worsening of underlying hypertension, and especially superimposed preeclampsia. Management of hypertension during pregnancy is the same as for patients without a transplant.

Because of increased incidences of fetal-growth restriction and preterm delivery, vigilant fetal surveillance is indicated (Chaps. 42, p. 842 and 44, p. 880). Although cesarean delivery is reserved for obstetrical indications, occasionally the transplanted kidney obstructs labor. In all women with a renal transplant, the cesarean delivery rate exceeds 60 percent (Bramham, 2013; Rocha, 2013).

### POLYCYSTIC KIDNEY DISEASE

This usually autosomally dominant systemic disease primarily affects the kidneys. Its basic pathophysiology is one of a ciliopathy (Hildebrandt, 2011). The disease is found in 1 in 800 live births and causes approximately 5 to 10 percent of end-stage renal disease in the United States (Bargman, 2012). Although genetically heterogeneous, almost 85 percent of cases are due to PKD1 gene mutations on chromosome 16, and the other 15 percent to PKD2 mutations on chromosome 4 (Salant, 2012). Prenatal diagnosis is available if the mutation has been identified in a family member or if linkage has been established in the family.

Renal complications are more common in men than in women, and symptoms usually appear in the third or fourth decade. Flank pain, hematuria, proteinuria, abdominal masses, and associated calculi and infection are common findings. Hypertension develops in 75 percent, and progression to renal failure is a major problem. Superimposed acute renal failure may also develop from infection or obstruction from ureteral angulation by cyst displacement.

Other organs are commonly involved. Hepatic involvement is more common and more aggressive in women than in men (Chapman, 2003). Asymptomatic hepatic cysts coexist in a third of patients with polycystic kidneys. Approximately 10 percent of patients with polycystic kidney disease die from rupture of an associated intracranial berry aneurysm. Up to a fourth of patients have cardiac valvular lesions, with mitral valve prolapse and mitral, aortic, and tricuspid valvular incompetence.

### Pregnancy Outcomes

The prognosis for pregnancy in women with polycystic kidney disease depends on the degree of associated hypertension and renal insufficiency. Urinary tract infections are common. Chapman and coworkers (1994) compared pregnancy outcomes in 235 affected women who had 605 pregnancies with those of 108 unaffected family members who had 244 pregnancies. Composite perinatal complication rates were similar—33 versus 26 percent—but hypertension, including preeclampsia, was more common in women with polycystic kidneys. Pregnancy does not seem to accelerate the natural disease course (Lindheimer, 2007b).

### GLOMERULAR DISEASES
The glomerulus and its capillaries are subject to numerous and various conditions and agents that can lead to acute and chronic diseases. Glomerular damage can be caused by several agents such as toxins or infections or from systemic disorders such as hypertension or diabetes. It may also be idiopathic. When there is capillary inflammation, the process is termed **glomerulonephritis**, and in many of these cases, an autoimmune process is involved. Glomerular disease or glomerulonephritis may result from a single stimulus such as that following group A streptococcal infections. However, it may be a manifestation of a multisystem disease such as systemic lupus erythematosus or diabetes (Sethi, 2012).

Persistent glomerulonephritis eventually leads to renal functional decline. Progression is variable and often does not become apparent until chronic renal insufficiency is diagnosed as discussed on page 1060. Lewis and Neilsen (2012) group glomerular injuries into six syndromes based on clinical patterns (Table 53-3). Some underlying disorders—examples include infections, vasculitides, and diabetes—can result in one clinical pattern in different individuals. Finally, within each of these categories, there are disorders encountered in young women, and thus, these may antedate or first manifest during pregnancy.

Adapted from Lewis, 2012.

#### Acute Nephritic Syndromes

Acute glomerulonephritis may result from any of several causes (see Table 53-3). The clinical presentation usually includes hypertension, hematuria, red-cell casts, pyuria, and proteinuria. Varying degrees of renal insufficiency and salt and water retention result in edema, hypertension, and circulatory congestion (Lewis, 2012). The prognosis and treatment of nephritic syndromes depends on their etiology. Some recede spontaneously or with treatment. However, in some patients, *rapidly progressive glomerulonephritis* leads to end-stage renal failure, whereas in others, *chronic glomerulonephritis* develops with slowly progressive renal disease.
The prototype is *acute poststreptococcal glomerulonephritis*, which is historically interesting because it was confused with eclampsia until the mid-1800s. *IgA nephropathy*, also known as *Berger disease*, is the most common form of acute glomerulonephritis worldwide (Wyatt, 2013). The isolated form occurs sporadically, and it may be related to *Henoch-Schönlein purpura* as the systemic form (Donadio, 2002). Isolated nephritis may be due to antiglomerular basement membrane (GBM) antibodies. These may also involve the lungs to manifest as a pulmonary-renal syndrome with alveolar hemorrhage, which is termed *Goodpasture syndrome* (Bazari, 2012; Vasilou, 2005).

**Pregnancy**

Acute nephritic syndromes during pregnancy can be difficult to differentiate from severe preeclampsia or eclampsia. One example is systemic lupus erythematosus with a flare during the second half of pregnancy (Bramham, 2012; Zhao, 2013). In some cases, renal biopsy may be necessary to determine etiology as well as to direct management (Lindheimer, 2007a; Ramin, 2006). This is discussed further in Chapter 59 (p. 1170).

Whatever the underlying etiology, acute glomerulonephritis has profound effects on pregnancy outcome. In an older study, Packham and coworkers (1989) described 395 pregnancies in 238 women with *primary* glomerulonephritis diagnosed before pregnancy. The most common lesions on biopsy were membranous glomerulonephritis, IgA glomerulonephritis, and diffuse mesangial glomerulonephritis. Although most of these women had normal renal function, half developed hypertension, a fourth were delivered preterm, and the perinatal mortality rate after 28 weeks’ gestation was 80 per 1000. As expected, the worst perinatal outcomes were in women with impaired renal function, early or severe hypertension, and nephrotic-range proteinuria.

Similar outcomes have been reported for pregnancies in women with IgA nephropathy. From their review of more than 300 such pregnancies, Lindheimer and colleagues (2000) concluded that pregnancy outcome was related to the degree of renal insufficiency and hypertension. Ronkainen and associates (2006) followed a cohort of children with IgA nephritis for an average of 19 years. They described 22 pregnancies of which half were complicated by hypertension and a third were delivered preterm.

**Nephrotic Syndromes**

Heavy proteinuria is the hallmark of the nephrotic syndromes, which may be caused by several primary and secondary kidney disorders. These can cause immunological- or toxic-mediated injury with glomerular capillary wall breakdown that allows excessive filtration of plasma proteins. In addition to heavy urine protein excretion, the syndrome is characterized by hypoalbuminemia, hypercholesterolemia, and edema. There frequently is hypertension, and along with albumin nephrotoxicity, renal insufficiency eventually develops.

Some of the more common causes of the nephrotic syndrome are shown in Table 53-4. In most cases, renal biopsy will disclose microscopic abnormalities that may help direct treatment, which depends on etiology. Edema is problematic, especially during pregnancy (Jakobi, 1995). Normal amounts of dietary protein of high biological value are encouraged—indeed, high-protein diets increase proteinuria. The incidence of thromboembolism is increased and varies with the severity of hypertension, proteinuria, and renal insufficiency (Stratta, 2006). Although both arterial and venous thromboses may develop, renal vein thrombosis is particularly worrisome. The value, if any, of prophylactic anticoagulation is unclear. Some cases of nephrosis from primary glomerular disease respond to glucocorticosteroids and other immunosuppressants or cytotoxic drug therapy.
In most of those cases caused by infection or drugs, proteinuria recedes when the underlying cause is corrected.

**Pregnancy**

Maternal and perinatal outcomes in women with the nephrotic syndromes depend on its underlying cause and severity. Whenever possible, these should be ascertained, and renal biopsy may be indicated to determine if there is a treatment-responsive etiology. Half of women with nephrotic-range proteinuria will have rise in daily protein excretion as pregnancy progresses (Packham, 1989). In women with nephrosis cared for at Parkland Hospital, we reported that two thirds had protein excretion that exceeded 3 g/day (Stettler, 1992). At the same time, however, if these women had only mild degrees of renal dysfunction, they had normally augmented glomerular filtration across pregnancy (Cunningham, 1990).

Management of edema during pregnancy can be particularly challenging as it is intensified by normally increasing hydrostatic pressure in the lower extremities. In some women, massive vulvar edema may develop as described by Jakobi and coworkers (1995) in diabetic women. Massive vulvar edema associated with the nephrotic syndrome caused by secondary syphilis is shown in **Figure 53-4**. Another major problem is that up to half of these women have chronic hypertension that may require treatment (Chap. 50, p. 1005). In these, as well as in previously normotensive women, preeclampsia is common and often develops early in pregnancy.
Most women with nephrotic syndromes who do not have severe hypertension or renal insufficiency will have successful pregnancy outcomes. Conversely, if there is renal insufficiency, moderate to severe hypertension, or both, the prognosis is much worse. Our experiences from women with 65 pregnancies cared for at Parkland Hospital noted that there are frequent complications (Stettler, 1992). Protein excretion during pregnancy averaged 4 g daily, and a third of the women had classic nephrotic syndrome. There was some degree of renal insufficiency in 75 percent, chronic hypertension in 40 percent, and persistent anemia in 25 percent. Importantly, preeclampsia developed in 60 percent, and 45 percent had preterm deliveries. Even so, after excluding abortions, 53 of 57 infants were born alive. Stratta and associates (2006) reported fetal-growth restriction in a third of these women.

Long-Term Outcomes

Women identified to have nephrotic syndromes either before or during pregnancy are at risk for serious long-term adverse outcomes. In women cared for at Parkland Hospital cited in the report above, all 21 women who subsequently underwent renal biopsy had abnormal histological findings (Stettler, 1992). At least 20 percent of women followed for 10 years progressed to end-stage renal failure. Similarly, Chen and colleagues (2001) reported short-term outcomes in 15 women with nephrotic syndromes in whom they had performed renal biopsy during pregnancy. By 2 years, three of these women had died, three had developed chronic renal failure, and two had progressed to end-stage renal disease. In the report by Imbasciati and coworkers (2007), women whose serum creatinine level was > 1.4 mg/dL and whose 24-hour protein excretion exceeded 1 g/day had the shortest renal survival times following pregnancy.
This describes a pathophysiological process that can progress to end-stage renal disease. The National Kidney Foundation describes six stages of chronic kidney disease defined by decreasing glomerular filtration rate (GFR). It progresses from stage 0—GFR > 90 mL/min/1.73 m² to stage 5—GFR < 15 mL/min/1.73 m². There are a number of diseases that result in progressively declining renal function, and many result from one of the glomerular diseases that were discussed earlier. Those that most commonly lead to end-stage disease requiring dialysis and kidney transplantation and their approximate percentages include: diabetes, 33 percent; hypertension, 25 percent; glomerulonephritis, 20 percent; and polycystic kidney disease, 15 percent (Abboud, 2010; Bargman, 2012).

Most reproductive-aged women with these diseases have varying degrees of renal insufficiency, proteinuria, or both. To counsel regarding fertility and pregnancy outcome, the degree of renal functional impairment and of associated hypertension are assessed. Successful pregnancy outcome in general may be more related to these two factors than to the specific underlying renal disorder. A general prognosis can be estimated by considering women with chronic renal disease in arbitrary categories of renal function (Davison, 2011). These include normal or mild impairment—defined as a serum creatinine < 1.5 mg/dL; moderate impairment—defined as a serum creatinine 1.5 to 3.0 mg/dL; and severe renal insufficiency—defined as a serum creatinine > 3.0 mg/dL. Although some have suggested adopting the classification of the National Kidney Foundation, others recommend using the older categories (Davison, 2011; Piccoli, 2010a, 2011). Thus, the obstetrician must be familiar with both.

Pregnancy and Chronic Renal Disease

Most women have relatively mild renal insufficiency, and its severity along with any underlying hypertension is prognostic of pregnancy outcome. Renal disease with comorbidities secondary to a systemic disorder—for example, diabetes or systemic lupus erythematosus—portends a worse prognosis (Davison, 2011; Fischer, 2004). For all women with chronic renal disease, the incidences of hypertension and preeclampsia, preterm and growth-restricted infants, and other problems are high. Despite these, the National High Blood Pressure Education Program Working Group (2000) has concluded that the prognosis has substantively improved since the 1980s. This has subsequently been verified by several reviews (Davison, 2011; Nevis, 2011; Ramin, 2006).

Loss of renal tissue is associated with compensatory intrarenal vasodilation and hypertrophy of the surviving nephrons. The resultant hyperperfusion and hyperfiltration eventually damage surviving nephrons to cause nephrosclerosis and worsening renal function. With mild renal insufficiency, pregnancy causes greater augmentation of renal plasma flow and glomerular filtration (Baylis, 2003; Helal, 2012). With progressively declining renal function, there is little, if any, augmented renal plasma flow. In one study, only half of women with moderate renal insufficiency demonstrated pregnancy-augmented glomerular filtration, and women with severe disease had no increase (Cunningham, 1990).

Importantly, chronic renal insufficiency also curtails normal pregnancy-induced hypervolemia. Blood volume expansion during pregnancy is related to disease severity and correlates inversely with serum creatinine concentration. As shown in Figure 53-5, women with mild to moderate renal dysfunction have normal blood volume expansion that averages 55 percent. With severe renal insufficiency, however, volume expansion averages only 25 percent, which is
similar to that seen with hemoconcentration from eclampsia. In addition, these women have variable degrees of chronic anemia due to intrinsic renal disease.

![Blood volume expansion in 44 normally pregnant women at term compared with 29 who had eclampsia; 10 with moderate chronic renal insufficiency (CRI)—serum creatinine 1.5 to 2.9 mg/dL; and four with severe CRI—serum creatinine ≥ 3.0 mg/dL. (Data from Zeeman, 2009; Cunningham, 1990.)](image)

Renal Disease with Preserved Function

In some women, although glomerular disease has not yet caused renal dysfunction, there is still an increased incidence of pregnancy complications. As shown in Table 53-5, these complications are less frequent than in cohorts of women with moderate and severe renal insufficiency. Two studies illustrate this. In one, Surian and colleagues (1984) described outcomes in 123 pregnancies in women with biopsy-proven glomerular disease. Although only a few of these women had renal dysfunction, 40 percent developed obstetrical or renal complications. In another study, Packham and coworkers (1989) described outcomes in 395 pregnancies in women with preexisting glomerulonephritis and minimal renal insufficiency. Impaired renal function developed in 15 percent of these women during pregnancy, and 60 percent had worsening proteinuria. Only 12 percent had antecedent chronic hypertension, however, more than half of the 395 pregnancies were complicated by hypertension. The perinatal mortality rate was 140 per 1000, but even without early-onset or severe hypertension or nephrotic-range proteinuria, the rate was 50 per 1000. Importantly, in 5 percent, worsening renal function was permanent.
Chronic Renal Insufficiency

As indicated, pregnancy complication rates are greater in women with chronic kidney disease who also have renal insufficiency compared with women with preserved renal function. Furthermore, adverse outcomes are generally directly related to the degree of renal impairment. Of the more recent reports shown in Table 53-5, outcomes of women with moderate versus severe renal insufficiency are usually not separated. That said, Piccoli and associates (2010a) described 91 pregnancies complicated by stage 1 chronic kidney disease. Primarily because of hypertension, 33 percent were delivered preterm, and 13 percent had fetal-growth restriction. Alsuwaida and colleagues (2011) reported similar observations.

Other investigators have described pregnancies complicated by moderate or severe renal insufficiency (Cunningham, 1990; Imbasciati, 2007; Jones, 1996). Despite a high incidence of chronic hypertension, anemia, preeclampsia, preterm delivery, and fetal-growth restriction, perinatal outcomes were generally acceptable. As shown in Figure 53-6, fetal growth is frequently impaired and related to renal dysfunction severity.

### Chronic Renal Insufficiency

As indicated, pregnancy complication rates are greater in women with chronic kidney disease who also have renal insufficiency compared with women with preserved renal function. Furthermore, adverse outcomes are generally directly related to the degree of renal impairment. Of the more recent reports shown in Table 53-5, outcomes of women with moderate versus severe renal insufficiency are usually not separated. That said, Piccoli and associates (2010a) described 91 pregnancies complicated by stage 1 chronic kidney disease. Primarily because of hypertension, 33 percent were delivered preterm, and 13 percent had fetal-growth restriction. Alsuwaida and colleagues (2011) reported similar observations.

Other investigators have described pregnancies complicated by moderate or severe renal insufficiency (Cunningham, 1990; Imbasciati, 2007; Jones, 1996). Despite a high incidence of chronic hypertension, anemia, preeclampsia, preterm delivery, and fetal-growth restriction, perinatal outcomes were generally acceptable. As shown in Figure 53-6, fetal growth is frequently impaired and related to renal dysfunction severity.
There are several important aspects of prenatal care for women with chronic renal disease. Frequent monitoring of blood pressure is paramount, and serum creatinine levels and 24-hour protein excretion are quantified as indicated. Bacteriuria is treated to decrease the risk of pyelonephritis and further nephron loss. Protein-restricted diets are not recommended (Lindheimer, 2000; Ruggenenti, 2001). In some women with anemia from chronic renal insufficiency, a response is seen with recombinant erythropoietin. However, hypertension is a common side effect. Serial sonography is performed to follow fetal growth (Chap. 44, p. 880). The differentiation between worsening hypertension and superimposed preeclampsia is problematic. Preliminary data indicate that the angiogenic biomarkers placental growth factor (PlGF) and its soluble receptor (sFlt-1) may be useful to separate chronic from gestational hypertension. This is described in Chapter 40 (p. 747).

Long-Term Effects

In some women, pregnancy may accelerate chronic renal disease progression by increasing hyperfiltration and glomerular pressure to worsen nephrosclerosis (Baylis, 2003; Helal, 2012). Women with more severe renal insufficiency have increased susceptibility. For example, Jungers and associates (1995) reported few long-term pregnancy-related adverse effects in 360 women with chronic glomerulonephritis and antecedent normal renal function. In women with severe chronic renal insufficiency, however, renal insufficiency may become worse during pregnancy (Abe, 1991; Jones, 1996). In the study by Imbasciati and coworkers (2007), worsening renal function was more likely in women who had a serum creatinine ≥ 1.4 mg/dL and > 1 g/day protein excretion.

As noted, progression is common for many women with chronic renal disorders. At 1 year after pregnancy, Jones and Hayslett (1996) reported that 10 percent of the women had developed end-stage renal failure—stage 5 chronic kidney disease. In a study from Parkland Hospital, we found that 20 percent of pregnant women with moderate to severe insufficiency had developed end-stage renal failure by a mean of 4 years (Cunningham, 1990). Similar findings in women with a median follow-up of 3 years were described by Imbasciati and colleagues (2007). By this time, end-stage disease was apparent in 30 percent of women whose serum creatinine was ≥ 1.4 mg/dL and who
had proteinuria > 1 g/day. Chronic proteinuria is also a marker for subsequent development of renal failure. In another report from Parkland Hospital, we found that 20 percent of women with chronic proteinuria discovered during pregnancy progressed to end-stage renal failure within several years (Stettler, 1992).

### Dialysis During Pregnancy

Significantly impaired renal function is accompanied by subfertility that may be corrected with chronic renal replacement therapy—either hemodialysis or peritoneal dialysis (Hladunewich, 2011; Shahir, 2013). Not unexpectedly, these pregnancies can be complicated. Chou and associates (2008) reviewed 131 cases reported since 1990. They found that mean fetal birthweight was higher in women who conceived while undergoing dialysis—1530 g versus 1245 g in women who conceived before starting dialysis. This was also true for 77 pregnancies reported to the Australian and New Zealand Dialysis and Transplantation Registry (Jesudason, 2014). Similar outcomes from several reports since 1999 are shown in Table 53-6.

| TABLE 53-6. Pregnancy Outcomes in 156 Women Undergoing Dialysis During Pregnancy |
|---------------------------------------------------------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| Study (Year)        | N    | Delivery (wk) | Birthweight (g) | Hypertension | Hydramnios | Perinatal Mortality | Surviving Infants |

<sup>a</sup>Preeclampsia only.

NS = not stated.

These reports described similar outcomes with either hemodialysis or peritoneal dialysis. Thus, for the woman already undergoing either method, it seems reasonable to continue that method with consideration for its increasing frequency. In the woman who has never been dialyzed, the threshold for initiation during pregnancy is unclear. Lindheimer and colleagues (2007a) recommend initiation when serum creatinine levels are between 5 and 7 mg/dL. Because it is imperative to avoid abrupt volume changes that cause hypotension, dialysis frequency may be extended to five to six times weekly (Reddy, 2007).

Hladunewich and coworkers (2011) recommend attention to certain protocols that include replacement of substances lost through dialysis. Multivitamin doses are doubled, and calcium and iron salts are provided along with sufficient dietary protein and calories. Chronic anemia is
treated with erythropoietin. To meet pregnancy changes, extra calcium is added to the dialysate along with less bicarbonate.

Maternal complications are common and include severe hypertension, placental abruption, heart failure, and sepsis. Piccoli and associates (2010b) reviewed reported outcomes in 90 pregnancies in 78 women. They found that these studies were heterogeneous for definitions; types of dialysis, frequency, and prescription; and perinatal outcomes. Although they were encouraged by their findings, they described high incidences of maternal hypertension and anemia, preterm and growth-restricted infants, stillbirths, and hydramnios.

ACUTE KIDNEY INJURY

Previously termed acute renal failure, acute kidney injury is now used to describe sudden impairment of kidney function with retention of nitrogenous and other waste products normally excreted by the kidneys (American Society of Nephrology, 2005; Waikar, 2012). Acute kidney injury has become less common today. For example, in a 6-year period the overall incidence at the Mayo Clinic was 0.4 percent (Gurrieri, 2012). Although the incidence of acute kidney injury in pregnancy has decreased substantially, it still occasionally causes significant obstetrical morbidity, and women who require acute dialysis have increased mortality rates (Kuklina, 2009; Singri, 2003). Outcomes are available from four older studies comprising a total of 266 women with renal failure (Drakeley, 2002; Nzerue, 1998; Sibai, 1990; Turney, 1989). Approximately 70 percent had preeclampsia, 50 percent had obstetrical hemorrhage, and 30 percent had a placental abruption. Almost 20 percent required dialysis, and the maternal mortality rate in these was approximately 15 percent.

Obstetrical cases of acute kidney injury that require dialysis have become less common today. That said, acute renal ischemia is still commonly associated with severe preeclampsia and hemorrhage (Gurrieri, 2012). Particularly contributory are HELLP syndrome and placental abruption (Audibert, 1996; Drakely, 2002). Septicemia is another common comorbidity, especially in resource-poor countries (Acharya, 2013; Srinil, 2011; Zeeman, 2003). Acute kidney injury is also common in women with acute fatty liver of pregnancy (Sibai, 2007). Nelson and colleagues (2013) reported some degree of renal insufficiency in virtually all of 52 such women cared for at Parkland Hospital (Chap. 55, p. 1087). Another woman from Parkland Hospital developed acute kidney injury from dehydration caused by severe hyperemesis gravidarum at 15 weeks (Hill, 2002). Her serum creatinine level peaked at 10.7 mg/dL, and she required hemodialysis for 5 days. Other causes that are discussed further in Chapter 56 (p. 1116) include thrombotic microcoagulopathies (Ganesan, 2011).

Diagnosis and Management

In most women, renal failure develops postpartum, thus management is usually not complicated by fetal considerations. An acute increase in serum creatinine is most often due to renal ischemia (Abuelo, 2007). Oliguria is an important sign of acutely impaired renal function. In obstetrical cases, both prerenal and intrarenal factors are commonly operative. For example, with total placental abruption, severe hypovolemia is common from massive hemorrhage, and frequently associated preeclampsia causes preexistent renal ischemia.

When azotemia is evident and severe oliguria persists, some form of renal replacement treatment is indicated, and hemofiltration or dialysis is initiated before marked deterioration
occurs. Hemodynamic measurements are normalized. Medication dose adjustments are imperative, and magnesium sulfate is a prominent example (Singri, 2003; Waikar, 2012). Early dialysis appears to reduce the mortality rate appreciably and may enhance the extent of renal function recovery. With time, renal function usually returns to normal or near normal.

Prevention

Acute kidney injury in obstetrics is most often due to acute blood loss, especially that associated with preeclampsia. Thus, it may often be prevented by the following means:

1. Prompt and vigorous volume replacement with crystalloid solutions and blood in instances of massive hemorrhage, such as in placental abruption, placenta previa, uterine rupture, and postpartum uterine atony (Chap. 41, p. 814).
2. Delivery or termination of pregnancies complicated by severe preeclampsia or eclampsia, and careful blood transfusion if loss is more than average (Chap. 40, p. 766).
3. Close observation for early signs of sepsis syndrome and shock in women with pyelonephritis, septic abortion, chorioamnionitis, or sepsis from other pelvic infections (Chap. 47, p. 946).
4. Avoidance of loop diuretics to treat oliguria before ensuring that blood volume and cardiac output are adequate for renal perfusion.
5. Judicious use of vasoconstrictor drugs to treat hypotension, and only after it has been determined that pathological vasodilatation is the cause.

Irreversible ischemic renal failure caused by acute cortical necrosis has become exceedingly uncommon in obstetrics. Before widespread availability of dialysis, it complicated a fourth of obstetrical renal failure cases (Grünfeld, 1987; Turney, 1989). Most cases followed placental abruption, preeclampsia-eclampsia, and endotoxin-induced shock. Once common with septic abortion, this is a rare cause in this country today (Lim, 2011; Srinil, 2011). Histologically, the lesion appears to result from thrombosis of segments of the renal vascular system. The lesions may be focal, patchy, confluent, or gross. Clinically, renal cortical necrosis follows the course of acute renal failure, and its differentiation from acute tubular necrosis is not possible during the early phase. The prognosis depends on the extent of the necrosis. Recovery of function is variable, and stable renal insufficiency may result (Lindheimer, 2007a).

Obstructive Renal Failure

Rarely, bilateral ureteral compression by a very large pregnant uterus is greatly exaggerated. Resultant ureteral obstruction in turn, may cause severe oliguria and azotemia. An extreme example is shown in Figure 53-7. Brandes and Fritsche (1991) reviewed 13 cases that were the consequence of a markedly overdistended uterus. They described a woman with twins who developed anuria and a serum creatinine level of 12.2 mg/dL at 34 weeks’ gestation. After amniotomy, urine flow resumed at 500 mL/hr and was followed by a rapid decline in serum creatinine levels to normal range. Eckford and Gingell (1991) described 10 women in whom ureteral obstruction was relieved by stenting. The stents were left in place for a mean of 15.5 weeks and removed 4 to 6 weeks postpartum. Sadan and coworkers (1994) reported a similar experience in eight such women who underwent stent placement at a mean of 29 weeks for moderate to severe hydronephrosis. The stents remained in situ for a mean of 9 weeks, during which time renal function remained normal.
FIGURE 53-7 A. Magnetic resonance image in a coronal plane of a pregnant woman with unilateral hydronephrosis caused by ureteral obstruction. The serum creatinine was 8 mg/dL and decreased to 0.8 mg/dL after a percutaneous nephrostomy tube was placed. B. Left kidney (arrow) and associated hydronephrosis (asterisk) are again noted in this axial plane image.

We have observed this phenomenon on several occasions (Satin, 1993). Partial ureteral obstruction may be accompanied by fluid retention and significant hypertension. When the obstructive uropathy is relieved, diuresis ensues and hypertension dissipates. In one woman with massive hydramnios (9.4 L) and an anencephalic fetus, amniocentesis and removal of some of the amniotic fluid was followed promptly by diuresis, a decline in the plasma creatinine concentration, and improvement of hypertension. In our experience, women with previous urinary tract surgery for reflux are more likely to have such obstructions.

LOWER GENITAL TRACT LESIONS

Urethral Diverticulum

Infrequently complicating pregnancy, this type of diverticulum is thought to originate from an enlarging paraurethral gland abscess that ruptures into the urethral lumen. As infection clears, the remaining dilated diverticular sac and its ostium into the urethra persist. Urine collecting within and dribbling from the sac, pain, palpable mass, and recurrent urinary infections may be associated findings. In general, a diverticulum is managed expectantly during pregnancy. Rarely, drainage may be necessary, or surgery required (Iyer, 2013). If additional antepartum evaluation is needed, MR imaging is preferred for its superior soft tissue resolution and ability to define complex diverticula (Dwarkasing, 2011; Pathi, 2013).
Genital Tract Fistulas

Fistulas found during pregnancy likely existed previously, but in rare cases, they form during pregnancy. In developed countries, *vesicovaginal fistula* following a McDonald cerclage has been reported (Massengill, 2012). These fistulas may also form with prolonged obstructed labor that is more commonly seen in resource-poor countries. In these cases, the genital tract is compressed between the fetal head and bony pelvis. Brief pressure is not significant, but prolonged pressure leads to tissue necrosis with subsequent fistula formation (Wall, 2012). *Vesicouterine fistula* that developed after prior cesarean delivery have been described (DiMarco, 2012; Manjunatha, 2012). Rarely, *vesicocervical fistula* may follow cesarean delivery or may form if the anterior cervical lip is compressed against the symphysis pubis (Dudderidge, 2005).

During normal pregnancy, the gastrointestinal tract and its appendages undergo remarkable anatomical, physiological, and functional changes. These changes, which are discussed in detail in Chapter 4 (p. 66), can appreciably alter clinical findings normally relied on for diagnosis and treatment of gastrointestinal disorders. Moreover, as pregnancy progresses, gastrointestinal symptoms become more difficult to assess. Physical findings are often obscured by a large uterus that displaces abdominal organs and can alter the location and intensity of pain and tenderness.
Various methods can evaluate the gastrointestinal tract during pregnancy without reliance on x-ray techniques. Fiberoptic endoscopic instruments have revolutionized diagnosis and management of most gastrointestinal conditions, and these are particularly well suited for pregnancy. With endoscopy, the esophagus, stomach, duodenum, and colon can be inspected (Cappell, 2006, 2011). The proximal jejunum can also be studied, and the ampulla of Vater cannulated to perform endoscopic retrograde cholangiopancreatography—ERCP (Fogel, 2014; Kamani, 2012; Tang, 2009). Experience in pregnancy with videocapsule endoscopy for small-bowel evaluation is limited (Storch, 2006).

Upper gastrointestinal endoscopy is used for management as well as diagnosis of several problems. Common bile duct exploration and drainage are used for choledocholithiasis as described in Chapter 55 (p. 1096). It is also used for sclerotherapy as well as placement of percutaneous endoscopic gastrostomy (PEG) tubes. A number of concise reviews have been provided (Cappell, 2011; Fogel, 2014; Gilinsky, 2006).

Flexible sigmoidoscopy can be used safely in pregnant women (Siddiqui, 2006). In nonpregnant patients, colonoscopy is indispensable for viewing the entire colon and distal ileum for diagnosis and management of inflammatory bowel disease. Except for the midtrimester, reports of colonoscopy during pregnancy are limited, but preliminary results indicate that it should be performed if indicated (Cappell, 2010, 2011). Bowel preparation is completed using polyethylene glycol electrolyte or sodium phosphate solutions. With these, serious maternal dehydration that may cause diminished uteroplacental perfusion should be avoided.

Noninvasive Imaging Techniques

The obvious ideal technique for gastrointestinal evaluation during pregnancy is abdominal sonography. Because computed tomography (CT) use is limited in pregnancy due to radiation exposure, magnetic resonance (MR) imaging is now commonly used to evaluate the abdomen and retroperitoneal space (Khandelwal, 2013). One example is magnetic-resonance cholangiopancreatography—MRCP (Oto, 2009). These and other imaging modalities, and their safe use in pregnancy, are considered in more detail in Chapter 46 (p. 933).

Laparotomy and Laparoscopy

Surgery is lifesaving for certain gastrointestinal conditions—perforative appendicitis being the most common example. From the Swedish Registry database through 1981, abdominal exploration by laparotomy or laparoscopy was performed in 1331 of 720,000 pregnancies—approximately 1 in every 500 (Mazze, 1989). A similar incidence of 1 in 635 in nearly 50,000 pregnancies was described by Kort (1993). In both studies, the most common indications for surgery were appendicitis, an adnexal mass, and cholecystitis.

Laparoscopic procedures have replaced traditional surgical techniques for many abdominal disorders during pregnancy (Carter, 2004). In an updated report from the Swedish Registry database, there were 2181 pregnant women who underwent laparoscopy and 1522 who had laparotomy for nonobstetrical indications (Reedy, 1997). Use of these procedures was similar to their first study—approximately 1 in every 800 pregnancies. Both approaches were used usually before 20 weeks, and they were found to be safe. Long-term surveillance studies also suggest no deleterious effects for mother or fetus (Rizzo, 2003).

The most common nongynecological laparoscopic procedures performed during pregnancy are cholecystectomy and appendectomy (Fatum, 2001; Rollins, 2004). For more details and for descriptions of surgical technique, see Chapter 46 (p. 928) as well as Operative Obstetrics, 2nd
Nutritional Support

Specialized nutritional support can be delivered enterally, usually via nasogastric tube feedings, or parenterally with nutrition given by venous catheter access, either peripherally or centrally.

When possible, enteral alimentation is preferable because it has fewer serious complications (Bistrian, 2012; Hamaoui, 2003). In obstetrical patients, very few conditions prohibit enteral nutrition as a first effort to prevent catabolism. Even in extreme cases, such as recalcitrant hyperemesis gravidarum, percutaneous endoscopic gastrostomy with a jejunal port—PEG (J) tube—has been described (Saha, 2009).

The purpose of parenteral feeding, or hyperalimentation, is to provide nutrition when the intestinal tract must be kept quiescent. Central venous access is necessary for total parenteral nutrition because its hyperosmolarity requires rapid dilution in a high-flow vascular system. These solutions provide 24 to 40 kcal/kg/day, principally as a hypertonic glucose solution.

There have been a variety of conditions for which total parenteral nutrition has been employed during pregnancy (Table 54-1). Gastrointestinal disorders are the most common indication, and in the many studies cited, feeding duration averaged 33 days. It is imperative to emphasize that complications of parenteral nutrition are frequent, and they may be severe (Guglielmi, 2006). In an early report of 26 pregnancies, a 50-percent rate of complications, which included pneumothorax, hemothorax, and brachial plexus injury, was described (Russo-Stieglitz, 1999).

a Some conditions are unique to pregnancy.
Risk are listed alphabetically.
From Folk, 2004; Guglielmi, 2006; Ogura, 2003; Russo-Stieglitz, 1999; Saha, 2009; Spiliopoulos, 2013.

The most frequent serious complication is catheter sepsis, and Folk (2004) reported a 25-percent incidence in 27 women with hyperemesis gravidarum. Although bacterial sepsis is most common, *Candida* septicemia has been described (Paranyuk, 2006). The Centers for Disease Control and Prevention (2002) has published detailed guidelines to prevent catheter-related sepsis, and these have served to lessen the dangers of serious infections. Perinatal complications are uncommon, however, fetal subdural hematoma caused by maternal vitamin K deficiency has been described (Sakai, 2003).

There is also appreciable morbidity from long-term use of a *peripherally inserted central catheter (PICC)*. Ogura (2003) reported infection with long-term access in 31 of 52 pregnant women. Holmgren (2008) reported complications in 21 of 33 women in whom a PICC line was placed for hyperemesis. Infections were the most common, and half of infected women also had bacteremia. From a review of 48 reports of nonpregnant adults, Turcotte and associates (2006) concluded that there were no advantages to peripherally placed catheters compared with centrally placed ones. Still, it seems reasonable for short-term nutrition—weeks—that PICC placement has a greater benefit-versus-risk ratio (Bistrian, 2012).

**DISORDERS OF THE UPPER GASTROINTESTINAL TRACT**

**Hyperemesis Gravidarum**

Mild to moderate nausea and vomiting are especially common in pregnant women until approximately 16 weeks (Chap. 9, p. 187). In a small proportion of these, however, it is severe and unresponsive to simple dietary modification and antiemetics. In an attempt to quantify nausea and vomiting severity, Lacasse and colleagues (2008) have proposed a *pregnancy-unique quantification of emesis and nausea (PUQE) scoring index*. Severe unremitting nausea and vomiting—hyperemesis gravidarum—is defined variably as being sufficiently severe to produce weight loss, dehydration, ketosis, alkalois from loss of hydrochloric acid, and hypokalemia. Acidosis develops from partial starvation. In some women, transient hepatic dysfunction develops, and there is accumulation of biliary sludge (Matsubara, 2012). Other causes should be considered because hyperemesis gravidarum is a diagnosis of exclusion (Benson, 2013).

Study criteria have not been homogeneous, thus reports of population incidences vary. There does, however, appear to be an ethnic or familial predilection (Grjibovski, 2008). In population-based studies from California and Nova Scotia, the hospitalization rate for hyperemesis gravidarum was 0.5 to 0.8 percent (Bailit, 2005; Fell, 2006). Up to 20 percent of those hospitalized in a previous pregnancy for hyperemesis will again require hospitalization (Dodds, 2006; Trogstad, 2005). In general, obese women are less likely to be hospitalized for this (Cedergren, 2008).

The etiopathogenesis of hyperemesis gravidarum is likely multifactorial and certainly is enigmatic. It appears to be related to high or rapidly rising serum levels of pregnancy-related hormones. Putative culprits include human chorionic gonadotropin (*hCG*), estrogens, progesterone, leptin, placental growth hormone, prolactin, thyroxine, and adrenocortical hormones (Verberg,
More recently implicated are other hormones that include ghrelin, leptin, nesfatin-1, and PYY-3 (Albayrak, 2013; Gungor, 2013).

Superimposed on this hormonal cornucopia are an imposing number of biological and environmental factors. Moreover, in some but not all severe cases, interrelated psychological components play a major role (Buckwalter, 2002; Christodoulou-Smith, 2011; McCarthy, 2011). Other factors that increase the risk for admission include hyperthyroidism, previous molar pregnancy, diabetes, gastrointestinal illnesses, some restrictive diets, and asthma and other allergic disorders (Fell, 2006; Mullin, 2012). The vestibular system has been implicated (Goodwin, 2008). An association of Helicobacter pylori infection has also been proposed, but evidence is not conclusive (Goldberg, 2007). And for unknown reasons—perhaps estrogen-related—a female fetus increases the risk by 1.5-fold (Schiff, 2004; Tan, 2006; Veenendaal, 2011). Finally, Bolin and coworkers (2013) reported an association between hyperemesis gravidarum and preterm labor, placental abruption, and preeclampsia.

**Complications**

Vomiting may be prolonged, frequent, and severe, and a list of potentially fatal complications is given in Table 54-2. Various degrees of acute kidney injury from dehydration are encountered (Nwoko, 2012). We have cared for a number of women with markedly impaired renal function. The extreme example was a woman who required 5 days of dialysis when her serum creatinine level rose to 10.7 mg/dL (Hill, 2002). Complications from continuous retching include a Mallory-Weiss tear, such as that shown in Figure 54-1. Others are pneumothorax, pneumomediastinum, diaphragmatic rupture, and gastroesophageal rupture, which is Boerhaave syndrome (Chen, 2012; Schwartz, 1994; Yamamoto, 2001).

</table>
In more severe cases, plasma zinc levels are increased, copper levels decreased, and magnesium levels unchanged (Dokmeci, 2004). At least two serious vitamin deficiencies have been reported with hyperemesis in pregnancy. Wernicke encephalopathy from thiamine deficiency has been reported with increasing frequency (Di Gangi, 2012; Palacios-Marqués, 2012). In a review of 49 such cases, Chiossi (2006) reported that only half had the triad of confusion, ocular findings, and ataxia. With this encephalopathy, an abnormal electroencephalogram (EEG) may be seen, and usually there are MR imaging findings (Vaknin, 2006; Zara, 2012). At least three maternal deaths have been described, and long-term sequelae include blindness, convulsions, and coma (Selitsky, 2006). Last, vitamin K deficiency has been reported to cause maternal coagulopathy and fetal intracranial hemorrhage (Kawamura, 2008; Robinson, 1998; Sakai, 2003).

Management
One algorithm for management of nausea and vomiting of pregnancy is shown in Figure 54-2. A Cochrane review reported a salutary effect from several antiemetics given orally or by rectal suppository as first-line agents (Jewell, 2000). The Food and Drug Administration (2013) recently approved Diclegis—a combination of doxylamine-pyridoxine—for morning sickness. Where simple measures fail, intravenous Ringer lactate or normal saline solutions are given to correct dehydration, ketonemia, electrolyte deficits, and acid-base imbalances. There are no benefits to using 5-percent dextrose along with crystalloids (Tan, 2013). Thiamine, 100 mg, is given to prevent Wernicke encephalopathy (Niebyl, 2010).
If vomiting persists after rehydration and failed outpatient management, hospitalization is recommended (American College of Obstetricians and Gynecologists, 2013). Antiemetics such as promethazine, prochlorperazine, chlorpromazine, or metoclopramide are given parenterally. There is little evidence that treatment with glucocorticosteroids is effective. Two small trials found no benefits of methylprednisolone compared with placebo, but the corticosteroid-treated group had significantly fewer readmissions (Duggar, 2001; Safari, 1998). In another study from Parkland Hospital, Yost (2003) compared placebo with intravenous methylprednisolone plus two different tapered oral steroid regimens. They noted that a third in each group required readmission. In a
study reported by Bondok (2006), pulsed hydrocortisone therapy was superior to metoclopramide to reduce vomiting and readmissions. Serotonin antagonists are most effective for controlling chemotherapy-induced nausea and vomiting (Hesketh, 2008). But when used for hyperemesis gravidarum, ondansetron was not superior to promethazine (Sullivan, 1996). Serotonin antagonist use in pregnancy is limited, but these drugs appear to be safe (Briggs, 2011).

With persistent vomiting after hospitalization, appropriate steps should be taken to exclude possible underlying diseases as a cause of hyperemesis. In one study, endoscopy did not change management in 49 women (Debby, 2008). Other potential causes include gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic ulcer, and pyelonephritis. In addition, severe preeclampsia and fatty liver are more likely after midpregnancy. And although clinical thyrotoxicosis has been implicated as a cause of hyperemesis, it is more likely that abnormally elevated serum thyroxine levels are a surrogate for higher-than-average serum hCG levels (Chap. 5, p. 103). This was termed “chemical hyperthyroidism” by Tan (2002). And of interest, Panesar and associates (2006) showed that a cohort of women with hyperemesis had lower serum thyrotropin levels. In our experiences, serum free thyroxine levels normalize quickly with hydration.

With treatment, most women will have a salutary response and may be sent home with antiemetic therapy. Their readmission rate is 25 to 35 percent in most prospective studies. If associated psychiatric and social factors contribute to the illness, the woman usually improves remarkably while hospitalized (Swallow, 2004). That said, symptoms may relapse in these women, and some go on to develop posttraumatic stress syndrome (Christodoulou-Smith, 2011; McCarthy, 2011). For some women, hyperemesis can be an indication for elective termination (Poursharif, 2007).

In the small percentage of women who continue to have recalcitrant vomiting, consideration is given for enteral nutrition. Vaisman (2004) described successful use of nasojejunal feeding for up to 21 days in 11 such women. Use of sonography to confirm correct placement of the tube has been described (Swartzlander, 2013). Percutaneous endoscopic gastrostomy with a jejunal port has also been reported (Saha, 2009; Schrag, 2007).

In our experiences, only a very few women will require parenteral nutrition (Yost, 2003). In a study of 166 women, Folk (2004) reported that 16 percent had central venous access established for nutrition. The litany of complications included line sepsis in 25 percent and thrombosis and infective endocarditis in one woman each.

Gastroesophageal Reflux Disease (GERD)

Reflux disease is seen in up to 15 percent of nonpregnant individuals (Kahrilas, 2012). Heartburn, or pyrosis, is especially common in late pregnancy, and it appears at some point in 50 to 80 percent of pregnancies (Mehta, 2010). The retrosternal burning sensation is caused by esophagitis from gastroesophageal reflux related to relaxation of the lower esophageal sphincter (Hytten, 1991). According to Costigan and colleagues (2006), common folklore is confirmed in that women with excessive heartburn do give birth to infants with more hair! Long-term complications are chronic esophagitis and adenocarcinoma.

Reflux symptoms usually respond to tobacco and alcohol abstinence, small meals, head of the bed elevation, and avoidance of postprandial recumbency and “trigger” foods. Oral antacids are first-line therapy. If severe symptoms persist, sucralfate is given with an H₂-receptor antagonist such as cimetidine or ranitidine. If these are not successful, commonly used proton-pump inhibitors such as omeprazole or pantoprazole are also safe for use in pregnancy (Briggs, 2011;
Mahadevan, 2006b). If there is still no relief, then endoscopy should be considered. Misoprostol is contraindicated because it stimulates labor (Chap. 26, p. 529).

For medical treatment failures in nonpregnant patients, surgical fundoplication is performed (Kahrilas, 2012). Although the procedure was not done during pregnancy, Biertho (2006) described 25 women who had undergone laparoscopic Nissen fundoplication before pregnancy. Only 20 percent had reflux symptoms during pregnancy.

### Hiatal Hernia

The older literature is informative regarding hiatal hernias in pregnancy. Upper gastrointestinal radiographs performed in 195 women in late pregnancy showed that 20 percent of 116 multiparas and 5 percent of 79 nulliparas had a hiatal hernia (Rigler, 1935). Of 10 women studied postpartum, hernia persisted in three at 1 to 18 months.

The relationship of hiatal hernia with reflux esophagitis, and thus symptoms, is not clear. One study demonstrated no relationship between reflux and hernia and showed that the lower esophageal sphincter functioned effectively even when displaced intrathoracically (Cohen, 1971). Nevertheless, during pregnancy, these hiatal hernias may cause vomiting, epigastric pain, and bleeding from ulceration. Schwentner (2011) reported severe herniation requiring surgical repair in a woman with a 12-week gestation. Curran (1999) described a 30-week pregnancy complicated by gastric outlet obstruction from a paraesophageal hernia.

### Diaphragmatic Hernia

These are caused by herniations of abdominal contents through either the foramen of Bochdalek or that of Morgagni. Fortunately, they rarely complicate pregnancy. Kurzel and associates (1988) reviewed the outcomes of 18 pregnant women with such a hernia and who developed acute obstruction. Because the maternal mortality rate was 45 percent, they recommend repair during pregnancy even if a woman is asymptomatic. Herniation has been reported in one pregnant woman from a previous traumatic diaphragmatic defect and in another who had antireflux surgery in early pregnancy (Brygger, 2013; Flick, 1999). Several case reports also describe spontaneous diaphragmatic rupture from increased intraabdominal pressure during delivery (Chen, 2012; Ortega-Carnicer, 1998; Sharifah, 2003).

### Achalasia

A rare disorder, achalasia is a motility disorder in which the lower esophageal sphincter does not relax properly with swallowing. There is also nonperistaltic contraction activity of the esophageal muscularis to cause symptoms (Kahrilas, 2012; Khudyak, 2006). The defect is caused by inflammatory destruction of the myenteric (Auerbach) plexus within smooth muscle of the lower esophagus and its sphincter. Postganglionic cholinergic neurons are unaffected, thus, there is unopposed sphincter stimulation. Symptoms are dysphagia, chest pain, and regurgitation. Barium swallow radiography demonstrates bird beak or ace of spades narrowing at the distal esophagus. Endoscopy is performed to exclude gastric carcinoma, and manometry is confirmatory. If dilatation of the esophagus and medical therapy does not provide relief, myotomy is considered (Torquati, 2006).

During pregnancy, normal relaxation of the lower esophageal sphincter in those with achalasia theoretically should not occur. Even so, in most women, pregnancy does not seem to worsen
achalasia. One report of 20 affected pregnant women found no excessive reflux esophagitis (Mayberry, 1987). Khudyak and coworkers (2006) reviewed 35 cases and described most women as symptom free, although esophageal dilatation was needed in a few. A maternal death at 24 weeks associated with perforation of a 14-cm diameter megaeosophagus has been reported (Fassina, 1995).

Management of achalasia includes soft diet and anticholinergic drugs. With persistent symptoms, other options include nitrates, calcium-channel antagonists, and botulinum toxin A injected locally (Khudyak, 2006; Wataganara, 2009). Balloon dilatation of the sphincter may be necessary, and 85 percent of nonpregnant patients respond to this. Satin (1992) and Fiest (1993) and their associates reported successful use of pneumatic dilatation in pregnancy. One caveat is that esophageal perforation is a serious complication of dilatation. Spiliopoulos and colleagues (2013) described a 29-week pregnant woman with achalasia treated for 10 weeks with parenteral nutrition with surgical correction done postpartum.

**Peptic Ulcer**

Erosive ulcer disease more often involves the duodenum rather than the stomach in young women. Gastroduodenal ulcers in nonpregnant women may be caused by chronic gastritis from *H pylori*, or they develop from use of aspirin or other nonsteroidal antiinflammatory drugs. Neither is common in pregnancy (McKenna, 2003; Weyermann, 2003). Acid secretion is also important, and thus underlies the efficacy of antisecretory agents (Suerbaum, 2002). Gastroprotection during pregnancy is probably due to reduced gastric acid secretion, decreased motility, and considerably increased mucus secretion (Hytten, 1991). Despite this, ulcer disease may be underdiagnosed because of frequent treatment for reflux esophagitis (Cappell, 1998; Mehta, 2010). In the past 45 years at Parkland Hospital, during which time we have cared for more than 500,000 pregnant women, we have encountered very few who had symptomatic ulcer disease. Before appropriate therapy was commonplace, Clark (1953) studied 313 pregnancies in 118 women with proven ulcer disease. They noted a clear remission during pregnancy in almost 90 percent. However, benefits were short lived. Symptoms recurred in more than half by 3 months postpartum and in almost all by 2 years.

Antacids are first-line therapy, and H$_2$-receptor blockers or proton-pump inhibitors are safely prescribed for those who do not respond (Briggs, 2011; Diav-Citrin, 2005; Mahadevan, 2006b). Sucralfate is the aluminum salt of sulfated sucrose that inhibits pepsin. It provides a protective coating at the ulcer base. Approximately 10 percent of the aluminum salt is absorbed, and it is considered safe for pregnant women (Briggs, 2011).

With active ulcers, a search for *H pylori* is undertaken. Diagnostic aids include the urea breath test, serological testing, or endoscopic biopsy. If any of these are positive, antimicrobial therapy is indicated. There are several effective oral treatment regimens that do not include tetracycline and that can be used during pregnancy. These 14-day regimens include amoxicillin, 1000 mg twice daily along with clarithromycin, 500 mg twice daily; or metronidazole, 500 mg twice daily (Dzieniszewski, 2006; Mehta, 2010).

**Upper Gastrointestinal Bleeding**

In some women, persistent vomiting is accompanied by worrisome upper gastrointestinal bleeding. Occasionally, there is a bleeding peptic ulceration, however, most of these women have small linear mucosal tears near the gastroesophageal junction—*Mallory-Weiss tears*, as shown in Figure
54-1. Bleeding usually responds promptly to conservative measures, including iced saline irrigations, topical antacids, and intravenously administered H$_2$-blockers or proton-pump inhibitors. Transfusions may be needed, and if there is persistent bleeding, then endoscopy may be indicated (O’Mahony, 2007). With persistent retching, the less common, but more serious, esophageal rupture—Boerhaave syndrome—may develop from greatly increased esophageal pressure.

**DISORDERS OF THE SMALL BOWEL AND COLON**

The small bowel has diminished motility during pregnancy. Using a nonabsorbable carbohydrate, Lawson (1985) showed that small bowel mean transit times were 99, 125, and 137 minutes in each trimester, compared with 75 minutes when nonpregnant. In a study cited by Everson (1992), mean transit time for a mercury-filled balloon from the stomach to the cecum was 58 hours in term pregnant women compared with 52 hours in nonpregnant women.

Muscular relaxation of the colon is accompanied by increased absorption of water and sodium that predisposes to constipation. This complaint is reported by almost 40 percent of women at some time during pregnancy (Everson, 1992). Such symptoms are usually only mildly bothersome, and preventive measures include a high-fiber diet and bulk-forming laxatives. Wald (2003) has reviewed treatment options. We have encountered several pregnant women who developed megacolon from impacted stool. These women almost invariably had chronically abused stimulatory laxatives.

**Acute Diarrhea**

Most cases of acute diarrhea are caused by infectious agents. The large variety of viruses, bacteria, helminths, and protozoa that cause diarrhea in adults inevitably also afflict pregnant women. Some of these are discussed in Chapter 64. Evaluation of acute diarrhea depends on its severity and duration. According to Camilleri and Murray (2012), some indications for evaluation include profuse diarrhea with dehydration, grossly bloody stools, fever $\geq 38.5^\circ$C, duration of $> 48$ hours without improvement, recent antimicrobial use, immunocompromise, and new community outbreaks. Cases of moderately severe diarrhea with fecal leukocytes or gross blood may best be treated with empirical antibiotics rather than evaluation. Some features of the more common acute diarrheal syndromes are shown in Table 54-3.
The mainstay of treatment is intravenous hydration using normal saline or Ringer lactate with potassium supplementation in amounts to restore maternal blood volume and to ensure uteroplacental perfusion. Vital signs and urine output are monitored for signs of sepsis syndrome. For moderately severe nonfebrile illness without bloody diarrhea, antimobility agents such as loperamide may be useful. Bismuth subsalicylate may also alleviate symptoms. Judicious use of antimicrobial agents is warranted. For moderate to severely ill women, some recommend empirical treatment with ciprofloxacin, 500 mg twice daily for 3 to 5 days. Specific pathogens are treated as needed when identified. Syndromes for which treatment is usually unnecessary include those caused by *Escherichia coli*, staphylococcus, *Bacillus cereus*, and Norwalk-like virus. Severe illness caused by *Salmonella* is treated with trimethoprim-sulfamethoxazole or azithromycin; *Campylobacter* with azithromycin; *Clostridium difficile* with oral metronidazole or vancomycin; and *Giardia* and *Entamoeba histolytica* with metronidazole (Mehta, 2010).

**Inflammatory Bowel Disease**

The two presumably noninfectious forms of intestinal inflammation are ulcerative colitis and Crohn disease. Differentiation between the two is important because treatment differs. That said, they both share common factors, and sometimes are indistinguishable if Crohn disease involves the colon. The salient clinical and laboratory features shown in Table 54-4 permit a reasonably confident diagnostic differentiation in most cases. The etiopathogenesis of both disorders is enigmatic, but there is genetic predisposition toward either. Inflammation is thought to result from dysregulated mucosal immune function in response to normal bacterial flora, with or without an autoimmune component (Friedman, 2012).

**TABLE 54-4. Some Shared and Differentiating Characteristics of Inflammatory Bowel Disease**
Ulcerative Colitis

This is a mucosal disorder with inflammation confined to the superficial luminal layers of the colon. It typically begins at the rectum and extends proximally for a variable distance. In approximately 40 percent, disease is confined to the rectum and rectosigmoid, and 20 percent have pancolitis. Endoscopic findings include mucosal granularity and friability that is interspersed with mucosal ulcerations and a mucopurulent exudate (Fig. 54-3).

---

### Ulcerative Colitis vs. Crohn Disease

#### Shared Characteristics

| Hereditary | More than 100 disease-associated genetic loci—a third shared; Jewish predominance; familial in 5–10% of cases; Turner syndrome; immune dysregulation |
| Other | Chronic and intermittent with exacerbations and remissions; arthritis, erythema nodosum; uveitis |

#### Differentiating Characteristics

| Major symptoms | Diarrhea, tenesmus, rectal bleeding, cramping pain; chronic, intermittent |
| Bowel involvement | Mucosa and submucosa of large bowel; usually begins at rectum (40% proctitis only) |
| Endoscopy | Granular and friable erythematous mucosa; rectal involvement |
| Serum antibodies | Antineutrophil cytoplasmic (pANCA) ~ 70% |
| Complications | Toxic megacolon; strictures; arthritis; cancer (3–5%) |
| Management | Medical; proctocolectomy curative |

| | Fibrostenotic—recurrent RLQ colicky pain; fever |
| | Fistulizing—cutaneous, bladder, interenteric |
| Bowel involvement | Deep layers small and large bowel; commonly transmural; discontinuous involvement; strictures and fistulas |
| Endoscopy | Patchy; rectum spared; perianal involvement |
| Serum antibodies | Anti-S cerevisiae ~ 50% |
| Complications | Fistulas; arthritis; toxic megacolon |
| Management | Medical; segmental and fistula resection |

RLQ = right lower quadrant.

From Friedman, 2012; Lichtenstein, 2009; Podolsky, 2002.
Major symptoms of ulcerative colitis include diarrhea, rectal bleeding, tenesmus, and abdominal cramps. The disease can be acute or intermittent and is characterized by exacerbations and remissions. For unknown reasons, prior appendectomy protects against development of ulcerative colitis (Friedman, 2012; Selby, 2002). *Toxic megacolon* and catastrophic hemorrhage are particularly dangerous complications that may necessitate colectomy. *Extraintestinal manifestations* include arthritis, uveitis, and erythema nodosum. Another serious problem is that the risk of colon cancer approaches 1 percent per year. With either ulcerative colitis or Crohn disease, there is also concern for possible increased risks for thromboembolism (Kappelman, 2011; Novacek, 2010).

**Crohn Disease**

Also known as regional enteritis, Crohn ileitis, and granulomatous colitis, Crohn disease has more protean manifestations than ulcerative colitis. It involves not only the bowel mucosa but also the deeper layers, and sometimes there is transmural involvement. Lesions can be seen throughout the entire gastrointestinal tract, from the mouth to the anus (Friedman, 2012). It is typically segmental. Approximately 30 percent of patients have small-bowel involvement, 25 percent have isolated colonic involvement, and 40 percent have both, usually with the terminal ileum and colon involved. Perirectal fistulas and abscesses develop in a third of those with colonic involvement.

Symptoms depend on which bowel segment(s) is involved. Thus, complaints may include right-sided lower cramping abdominal pain, diarrhea, weight loss, low-grade fever, and obstructive symptoms. The disease is chronic with exacerbations and remissions, and importantly, it cannot be cured medically or surgically (Lichtenstein, 2009). Approximately a third of patients require surgery within the first year after diagnosis, and thereafter, 5 percent per year. Reactive arthritis is common, and the gastrointestinal cancer risk, although not as great as with ulcerative colitis, is increased substantially.
Inflammatory Bowel Disease and Fertility

Subfertility is commonly linked to chronic medical disease. That said, Mahadevan (2006a) cited a normal fertility rate for inflammatory bowel disease unless severe disease warranted surgery. Alstead (2003) reported that decreased female fertility from active Crohn disease returned to normal with remission. For women requiring surgical resection, laparoscopic anastomosis has a higher subsequent fertility rate (Beyer-Berjot, 2013). Even though fertility is improved after colectomy, up to half of women will still be infertile (Bartels, 2012; Waljee, 2006). Subfertility may also be partially due to sulfasalazine, which causes reversible sperm abnormalities (Feagins, 2009).

Inflammatory Bowel Disease and Pregnancy

Because ulcerative colitis and Crohn disease are relatively common in young women, they are encountered with some frequency in pregnancy. In this regard, a few generalizations can be made. The consensus is that pregnancy does not increase the likelihood of an inflammatory bowel disease flare. To the contrary, in a 10-year surveillance of women in the European Collaborative on Inflammatory Bowel Disease, the likelihood of a flare during pregnancy was decreased compared with the preconceptional rate (Riis, 2006). This diminished rate persisted for years after pregnancy and was attributed to close attention and monitoring of enrolled women.

Although most of those with quiescent disease in early pregnancy uncommonly have relapses, when a flare develops, it may be severe. Conversely, active disease in early pregnancy increases the likelihood of poor pregnancy outcome. In general, most usual treatment regimens may be continued during pregnancy. If needed to direct management, diagnostic evaluations should be undertaken, and if indicated, surgery should be performed. For women who successfully complete pregnancy, half experience improvement in their health-related quality of life (Ananthakrishnan, 2012).

At first glance, it appears that adverse pregnancy outcomes are increased with inflammatory bowel disease (Bush, 2004; Cornish, 2012; Elbaz, 2005; Mahadevan, 2005). Initially, this was attributed to the fact that most studies included women with either form of disease. Specifically, Crohn disease was noted to be linked to excessive morbidity (Dominitz, 2002; Stephansson, 2010). But, according to Reddy (2008) as well as others, these adverse outcomes were in women with severe disease and multiple recurrences. Indeed, in the prospective European case-control ECCO-EpiCom study of 332 pregnant women with inflammatory disease, Bortoli and coworkers (2011) found similar outcomes in women with ulcerative colitis or Crohn disease compared with normally pregnant women. Importantly, even reports of adverse outcomes found that perinatal mortality rates are not appreciably increased.

Ulcerative Colitis and Pregnancy

Pregnancy has no significant effects on ulcerative colitis. In a metaanalysis of 755 pregnancies, Fonager (1998) reported that ulcerative colitis quiescent at conception worsened in approximately a third of pregnancies. In women with active disease at the time of conception, approximately 45 percent worsened, 25 percent remained unchanged, and only 25 percent improved. These observations are similar to those previously described in an extensive review by Miller (1986) and a report from Oron and colleagues (2012).

Calcium supplementation is provided for osteoporosis. Folic acid is given in high doses to counteract the antifolate actions of sulfasalazine. Flares may be caused by psychogenic stress, and reassurance is important. Management for colitis for the most part is the same as for nonpregnancy. Treatment of active colitis, as well as maintenance therapy, is with drugs that deliver 5-aminosalicylic acid (5-ASA) or mesalamine. Sulfasalazine is the prototype, and its 5-ASA
moiety inhibits prostaglandin synthase in colonic mucosa. Others include olsalazine (Dipentum) and coated 5-ASA derivatives (Asacol, Pentasa, Lialda). Glucocorticoids are given orally parenterally, or by enema for more severe disease that does not respond to 5-ASA. Recalcitrant disease is managed with immunomodulating drugs, including azathioprine, 6-mercaptopurine, or cyclosporine, which appear relatively safe in pregnancy (Briggs, 2011; Moskovitz, 2004). Importantly, methotrexate is contraindicated in pregnancy. High-dose intravenous cyclosporine may be beneficial for severely ill patients and used in lieu of colectomy. Parenteral nutrition is occasionally necessary for women with prolonged exacerbations.

Colorectal endoscopy is performed as indicated (Katz, 2002). During pregnancy, colectomy and ostomy creation for fulminant colitis may be needed as a lifesaving measure, and it has been described during each trimester. Dozois (2006) reviewed 42 such cases and found that, in general, outcomes have been good in recent reports. Most women underwent partial or complete colectomy, but Ooi and colleagues (2003) described decompression colostomy with ileostomy in a 10- and a 16-week pregnancy.

More commonly for nonpregnant women undergoing proctocolectomy for ulcerative colitis, an ileal pouch is constructed and an anal anastomosis completed. For women with this procedure performed before pregnancy, sexual function and fertility are improved (Cornish, 2007). Disadvantages include frequent bowel movements, fecal incontinence that includes nocturnal soilage in almost half of patients, and pouchitis. Pouchitis is an inflammatory condition of the ileoanal pouch, probably due to bacterial proliferation, stasis, and endotoxin release. It usually responds to cephalosporins or metronidazole. Although these disadvantages temporarily worsen during pregnancy, they typically abate postpartum. In one rare case, adhesions to the growing uterus led to ileal pouch perforation (Aouthmany, 2004).

Women who have had a prior proctocolectomy and ileal pouch–anal anastomosis can safely deliver vaginally (Ravid, 2002). Hahnloser (2004) reviewed routes of delivery in women with 235 pregnancies before and 232 pregnancies after ileoanal pouch surgery. Functional outcomes were similar, and it was concluded that cesarean delivery should be reserved for obstetrical indications. Postcesarean delivery ileoanal pouch obstruction has been described (Malecki, 2010).

As previously discussed, ulcerative colitis likely has minimal adverse effects on pregnancy outcome. Modigliani (2000) reviewed perinatal outcomes in 2398 pregnancies and reported them to be not substantively different from those in the general obstetrical population. Specifically, the incidences of spontaneous abortion, preterm delivery, and stillbirth were remarkably low. In a population-based cohort study of 107 women from Washington state, perinatal outcomes, with two exceptions, were similar to those of 1308 normal pregnancies (Dominitz, 2002). One exception was an inexplicably increased incidence of congenital malformations, and the other was a cesarean delivery rate that was increased from 20 to 29 percent compared with normal controls. The previously described ECCO-EpiCom study reported similar outcomes in 187 women with ulcerative colitis compared with their normal controls (Bortoli, 2011). There are smaller studies in which the risks for preterm birth and low birthweight are increased (Emerson, 2013).

**Crohn Disease and Pregnancy.** In general, Crohn disease activity during pregnancy is related to its status around the time of conception. In a cohort study of 279 pregnancies, for 186 women whose disease was inactive at conception, a fourth relapsed during pregnancy (Fonager, 1998). In 93 with active disease at conception, however, two thirds either remained active or worsened. Miller (1986) had described similar findings from his earlier review as did Oron and associates (2012).

Calcium and folic acid supplementation are given as for ulcerative colitis. There is no regimen
that is universally effective for maintenance during asymptomatic periods. Sulfasalazine is effective for some, but the newer 5-ASA formulations are better tolerated. As a class, they appear to be safe in pregnancy (Briggs, 2011; Rahimi, 2008). Prednisone therapy may control moderate to severe flares but is less effective for small-bowel involvement. Immunomodulators such as azathioprine, 6-mercaptopurine, and cyclosporine are used for active disease and for maintenance and appear relatively safe during pregnancy (Briggs, 2011; Moskovitz, 2004; Prefontaine, 2009). As discussed in Chapter 12 (p. 248), methotrexate, mycophenolate mofetil, and mycophenolic acid are contraindicated in pregnancy (Briggs, 2011; Food and Drug Administration, 2008). Anti-tumor necrosis factor (TNF)-α antibodies, which include infliximab, adalimumab, and certolizumab, are also effective for active Crohn disease and maintenance (Casanova, 2013; Colombel, 2010; Cominelli, 2013; Friedman, 2012; Sandborn, 2007; Schreiber 2007). This class of immunomodulators is considered safe in pregnancy, but data are limited (Katz, 2004; Roux, 2007; Schnitzler, 2011). Parenteral hyperalimentation has been used successfully during severe recurrences (Russo-Stieglitz, 1999).

Endoscopy or conservative surgery is indicated for complications. Patients with small-bowel involvement more likely will require surgery for complications that include fistulas, strictures, abscesses, and intractable disease. An abdominal surgical procedure was required during 5 percent of pregnancies described by Woolfson (1990). Those with an ileal loop colostomy may have significant problems as discussed below. Women with a perianal fistula—unless these are rectovaginal—usually can undergo vaginal delivery without complications (Forsnes, 1999; Takahashi, 2007).

As discussed, there seems to be a greater likelihood that Crohn disease may be associated with adverse pregnancy outcomes compared with ulcerative colitis (Stephansson, 2010). Outcomes are probably related to disease activities. For example, based on a 20-year review, Korelitz (1998) concluded that perinatal outcomes were generally good with quiescent disease. That said, in a case-control Danish study, Norgård (2007) reported a twofold risk of preterm births. Dominitz (2002) reported a two- to threefold increase in preterm delivery, low birthweight, fetal-growth restriction, and cesarean delivery in 149 women with Crohn disease. Recall, however, that the prospective ECCO-EpiCom study found outcomes to be similar to those for normal pregnancies.

**Ostomy and Pregnancy**

A colostomy or an ileostomy can be problematic during pregnancy because of its location (Hux, 2010). In a report of 82 pregnancies in 66 women with an ostomy, stomal dysfunction was common, but it responded to conservative management in all cases (Gopal, 1985). Surgical intervention was necessary, however, in three of six women who developed bowel obstruction and in another four with ileostomy prolapse—almost 10 percent overall. In this older study, only a third of 82 women underwent cesarean delivery, but Takahashi (2007) described six of seven cesarean deliveries in women with Crohn disease and a stoma. Fortunately, Farouk and coworkers (2000) reported that pregnancy did not worsen long-term ostomy function.

**Intestinal Obstruction**

The incidence of bowel obstruction is not increased during pregnancy, although it generally is more difficult to diagnose. Meyerson (1995) reported a 20-year incidence of 1 in 17,000 deliveries at two Detroit hospitals. In one study, adhesive disease leading to small bowel obstruction was the second most common cause of an acute abdomen in pregnancy following...
appendicitis—15 versus 30 percent, respectively (Unal, 2011). As shown in Table 54-5, approximately half of cases are due to adhesions from previous pelvic surgery that includes cesarean delivery (Al-Sunaidi, 2006; Andolf, 2010; Lyell, 2011). Another 25 percent of bowel obstruction is caused by volvulus—sigmoid, cecal, or small bowel. These have been reported in late pregnancy or early puerperium (Alshawi, 2005; Biswas, 2006; Lal, 2006). Wax and colleagues (2013) described small bowel obstruction in pregnancy following the currently popular Roux-en-Y gastric bypass. Intussusception is occasionally encountered (Gould, 2008; Harma, 2011). Bowel obstruction subsequent to colorectal surgery for cancer was increased threefold in women who had open versus laparoscopic surgery (Haggar, 2013).

Data from Connolly, 1995; Khan, 2012; Redlich, 2007.

Most cases of intestinal obstruction during pregnancy result from pressure of the growing uterus on intestinal adhesions. According to Davis and Bohon (1983), this more likely occurs: (1) around midpregnancy, when the uterus becomes an abdominal organ; (2) in the third trimester, when the fetal head descends; or (3) immediately postpartum, when there is a acute change in uterine size. Perdue (1992) reported that 98 percent of pregnant women had either continuous or colicky abdominal pain, and 80 percent had nausea and vomiting. Abdominal tenderness was found in 70 percent, and abnormal bowel sounds noted in only 55 percent. Plain abdominal radiographs following soluble contrast showed evidence of obstruction in 90 percent of women. Plain radiographs, however, are less accurate for diagnosing small-bowel obstruction, and we and others have found that CT and MR imaging can be diagnostic (Biswas, 2006; Essilfie, 2007; McKenna, 2007). Colonoscopy can be both diagnostic and therapeutic for colonic volvulus (Dray, 2012; Khan, 2012).

During pregnancy, mortality rates with obstruction can be excessive because of difficult and thus delayed diagnosis, reluctance to operate during pregnancy, and the need for emergency surgery (Firstenberg, 1998; Shui, 2011). In an older report of 66 pregnancies, Perdue and associates (1992) described a 6-percent maternal mortality rate and 26-percent fetal mortality rate. Two of the four women who died were in late pregnancy, and they had sigmoid or cecal volvulus caused by adhesions. Perforation from massive bowel dilation such as that shown in Figure 54-4...
causes severe sepsis syndrome.

**FIGURE 54-4** Massively dilated colon in a pregnant woman with colonic volvulus. (Courtesy of Dr. Lowell Davis.)

## Colonic Pseudo-obstruction

Also known as Ogilvie syndrome, pseudo-obstruction is caused by adynamic colonic ileus. It is characterized by massive abdominal distention with cecal and right-hemicolon dilatation. Approximately 10 percent of all cases are associated with pregnancy. The syndrome usually develops postpartum—most commonly after cesarean delivery—but it has been reported antepartum (Tung, 2008). Although this is unusual, the large bowel may rupture (Singh, 2005). Treatment with an intravenous infusion of neostigmine, 2 mg, usually results in prompt decompression (Ponec, 1999). In some cases, colonoscopic decompression is performed, but laparotomy is done for perforation (De Giorgio, 2009; Rawlings, 2010).

## Appendicitis

Suspected appendicitis is one of the most common indications for abdominal exploration during pregnancy. The frequency for suspected appendicitis approximated 1 in 1000 women in the Swedish registry of 720,000 pregnancies (Mazze, 1991). Disease was confirmed in 65 percent for an incidence of approximately 1 in 1500 births. Inexplicably, the incidence was much lower in the Danish registry of more than 320,000 pregnancies—the confirmed appendicitis rate was only 1 per 5500 pregnancies (Hée, 1999).

It is repeatedly—and appropriately—emphasized that pregnancy makes the diagnosis of appendicitis more difficult. Nausea and vomiting accompany normal pregnancy, but also, as the uterus enlarges, the appendix commonly moves upward and outward from the right-lower quadrant.
Another often-stated reason for late diagnosis is that some degree of leukocytosis accompanies normal pregnancy. For these and other reasons, pregnant women—especially those late in gestation—frequently do not have clinical findings “typical” for appendicitis. Thus, it commonly is confused with cholecystitis, preterm labor, pyelonephritis, renal colic, placental abruption, or uterine leiomyoma degeneration.

Most reports indicate increasing morbidity and mortality rates with increasing gestational age. And as the appendix is progressively deflected upward by the growing uterus, omental containment of infection becomes increasingly unlikely. It is indisputable that appendiceal perforation is more common during later pregnancy. In the studies by Andersson (2001) and Ueberrueck (2004), the incidence of perforation was approximately 8, 12, and 20 percent in successive trimesters.

**Diagnosis**

Persistent abdominal pain and tenderness are the most reproducible findings. Right-lower quadrant pain is the most frequent, although pain migrates upward with appendiceal displacement (Mourad, 2000). For evaluation, sonographic abdominal imaging is reasonable in suspected appendicitis, even if to exclude an obstetrical cause of right-lower quadrant pain (Butala, 2010). That said, graded compression sonography is difficult because of cecal displacement and uterine imposition (Pedrosa, 2009). Appendiceal computed tomography is more sensitive and accurate than sonography to confirm suspected appendicitis (Gearhart, 2008; Katz, 2012; Raman, 2008). Specific views can be designed to decrease fetal radiation exposure (Chap. 46, p. 933). In one study, the negative appendectomy rate was 54 percent with clinical diagnosis alone, but only 8 percent if sonography and CT scanning were used (Wallace, 2008). MR imaging may be preferable, and as shown in Figure 54-5, we and others have had good results with its use (Dewhurst, 2013; Israel, 2008). One metaanalysis cited positive- and negative-predictive values of 90 and 99.5 percent, respectively (Blumenfeld, 2011). Using a decision-analysis model, CT and MR imaging were found to be cost effective (Kastenberg, 2013).
Management

When appendicitis is suspected, treatment is prompt surgical exploration. Although diagnostic errors may lead to removal of a normal appendix, surgical evaluation is preferable to postponed intervention and generalized peritonitis. In earlier reports, the diagnosis was verified in only 60 to 70 percent of pregnant women. However, as indicated above, with CT and MR imaging, these figures have improved (Blumenfeld, 2011; Wallace, 2008). Importantly, the accuracy of diagnosis is inversely proportional to gestational age (Mazze, 1991).

Laparoscopy is almost always used to treat suspected appendicitis during the first two trimesters. There were similar perinatal outcomes reported from the Swedish database of nearly 2000 laparoscopic appendectomies compared with those of more than 1500 open laparotomies done before 20 weeks (Reedy, 1997). Conversely, from their review, Wilasrusmee and coworkers (2012) reported a higher fetal loss with laparoscopy. It has evolved that in many centers, laparoscopic appendectomy is performed in most cases during the third trimester (Barnes, 2004; Donkervoort, 2011). This is sanctioned and encouraged by the Society of American Gastrointestinal and Endoscopic Surgeons (Pearl, 2011; Soper, 2011). Some are of the opinion that laparoscopic surgery in pregnancy after 26 to 28 weeks should be performed only by the most experienced endoscopic surgeons (Parangi, 2007).

Before exploration, intravenous antimicrobial therapy is begun, usually with a second-generation cephalosporin or third-generation penicillin. Unless there is gangrene, perforation, or a periappendiceal phlegmon, antimicrobial therapy can usually be discontinued after surgery. Without generalized peritonitis, the prognosis is excellent. Seldom is cesarean delivery indicated at the time of appendectomy. Uterine contractions are common, and although some clinicians recommend tocolytic agents, we do not. De Veciana (1994) reported that tocolytic use substantially increased the risk for pulmonary-permeability edema caused by sepsis syndrome (Chap. 47, p. 947).

Pregnancy Outcomes

Appendicitis increases the likelihood of abortion or preterm labor, especially if there is peritonitis. In two studies, spontaneous labor after 23 weeks ensued with greater frequency following surgery for appendicitis compared with surgery for other indications (Cohen-Kerem, 2005; Mazze, 1991). In one study, the fetal loss rate was 22 percent if surgery was performed after 23 weeks. There are at least two large population-based studies that attest to the adverse outcomes from appendicitis in pregnancy. From the California Inpatient File of 3133 pregnant women undergoing surgery for suspected appendicitis, the fetal loss rate was 23 percent, and it was doubled—6 versus 11 percent—with simple versus complicated disease (McGory, 2007). A nationwide study from Taiwan found that there were 1.5- to twofold increased risks for low birthweight and preterm delivery when outcomes in 908 women with acute appendicitis were compared with those of controls (Wei, 2012).

Long-term complications are not common. The possible link between sepsis and neonatal neurological injury has not been verified (Mays, 1995). Finally, appendicitis during pregnancy does not appear to be associated with subsequent infertility (Viktrup, 1998).

Postpartum Acute Appendicitis
Although new-onset appendicitis during the immediate puerperium is uncommon, in some women it is undiagnosed before delivery. Appendicitis in these women often stimulated labor and when the large uterus rapidly empties, walled-off infection may be disrupted to result in an acute surgical abdomen. In some cases, acute appendicitis or a periappendiceal abscess or phlegmon may be found at the time of cesarean delivery or puerperal tubal ligation (see Fig. 54-5). It is important to remember that puerperal pelvic infections typically do not cause peritonitis.

Disorders of the liver, gallbladder, and pancreas together comprise a formidable list of complications that may arise in pregnancy from preexisting conditions or from some that are unique to pregnancy. The relationships of several of these with pregnancy can be fascinating, intriguing, and challenging.

HEPATIC DISORDERS
INTRAHEPATIC CHOLESTASIS OF PREGNANCY
ACUTE FATTY LIVER OF PREGNANCY
VIRAL HEPATITIS
NONALCOHOLIC FATTY LIVER DISEASE
CIRRHOSIS
ACUTE ACETAMINOPHEN OVERDOSE
HEPATIC ADENOMA
GALLBLADDER DISORDERS
PANCREATIC DISORDERS

It is customary to divide liver diseases complicating pregnancy into three general categories. The first includes those specifically related to pregnancy that resolve either spontaneously or following delivery. Examples are hepatic dysfunction from hyperemesis gravidarum, intrahepatic cholestasis, acute fatty liver, and hepatocellular damage with preeclampsia—the HELLP syndrome—hemolysis, elevated serum liver aminotransferase levels, and low platelet counts (Mufti, 2012; Reau, 2014). The second category includes acute hepatic disorders that are coincidental to pregnancy, such as acute viral hepatitis. The third category includes chronic liver diseases that predate pregnancy, such as chronic hepatitis, cirrhosis, or esophageal varices.
There are several pregnancy-induced physiological changes that induce appreciable liver-related clinical and laboratory manifestations (Chap. 4, p. 67, and Appendix, p. 1289). Findings such as elevated serum alkaline phosphatase levels, palmar erythema, and spider angiomas, which might suggest liver disease, are commonly found during normal pregnancy. Metabolism is also affected, due to altered expression of the cytochrome P450 system that is mediated by higher levels of estrogen, progesterone, and other hormones. For example, in pregnancy, hepatic CYP1A2 expression is decreased, whereas that of CYP2D6 and CYP3A4 is increased. Importantly, cytochrome enzymes are expressed in many organs besides the liver, most notably the placenta. The net effect is complex and likely influenced by gestational age and organ of expression (Isoherranen, 2013). Despite all of these functional changes, no major hepatic histological changes are induced by normal pregnancy.

### Hyperemesis Gravidarum

Pernicious nausea and vomiting of pregnancy may involve the liver. There may be mild hyperbilirubinemia with serum aminotransferase levels elevated in up to half of women hospitalized. However, these levels seldom exceed 200 U/L (Table 55-1). Liver biopsy may show minimal fatty changes. Hyperemesis gravidarum is discussed in detail in Chapter 54 (p. 1070).

### Intrahepatic Cholestasis of Pregnancy

This disorder also has been referred to as recurrent jaundice of pregnancy, cholestatic hepatosis, and icterus gravidarum. It is characterized clinically by pruritus, icterus, or both. It may be more common in multifetal pregnancy, and there is a significant genetic influence (Lausman, 2008;...
Webb, 2014). Because of this, the incidence of the disorder varies by population. For example, cholestasis is uncommon in North America, with an overall incidence of approximately 1 in 500 to 1000 pregnancies, but is as high as 5.6 percent among Latina women in Los Angeles (Lee, 2006). In Israel, the incidence reported by Sheiner and associates (2006) is approximately 1 in 400. In Sweden, it is 1.5 percent, and in Chile, it is 4 percent (Glantz, 2004; Lee, 2006; Reyes, 1997).

**Pathogenesis**

The cause of obstetrical cholestasis is unknown. Both increases and decreases in sex steroid levels have been implicated, but current research centers on the numerous mutations that have been identified in the many genes that control hepatocellular transport systems. One example involves mutations of the *ABCB4* gene, which encodes multidrug resistance protein 3 (MDR3) associated with *progressive familial intrahepatic cholestasis*, as well as a bile salt export pump encoded by *ABCB11* (Anzivino, 2013; Davit-Spraul, 2010, 2012; Dixon, 2014). Other potential gene products of interest include the Farnesoid X receptor and transporting ATPase encoded by *ATP8B1* (Davit-Spraul, 2012; Müllenbach, 2005). Some drugs that similarly decrease canalicular transport of bile acids aggravate the disorder. For example, we have encountered impressive cholestatic jaundice in pregnant women taking azathioprine following renal transplantation.

Whatever the inciting cause(s), bile acids are cleared incompletely and accumulate in plasma. Hyperbilirubinemia results from retention of conjugated pigment, but total plasma concentrations rarely exceed 4 to 5 mg/dL. Alkaline phosphatase is usually elevated even more so than in normal pregnancy. Serum aminotransferase levels are normal to moderately elevated but seldom exceed 250 U/L (see Table 55-1). Liver biopsy shows mild cholestasis with bile plugs in the hepatocytes and canaliculi of the centrilobular regions, but without inflammation or necrosis. These changes disappear after delivery but often recur in subsequent pregnancies or with estrogen-containing contraceptives.

**Clinical Presentation**

Pruritus develops in late pregnancy, although it occasionally manifests earlier. There are no constitutional symptoms, and generalized pruritus shows predilection for the soles. Skin changes are limited to excoriations from scratching. Biochemical tests may be abnormal at presentation, but pruritus may precede laboratory findings by several weeks. Approximately 10 percent of women have jaundice.

With normal liver enzymes, the differential diagnosis of pruritus includes other skin disorders (Chap. 62, p. 1214). Findings are unlikely to be due to preeclamptic liver disease if there are no blood pressure changes or proteinuria. Sonography may be warranted to exclude cholelithiasis and biliary obstruction. Acute viral hepatitis is an unlikely diagnosis because of the usually low serum aminotransferase levels seen with cholestasis. Conversely, chronic hepatitis C is associated with a significantly increased risk of cholestasis, which may be as high as 20-fold among women who are hepatitis C RNA positive (Marschall, 2013; Paternoster, 2002).

**Management**

Pruritus may be troublesome and is thought to result from elevated serum bile salt concentrations. Antihistamines and topical emollients may provide some relief. Although cholestyramine has been reported to be effective, this compound also causes further decreased absorption of fat-soluble vitamins, which may lead to vitamin K deficiency. Fetal coagulopathy may develop, and there are reports of intracranial hemorrhage and stillbirth (Matos, 1997; Sadler, 1995).
A recent metaanalysis suggests that ursodeoxycholic acid relieves pruritus, lowers bile acid and serum enzyme levels, and may reduce certain neonatal complications such as preterm birth, fetal distress, respiratory distress syndrome, and neonatal intensive care unit (NICU) admission (Bacz, 2012). Lucangioli and colleagues (2009) documented an especially profound decrease in serum lithocholic acid levels. Kondrackiene and associates (2005) randomly assigned 84 symptomatic women to receive either ursodeoxycholic acid (8 to 10 mg/kg/d) or cholestyramine (8 g/d). They reported superior relief with ursodeoxycholic acid—67 versus 19 percent, respectively. Similarly, Glantz and coworkers (2005) found superior benefits to women randomly assigned to ursodeoxycholic acid versus dexamethasone. The American College of Obstetricians and Gynecologists (2012a) has concluded that ursodeoxycholic acid both relieves pruritus and improves fetal outcomes, although evidence for the latter is not compelling.

**Cholestasis and Pregnancy Outcomes**

Earlier reports described excessive adverse pregnancy outcomes in women with cholestatic jaundice. Data accrued during the past two decades are ambiguous concerning increased perinatal mortality rates and whether close fetal surveillance is preventative. A review of a few studies illustrates this. Glantz and colleagues (2004) described outcomes in 693 Swedish women. Perinatal mortality rates were slightly increased, but death was limited to infants of mothers with severe disease characterized by total bile acid levels ≥ 40 μmol/L. Sheiner and coworkers (2006) described no differences in perinatal outcomes in 376 affected pregnancies compared with their overall obstetrical population. There was, however, a significant increase in labor inductions and cesarean deliveries in affected women. Lee and associates (2009) described two cases of sudden fetal death not predicted by nonstress testing. Rook and colleagues (2012) reported outcomes of 101 affected women in Northern California. Although there were no term fetal demises, 87 percent of women underwent labor induction, ostensibly to avoid adverse outcomes. Nonetheless, neonatal complications occurred in a third of the pregnancies, particularly respiratory distress, fetal distress, and meconium-stained amniotic fluid, all of which were reported more frequently with higher total bile acid levels. Finally, Wikström Shemer and coworkers (2013) reported outcomes for a population-based Swedish study of 5477 pregnancies complicated by intrahepatic cholestasis of pregnancy among 1,213,668 singleton deliveries. The authors reported novel associations of cholestasis with preeclampsia and gestational diabetes. Although neonates were more likely to have a low 5-minute Apgar score and to be large for gestational age, there was no increased risk of stillbirth. Importantly, the pregnancies were actively managed to avoid stillbirths, and this was reflected in the higher induction and preterm birth rates. Many recommend early delivery by labor induction to avoid stillbirth.

An intriguing finding indicates that bile acids may cause fetal death. Strehlow and associates (2010) reported that the PR interval on fetal echocardiography was significantly prolonged in women with intrahepatic cholestasis. Gorelik and colleagues (2006) suggest that bile acids may cause fetal cardiac arrest after entering cardiomyocytes in abnormal amounts. Using fetal myocyte cultures, they showed expression of several genes that may play a role in bile transport.

**Acute Fatty Liver of Pregnancy**

The most common cause of acute liver failure during pregnancy is acute fatty liver—also called acute fatty metamorphosis or acute yellow atrophy. In its worst form, the incidence probably approximates 1 in 10,000 pregnancies (Nelson, 2013). Fatty liver recurring in subsequent pregnancy is uncommon, but a few cases have been described (Usta, 1994).
Fatty liver is characterized by accumulation of microvesicular fat that literally “crowds out” normal hepatocytic function (Fig. 55-1). Grossly, the liver is small, soft, yellow, and greasy.

**FIGURE 55-1** Acute fatty liver of pregnancy. Cross section of the liver from a woman who died as the result of pulmonary aspiration and respiratory failure. The liver has a greasy yellow appearance, which was present throughout the entire specimen. Inset: Electron photomicrograph of two swollen hepatocytes containing numerous microvesicular fat droplets (*). The nuclei (N) remain centered within the cells, in contrast to the case with macrovesicular fat deposition. (Photograph contributed by Dr. Don Wheeler.)

**Etiopathogenesis**

Although much has been learned about this disorder, interpretation of conflicting data has led to incomplete but intriguing observations. For example, some if not most cases of maternal fatty liver are associated with recessively inherited mitochondrial abnormalities of fatty acid oxidation. These are similar to those in children with Reye-like syndromes. Several mutations have been described for the mitochondrial trifunctional protein enzyme complex that catalyzes the last oxidative steps in the pathway. The most common are the G1528C and E474Q mutations of the
gene on chromosome 2 that code for long-chain-3-hydroxyacyl-CoA-dehydrogenase—known as LCHAD. There are other mutations for medium-dehydrogenase—MCHAD, as well as carnitine palmitoyltransferase 1 (CPT1) deficiency (Santos, 2007; Ylitalo, 2005).

Sims and coworkers (1995) observed that some homozygous LCHAD-deficient children with Reye-like syndromes had heterozygous mothers with fatty liver. This was also seen in women with a compound heterozygous fetus. Although some conclude that only heterozygous LCHAD-deficient mothers are at risk when their fetus is homozygous, this is not always true (Baskin, 2010).

There is a controversial association between fatty acid β-oxidation enzyme defects and severe preeclampsia—especially in women with HELLP syndrome (Chap. 40, p. 742). Most of these observations have been arrived at by retrospectively studying mothers delivered of a child who later developed Reye-like syndrome. For example, Browning and coworkers (2006) performed a case-control study of 50 mothers of children with a fatty-acid oxidation defect and 1250 mothers of matched control infants. During their pregnancy, 16 percent of mothers with an affected child developed liver problems compared with only 0.9 percent of control women. Problems included HELLP syndrome in 12 percent and fatty liver in 4 percent. Despite these findings, the clinical biochemical, and histopathological findings are sufficiently disparate to suggest that severe preeclampsia, with or without HELLP syndrome, and fatty liver are distinct syndromes (American College of Obstetricians and Gynecologists, 2012a; Sibai, 2007).

Clinical and Laboratory Findings

Acute fatty liver almost always manifests late in pregnancy. Nelson and colleagues (2013) described 51 such women at Parkland Hospital with a mean gestational age of 37 weeks—range 31.7 to 40.9. Almost 20 percent were delivered at 34 weeks’ gestation or earlier. Of these 51 women, 41 percent were nulliparous, and two thirds carried a male fetus. Ten to 20 percent of cases are in women with a multifetal gestation (Fesenmeier, 2005; Vigil-De Gracia, 2011).

Fatty liver has a clinical spectrum of severity. In the worst cases, symptoms usually develop over several days. Persistent nausea and vomiting are major complaints, and there are varying degrees of malaise, anorexia, epigastric pain, and progressive jaundice. Perhaps half of affected women have hypertension, proteinuria, and edema, alone or in combination—signs suggestive of preeclampsia. As shown in Tables 55-1 and 55-2, there are variable degrees of moderate to severe liver dysfunction manifest by hypofibrinogenemia, hypoalbuminemia, hypocolesterolemia, and prolonged clotting times. Serum bilirubin levels usually are < 10 mg/dL, and serum aminotransferase levels are modestly elevated and usually < 1000 U/L.

**TABLE 55-2. Laboratory Findings in 137 Women with Acute Fatty Liver of Pregnancy**
In almost all severe cases, there is profound endothelial cell activation with capillary leakage causing hemoconcentration, acute kidney injury, ascites, and sometimes pulmonary permeability edema (Bernal, 2013). With severe hemoconcentration, uteroplacental perfusion is reduced and this, along with maternal acidosis, can cause fetal death even before presentation for care. Maternal and fetal acidemia is also related to a high incidence of fetal jeopardy with a concordantly high cesarean delivery rate.

Hemolysis can be severe and evidenced by leukocytosis, nucleated red cells, mild to moderate thrombocytopenia, and elevated serum levels of lactic acid dehydrogenase (LDH). Because of hemoconcentration, however, the hematocrit is often within the normal range. The peripheral blood smear demonstrates echinocytosis, and it has been suggested that hemolysis is caused by the effects of hypocholesterolemia on erythrocyte membranes (Cunningham, 1985).

Various liver imaging techniques have been used to confirm the diagnosis, however, none are particularly reliable. Specifically, Castro and associates (1996) reported poor sensitivity for confirmation by sonography—three of 11 patients, computed tomography (CT)—five of 10, and magnetic resonance (MR) imaging—none of five. Similarly, in a prospective evaluation of the Swansea criteria proposed by Ch’ng and coworkers (2002), only a quarter of women had classic sonographic findings such as maternal ascites or an echogenic hepatic appearance (Knight, 2008). Our experiences are similar (Nelson, 2013).

The syndrome typically continues to worsen after diagnosis. Hypoglycemia is common, and obvious hepatic encephalopathy, severe coagulopathy, and some degree of renal failure each develop in approximately half of women. Fortunately, delivery arrests liver function deterioration.

We have encountered several women with a forme fruste of this disorder. Clinical involvement is relatively minor and laboratory aberrations—usually only hemolysis and decreased plasma fibrinogen—herald the syndrome. Thus, the spectrum of liver involvement varies from milder cases that go unnoticed or are attributed to preeclampsia, to overt hepatic failure with encephalopathy.

### Coagulopathy.

The degree of clotting dysfunction is also variable and can be serious and life threatening, especially if operative delivery is undertaken. Coagulopathy is caused by diminished

hepatic procoagulant synthesis, although there is also some evidence for increased consumption with disseminated intravascular coagulation. As shown in Table 55-2, hypofibrinogenemia sometimes is profound. Of 51 women with fatty liver cared for at Parkland Hospital, almost a third had a plasma fibrinogen nadir < 100 mg/dL (Nelson, 2013). Modest elevations of serum d-dimers or fibrin split product levels indicate an element of consumptive coagulopathy. Although usually modest, occasionally there is profound thrombocytopenia (Table 55-2). Among the 51 women from Parkland Hospital, 20 percent had platelet counts < 100,000/μL and 10 percent had platelet counts < 50,000/μL (Nelson, 2013).

Management

Intensive supportive care and good obstetrical management are essential. In some cases, the fetus may be already dead when the diagnosis is made, and the route of delivery is less problematic. Often, viable fetuses tolerate labor poorly. Because significant procrastination in effecting delivery may increase maternal and fetal risks, we prefer a trial of labor induction with close fetal surveillance. Although some recommend cesarean delivery to hasten hepatic healing, this increases maternal risk when there is severe coagulopathy. Nonetheless, cesarean delivery is common, and rates approach 90 percent. Transfusions with whole blood or packed red cells, along with fresh-frozen plasma, cryoprecipitate, and platelets, are usually necessary if surgery is performed or if obstetrical lacerations complicate vaginal delivery (Chap. 41, p. 815).

Hepatic dysfunction resolves postpartum. It usually normalizes within a week, and in the interim, intensive medical support may be required. There are two associated conditions that may develop around this time. Perhaps a fourth of women have evidence for transient diabetes insipidus. This presumably is due to elevated vasopressinase concentrations caused by diminished hepatic production of its inactivating enzyme. Finally, acute pancreatitis develops in approximately 20 percent.

With supportive care, recovery usually is complete. Maternal deaths are caused by sepsis, hemorrhage, aspiration, renal failure, pancreatitis, and gastrointestinal bleeding. There were two maternal deaths in the series of 51 women at Parkland Hospital. One was an encephalopathic woman who aspirated before intubation during transfer to Parkland Hospital. The other was in a woman with massive liver failure and nonresponsive hypotension (Nelson, 2013). In some centers, other measures have included plasma exchange and even liver transplantation (Fesenmeier, 2005; Franco, 2000; Martin, 2008).

Maternal and Perinatal Outcomes

Although maternal mortality rates with acute fatty liver of pregnancy have approached 75 percent in the past, the contemporaneous outlook is much better. From his review, Sibai (2007) cites an average mortality rate of 7 percent. He also cited a 70-percent preterm delivery rate and a perinatal mortality rate of approximately 15 percent, which in the past was nearly 90 percent. At Parkland Hospital, the maternal and perinatal mortality rates during the past four decades have been 4 percent and 12 percent, respectively (Nelson, 2013).

Preeclampsia Syndrome

Hepatic involvement is relatively common in women with severe preeclampsia and eclampsia (see Table 55-1). These changes are discussed in detail in Chapter 40 (p. 741).
Viral Hepatitis

Although most viral hepatitis syndromes are asymptomatic, during the past 25 years, acute symptomatic infections have become even less common in the United States (Centers for Disease Control and Prevention, 2008). There are at least five distinct types of viral hepatitis: A (HAV), B (HBV), D (HDV) caused by the hepatitis B-associated delta agent, C (HCV), and E (HEV). The clinical presentation is similar in all, and although the viruses themselves probably are not hepatotoxic, the immunological response to them causes hepatocellular necrosis (Dienstag, 2012a,b). Asymptomatic chronic viral hepatitis remains the leading cause of liver cancer and the most frequent reason for liver transplantation.

Acute Hepatitis

As discussed above, acute infections are most often subclinical and anicteric. When they are clinically apparent, nausea and vomiting, headache, and malaise may precede jaundice by 1 to 2 weeks. Low-grade fever is more common with hepatitis A. By the time jaundice develops, symptoms are usually improving. Serum aminotransferase levels vary, and their peaks do not correspond with disease severity (see Table 55-1). Peak levels that range from 400 to 4000 U/L are usually reached by the time jaundice develops. Serum bilirubin typically continues to rise, despite falling aminotransferase levels, and peaks at 5 to 20 mg/dL.

Any evidence for severe disease should prompt hospitalization. These include incessant nausea and vomiting, prolonged prothrombin time, low serum albumin level, hypoglycemia, high serum bilirubin level, or central nervous system symptoms. In most cases, however, there is complete clinical and biochemical recovery within 1 to 2 months in all cases of hepatitis A, in most cases of hepatitis B, but in only a small proportion of cases of hepatitis C.

When patients are hospitalized, their feces, secretions, bedpans, and other articles in contact with the intestinal tract should be handled with glove-protected hands. Extra precautions, such as double gloving during delivery and surgical procedures, are recommended. Due to significant exposure of health-care personnel to hepatitis B, the Centers for Disease Control and Prevention (CDC) recommend active and passive vaccination. There is no vaccine for hepatitis C, so recommendations are for postexposure serosurveillance only.

Acute hepatitis has a case-fatality rate of 0.1 percent. For patients ill enough to be hospitalized, it is as high as 1 percent. Most fatalities are due to fulminant hepatic necrosis, which in later pregnancy may resemble acute fatty liver. In these cases, hepatic encephalopathy is the usual presentation, and the mortality rate is 80 percent. Approximately half of patients with fulminant disease have hepatitis B infection, and co-infection with the delta agent is common.

Chronic Hepatitis

The Centers for Disease Control and Prevention (2012) estimates that 4.4 million Americans are living with chronic viral hepatitis. By far, the most frequent complication of hepatitis B and C is subsequent development of chronic hepatitis, which is usually diagnosed serologically (Table 55-3). Chronic infection follows acute hepatitis B in approximately 5 to 10 percent of cases in adults. Most become asymptomatic carriers, but a small percentage have low-grade chronic persistent hepatitis or chronic active hepatitis with or without cirrhosis. With acute hepatitis C, however, chronic hepatitis develops in most patients. With persistently abnormal biochemical tests, liver biopsy usually discloses active inflammation, continuing necrosis, and fibrosis that may lead to cirrhosis. Chronic hepatitis is classified by cause; grade, defined by histological activity; and stage, which is the degree of progression (Dienstag, 2012b). In these cases, there is evidence that a
The cellular immune reaction is interactive with a genetic predisposition.

HAV = hepatitis A virus; HBc = hepatitis B core; HBsAg = hepatitis B surface antigen; HCV = hepatitis C virus.

From the Centers for Disease Control and Prevention, 2010; Dienstag, 2012a.

Although most chronically infected persons are asymptomatic, approximately 20 percent develop cirrhosis within 10 to 20 years (Dienstag, 2012b). When present, symptoms are nonspecific and usually include fatigue. Diagnosis can be confirmed by liver biopsy, however, treatment is usually given to patients after serological or virological diagnosis. In some patients, cirrhosis with liver failure or bleeding varices may be the presenting findings. The management of chronic hepatitis B and hepatitis C is discussed in their respective sections.

**Chronic Hepatitis and Pregnancy.** Most young women with chronic hepatitis either are asymptomatic or have only mild liver disease. For seropositive asymptomatic women, there usually are no problems with pregnancy. With *symptomatic* chronic active hepatitis, pregnancy outcome depends primarily on disease and fibrosis intensity, and especially on the presence of portal hypertension. The few women whom we have managed have done well, but their long-term prognosis is poor. Accordingly, they should be counseled regarding possible liver transplantation as well as abortion and sterilization options.

**Hepatitis A**

Because of vaccination programs, the incidence of hepatitis A has decreased 95 percent since 1995. In 2010, the rate was 0.6 per 100,000 individuals—the lowest rate ever reported in the United States (Centers for Disease Control and Prevention, 2012). This 27-nm RNA picornavirus is transmitted by the fecal–oral route, usually by ingestion of contaminated food or water. The incubation period is approximately 4 weeks. Individuals shed virus in their feces, and during the relatively brief period of viremia, their blood is also infectious. Signs and symptoms are often nonspecific and usually mild, although jaundice develops in most patients. Symptoms usually last less than 2 months, although 10 to 15 percent of patients may remain symptomatic or relapse for up to 6 months (Dienstag, 2012a). Early serological detection is by identification of IgM anti-HAV antibody that may persist for several months. During convalescence, IgG antibody predominates.
and it persists and provides subsequent immunity. There is no chronic stage of hepatitis A.

Management of hepatitis A in pregnant women consists of a balanced diet and diminished physical activity. Women with less severe illness may be managed as outpatients. In developed countries, the effects of hepatitis A on pregnancy outcomes are not dramatic (American College of Obstetricians and Gynecologists, 2012a,b). Both perinatal and maternal mortality rates, however, are substantively increased in resource-poor countries. There is no evidence that hepatitis A virus is teratogenic, and transmission to the fetus is negligible. Preterm birth may be increased, and neonatal cholestasis has been reported (Urganci, 2003). Although hepatitis A RNA has been isolated in breast milk, no cases of neonatal hepatitis A have been reported secondary to breast feeding (Daudi, 2012).

Preventatively, vaccination during childhood with formalin-inactivated hepatitis viral vaccine is more than 90-percent effective. HAV vaccination is recommended by the American College of Obstetricians and Gynecologists (2012b) and the Centers for Disease Control and Prevention (2010) for high-risk adults, a category that includes behavioral and occupational populations and travelers to high-risk countries. These countries are listed by the Centers for Disease Control and Prevention in the 2014 CDC Health Information for International Travel “yellow book,” which is available at: http://wwwnc.cdc.gov/travel/yellowbook/2014/table-of-contents.

Passive immunization for the pregnant woman recently exposed by close personal or sexual contact with a person with hepatitis A is provided by a 0.02 mL/kg dose of immune globulin (Centers for Disease Control and Prevention, 2010). Victor and colleagues (2007) reported that a single dose of HAV vaccine given in the usual dosage within 2 weeks of exposure to exposed persons was as effective as immune serum globulin to prevent hepatitis A. In both groups, HAV developed in 3 to 4 percent.

**Hepatitis B**

This is a double-stranded DNA virus of the Hepadnaviridae family. It is found worldwide and is endemic in Africa, Central and Southeast Asia, China, Eastern Europe, the Middle East, and certain areas of South America, with prevalence rates as high as 5 to 20 percent. The World Health Organization (2009) estimates that more than two billion people worldwide are infected with HBV, and of these, 370 million have chronic infection. The Centers for Disease Control and Prevention (2012) estimated that there were 43,000 acute hepatitis B cases in the United States in 2010—a decline of more than 80 percent since vaccination was introduced in the 1980s. The World Health Organization considers hepatitis B to be second only to tobacco among human carcinogens.

The hepatitis B virus is transmitted by exposure to blood or body fluids from infected individuals. In endemic countries, vertical transmission, that is, from mother to fetus or newborn, accounts for at least 35 to 50 percent of chronic HBV infections. In low-prevalence countries such as the United States, which has a prevalence < 2 percent, the more frequent mode of HBV transmission is via sexual transmission or sharing of contaminated needles. HBV can be transmitted by any body fluid, but exposure to virus-laden serum is the most efficient.

Acute hepatitis B develops after an incubation period of 30 to 180 days with a mean of 8 to 12 weeks. At least half of acute infections are asymptomatic. If symptoms are present, they are usually mild and include anorexia, nausea, vomiting, fever, abdominal pain, and jaundice. Acute HBV accounts for half of cases of fulminant hepatitis. Complete resolution of symptoms occurs within 3 to 4 months in more than 90 percent of patients. Figure 55-2 details the sequence of the various HBV antigens and antibodies in acute infection. The first serological marker to be detected is the
hepatitis B surface antigen (HBsAg), often preceding the increase in aminotransferase levels. As HBsAg disappears, antibodies to the surface antigen develop (anti-HBs), marking complete resolution of disease. Hepatitis B core antigen is an intracellular antigen and not detectable in serum. However, anti-HBc is detectable within weeks of HBsAg appearance. The hepatitis B e antigen (HBeAg) is present during times of high viral replication and often correlates with detectable HBV DNA. After acute hepatitis, approximately 90 percent of adult persons recover completely. The 10 percent who remain chronically infected are considered to have chronic hepatitis B.

**FIGURE 55-2** Sequence of various antigens and antibodies in acute hepatitis B. ALT = alanine aminotransferase; anti-HBc = antibody to hepatitis B core antigen; anti-HBe = antibody to hepatitis B e antigen; anti-HBs = antibody to hepatitis B surface antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen. (Redrawn from Dienstag, 2012a.)

Chronic HBV infection is often asymptomatic but may be clinically suggested by persistent anorexia, weight loss, fatigue, and hepatosplenomegaly. Extrahepatic manifestations may include arthritis, generalized vasculitis, glomerulonephritis, pericarditis, myocarditis, transverse myelitis, and peripheral neuropathy. One risk factor for chronic disease is age at acquisition—more than 90 percent in newborns, 50 percent in young children, and less than 10 percent in immunocompetent adults. Another risk is an immunocompromised state such as those with human immunodeficiency virus (HIV) infection, transplant recipients, or persons receiving chemotherapy. Chronically infected persons may be asymptomatic carriers or have chronic disease with or without cirrhosis. Patients with chronic disease have persistent HBsAg serum positivity. The patients with evidence of high viral replication—HBV DNA with or without HBeAg, have the highest likelihood of developing cirrhosis and hepatocellular carcinoma. HBV DNA has been found to be the best correlate of liver injury and disease progression risk.

**Pregnancy**

Hepatitis B infection is not a cause of excessive maternal morbidity and mortality. It is often
asymptomatic and found only on routine prenatal screening (Connell, 2011; Stewart, 2013). A review of the National Inpatient Sample (NIS) Agency for Healthcare Research and Quality reported a modest increase in preterm birth rates in HBV-positive mothers but no effect on fetal-growth restriction or preeclampsia rates (Reddick, 2011). Others have shown similar results (Connell, 2011; Safir, 2010). Transplacental viral infection is uncommon, and Towers and associates (2001) reported that viral DNA is rarely found in amniotic fluid or cord blood. Interestingly, HBV DNA has been found in the ovaries of HBV-positive pregnant women, and the highest levels were found in women who transmitted HBV to their fetuses (Hu, 2012; Lou, 2010; Yu, 2012).

In the absence of HBV immunoprophylaxis, 10 to 20 percent of women positive for HBsAg transmit viral infection to their infant. This rate increases to almost 90 percent if the mother is HBsAg and HBeAg positive. Immunoprophylaxis and hepatitis B vaccine given to infants born to HBV-infected mothers has decreased transmission dramatically and prevented approximately 90 percent of infections (Smith, 2012). But, women with high HBV viral loads—106 to 108 copies/mL, or those who are HBeAg positive, still have a least a 10-percent vertical transmission rate, regardless of immunoprophylaxis.

To decrease vertical transmission in women at highest risk because of high HBV DNA levels, some have recommended antiviral therapy. Lamivudine, a cytidine nucleoside analogue, has been found to significantly decrease the risk of fetal HBV infection in women with high HBV viral loads (Dusheiko, 2012; Giles, 2011; Han, 2011; Shi, 2010; Xu, 2009). Safety data in early pregnancy, although limited, are promising (Yi, 2012; Yu, 2012). Early reports of two other antiviral medications, telbivudine and tenofovir, for use in pregnancy also show promise (Deng, 2012; Han, 2011; Liu, 2013; Pan, 2012a,b). Hepatitis B immunoglobulin (HBIG) given antepartum to women at highest risk of transmission has also been shown to be effective in decreasing transmission rates (Shi, 2010). Antiviral therapy or HBIG has been shown to be cost-effective in recent analyses (Nayeri, 2012).

Infants born to seropositive mothers are given HBIG very soon after birth. This is accompanied by the first of a three-dose hepatitis B recombinant vaccine. Hill and colleagues (2002) applied this strategy in 369 infants and reported that the 2.4-percent transmission rate was not increased with breast feeding if vaccination was completed. Although virus is present in breast milk, the incidence of transmission is not lowered by formula feeding (Shi, 2011). The American Academy of Pediatrics does not consider maternal HBV infection a contraindication to breast feeding.

For high-risk mothers who are seronegative, hepatitis B vaccine can be given during pregnancy. The efficacy has been shown to be similar to that for nonpregnant adults, with overall seroconversion rates approaching 95 percent after three doses (Stewart, 2013). The traditional vaccination schedule of 0, 1, and 6 months may be difficult to complete during a pregnancy, and compliance rates decline after delivery. Sheffield and coworkers (2006) reported that the three-dose regimen given prenatally—initially and at 1 and 4 months—resulted in seroconversion rates of 56, 77, and 90 percent, respectively. This regimen was noted to be easily be completed during routine prenatal care.

**Hepatitis D**

Also called delta hepatitis, this is a defective RNA virus that is a hybrid particle with an HBsAg coat and a delta core. The virus must co-infect with hepatitis B either simultaneously or secondarily. It cannot persist in serum longer than hepatitis B virus. Transmission is similar to hepatitis B. Chronic co-infection with B and D hepatitis is more severe and accelerated than with
HBV alone, and up to 75 percent of affected patients develop cirrhosis. HDV infection is detected by the presence of anti-HDV and HDV DNA. Neonatal transmission is unusual as neonatal HB vaccination usually prevents delta hepatitis.

**Hepatitis C**

This is a single-stranded RNA virus of the family Flaviviridae. There are at least six major genotypes—type 1 accounts for 70 percent of HCV infections in the United States. Transmission occurs via blood and body fluids, although sexual transmission is inefficient. Up to a third of anti-HCV positive persons have no identifiable risk factors (Dienstag, 2012b). Screening for HCV is recommended for HIV-infected individuals, persons with injection drug use, hemodialysis patients, children born to mothers with HCV, persons exposed to HCV-positive blood or body fluids, persons with unexplained elevations in aminotransferase values, and recipients of blood or transplants before July 1992. Prenatal screening has been recommended in high-risk women, and in the United States, seroprevalence rates as high as 1 to 2.4 percent have been reported (American College of Obstetricians and Gynecologists, 2012b; Arshad, 2011; Connell, 2011). It is higher in women who are HIV positive, and Santiago-Munoz and associates (2005) found that 6.2 percent of HIV-infected pregnant women at Parkland Hospital were co-infected with hepatitis B or C.

Acute HCV infection is usually asymptomatic or with mild symptoms. Only 10 to 15 percent develop jaundice. The incubation period ranges from 15 to 160 days with a mean of 7 weeks. Aminotransferase levels are elevated episodically during the acute infection. Hepatitis C RNA testing is now considered the “gold standard” for the diagnosis of HCV—levels may be detected even before aminotransferase elevations and the development of anti-HCV. Anti-HCV antibody is not detected for an average of 15 weeks and in some cases as long as a year (Dienstag, 2012a).

As many as 80 to 90 percent of patients with acute HCV will be chronically infected. Although most remain asymptomatic, approximately 20 to 30 percent progress to cirrhosis within 20 to 30 years. Aminotransferase values fluctuate, and HCV RNA levels vary over time. Liver biopsy reveals chronic disease and fibrosis in up to 50 percent, however, these findings are often mild. Overall, the long-term prognosis for most patients is excellent.

As expected, most pregnant women diagnosed with HCV have chronic disease. HCV infection was initially thought to have limited pregnancy effects. However, more recent reports have chronicled modestly increased fetal risks for low birthweight, NICU admission, preterm delivery, and mechanical ventilation (Berkley, 2008; Pergam, 2008; Reddick, 2011). In some women, these adverse outcomes may have been influenced by concurrent high-risk behaviors associated with HCV infection.

The primary adverse perinatal outcome is vertical transmission of HCV infection to the fetus-infant. This is higher in mothers with viremia (Indolfi, 2014; Joshi, 2010). From their review, Airoldi and Berghella (2006) cited a rate of 1 to 3 percent in HCV-positive, RNA-negative women compared with 4 to 6 percent in those who were RNA-positive. In a report from Dublin McMenamin and colleagues (2008) described transmission rates in 545 HCV-positive women. They found a 7.1-percent vertical transmission rate in RNA-positive women compared with none in those who were RNA-negative. Some have found an even greater risk when the mother is co-infected with HIV (Ferrero, 2003). Approximately two thirds of prenatal transmission occurs peripartum. HCV genotype, invasive prenatal procedures, breast feeding, and delivery mode are not associated with mother-to-child transmission (Babik, 2011; Cottrell, 2013; Ghamar Chehreh, 2011; López, 2010). That said, invasive procedures such as internal electronic fetal heart rate
monitoring should be avoided. HCV infection is not a contraindication to breast feeding.

There is currently no licensed vaccine for HCV prevention. The chronic HCV infection treatment has traditionally included alpha interferon (standard and pegylated), alone or in combination with ribavirin. This regimen is contraindicated in pregnancy because of the teratogenic potential of ribavirin in animals (Joshi, 2010). The initial 5-year review of the Ribavirin Pregnancy Registry found no evidence for human teratogenicity. However, the registry has enrolled fewer than half of the necessary numbers to allow a conclusive statement to be made (Roberts, 2010). The development and study of direct acting and host-targeted antiviral drugs in the past decade has shown great promise for the management of chronic hepatitis C (Liang, 2013; Lok, 2012; Poordad, 2013). Current interferon-free, ribavirin-free regimens are being evaluated, although no data are available for pregnant women.

### Hepatitis E

This water-borne RNA virus usually is enterically transmitted by contaminated water supplies. Hepatitis E is probably the most common cause of acute hepatitis (Hoofnagle, 2012). It causes epidemic outbreaks in third-world countries with substantial morbidity and mortality rates. Pregnant women have a higher case-fatality rate than nonpregnant individuals. Rein and coworkers (2012) suggested a 20-percent mortality rate using modeling estimates from the developing world. Fulminant hepatitis, although rare overall, is more common in pregnant women and contributes to the increased mortality rates (Labrique, 2012; Mehta, 2012).

Higher hepatitis E viral loads and increased cytokine secretion in pregnant compared with nonpregnant women may be factors in the development of fulminant hepatitis (Borkakoti, 2013; Salam, 2013). Recombinant HEV vaccine efficacy is reported to be > 90 percent, and preliminary data from inadvertently vaccinated pregnant women have shown no adverse maternal or fetal events. Even so, there is no currently available Food and Drug Administration (FDA)-approved vaccine (Labrique, 2012; Wedemeyer, 2012; Wu, 2012).

### Hepatitis G

This blood-borne infection with a flavivirus-like RNA virus does not actually cause hepatitis (Dienstag, 2012a). Its seroprevalence ranges from 0.08 to 5 percent, and there is currently no recommended treatment aside from basic blood and body fluid precautions. Infant transmission has been described (Feucht, 1996; Inaba, 1997).

### Autoimmune Hepatitis

This is a generally progressive chronic hepatitis that is important to distinguish from chronic viral hepatitis because treatments are markedly different. According to Krawitt (2006), an environmental agent—a virus or drug—triggers events that mediate T cells to destroy liver antigens in genetically susceptible patients. Type 1 hepatitis is more common and is characterized by multiple autoimmune antibodies such as antinuclear antibodies (ANA) as well as certain human leukocyte genes. Treatment employs corticosteroids, alone or combined with azathioprine (Gossard, 2012). In some patients, cirrhosis or hepatocellular carcinoma develops.

As with other autoimmune disorders, chronic autoimmune hepatitis is more common in women and frequently coexists with thyroiditis, ulcerative colitis, type 1 diabetes, and rheumatoid arthritis. Hepatitis is usually subclinical, but exacerbations can cause fatigue and malaise that can
be debilitating.

In general, pregnancy outcomes of women with autoimmune hepatitis are poor, but the prognosis is good with well-controlled disease (Uribe, 2006). In one study, Schramm and colleagues (2006) described 42 pregnancies in 22 German women with autoimmune hepatitis. A fifth had a flare antepartum, and half had a flare postpartum. One woman underwent liver transplantation at 18 weeks’ gestation, and another died of sepsis at 19 weeks. In their 38-year review, Candia and associates (2005) found 101 pregnancies in 58 women. They reported that preeclampsia developed in approximately a fourth, and there were two maternal deaths. Westbrook and coworkers (2012) reported the outcomes of 81 pregnancies in 53 women. Flares occurred in a third of the women. There were more common in those not taking medication and those with active disease in the year before conception. Only a minority—20 of 81—were not taking medications. Maternal and fetal complications were higher among women with cirrhosis, particularly with respect to the risks of death or need for liver transplantation during the pregnancy or within 12 months postpartum.

### Nonalcoholic Fatty Liver Disease

*Steatohepatitis* is an increasingly recognized condition that may occasionally progress to hepatic cirrhosis. As a macrovesicular fatty liver condition, it resembles alcohol-induced liver injury but is seen without alcohol abuse. Obesity, type 2 diabetes, and hyperlipidemia—*syndrome X*—frequently coexist and likely are etiological agents or “triggers” (McCullough, 2006). Nonalcoholic fatty liver disease (NAFLD) is common in obese persons, and as many as 50 percent of the morbidly obese are affected (Chap. 48, p. 963). Moreover, half of persons with type 2 diabetes have NAFLD. Browning and associates (2004) used magnetic resonance spectroscopy to determine the prevalence of NAFLD in Dallas County and found that approximately a third of adults were affected. This varied by ethnicity, with 45 percent of Hispanics, 33 percent of whites, and 24 percent of blacks being affected. Most people—80 percent—found to have steatosis had normal liver enzymes. Welsh and colleagues (2013) showed that nonalcoholic fatty liver disease among adolescents increased from 3.9 to 10.7 percent between 1988 to 1994 and 2007 to 2010. The risk increased with age, body mass index, male gender, and Mexican American race. And half of obese male adolescents are affected.

There is a continuum or spectrum of liver damage in which fatty liver progresses to *nonalcoholic steatohepatitis—NASH*, and then *hepatic fibrosis* develops that may progress to cirrhosis (Levene, 2012). Still, in most persons, the disease is usually asymptomatic, and it is a frequent explanation for elevated aminotransferase levels found in blood donors and other routine screening testing. Indeed, it is the cause of elevated asymptomatic aminotransferase levels in up to 90 percent of cases in which other liver disease is excluded. It also is the most common cause of abnormal liver tests among adults in this country. Currently, weight loss along with diabetes and dyslipidemia control is the only recommended treatment.

### Pregnancy

Fatty liver infiltration is probably much more common than realized in obese and diabetic pregnant women. During the past decade, we encountered an increasing number of pregnant women with these disorders. Once severe liver injury, that is, acute fatty liver of pregnancy, was excluded, gravidas with fatty liver infiltration had no adverse outcomes relative to liver involvement. Page and Girling (2011) reported five women who had mild liver enzyme abnormalities after exclusion of other obstetrical and nonobstetrical etiologies. Four women had steatosis diagnosed by
sonography, and a fifth woman without sonographic abnormalities had biopsy-confirmed steatosis postpartum. Forbes and colleagues (2011) studied women with and without a history of gestational diabetes who had nondiabetic glucose tolerance testing postpartum. Although body mass index did not differ significantly, women with a history of gestational diabetes were more than twice as likely to have NAFLD diagnosed sonographically, and this correlated with increased dyslipidemia and measures of insulin resistance. As the obesity endemic worsens, any adverse effects of this liver disorder on pregnancy outcome should become apparent.

Cirrhosis

Irreversible chronic liver injury with extensive fibrosis and regenerative nodules is the final common pathway for several disorders. Laënnec cirrhosis from chronic alcohol exposure is the most frequent cause in the general population. But in young women—including pregnant women—most cases are caused by postnecrotic cirrhosis from chronic hepatitis B and C. Many cases of cryptogenic cirrhosis are now known to be caused by nonalcoholic fatty liver disease (Dienstag, 2012b). Clinical manifestations of cirrhosis include jaundice, edema, coagulopathy, metabolic abnormalities, and portal hypertension with gastroesophageal varices and splenomegaly. The incidence of deep-vein thromboembolism is increased (Søgaard, 2009). The prognosis is poor, and 75 percent have progressive disease that leads to death in 1 to 5 years.

Cirrhosis and Pregnancy

Women with symptomatic cirrhosis frequently are infertile. Those who become pregnant generally have poor outcomes. Common complications include transient hepatic failure, variceal hemorrhage, preterm delivery, fetal-growth restriction, and maternal death (Tan, 2008). Outcomes are generally worse if there are coexisting esophageal varices.

Another potentially fatal complication of cirrhosis arises from associated splenic artery aneurysms. Up to 20 percent of ruptures occur during pregnancy, and 70 percent of these rupture in the third trimester (Tan, 2008). In a review of 32 cases of these aneurysms, Ha and coworkers (2009) found that the mean diameter was 2.25 cm, and in half of cases, the diameter was < 2 cm. The maternal mortality rate of 22 percent was likely related to the emergent diagnosis of these cases, as almost all were diagnosed at the time of rupture.

Portal Hypertension and Esophageal Varices

Approximately half of esophageal varices cases in pregnant women are caused by either cirrhosis or extrahepatic portal vein obstruction, which leads to portal system hypertension. Some cases of extrahepatic hypertension develop following portal vein thrombosis associated with one of the thrombophilia syndromes (Chap. 52, p. 1029). Others follow thrombosis from umbilical vein catheterization when the woman was a neonate, especially if she was born preterm.

With either intrahepatic or extrahepatic resistance to flow, portal vein pressure rises from its normal range of 5 to 10 mm Hg, and values may exceed 30 mm Hg. Collateral circulation develops that carries portal blood to the systemic circulation. Drainage is via the gastric, intercostal, and other veins to the esophageal system, where varices develop. Bleeding is usually from varices near the gastroesophageal junction, and hemorrhage can be torrential. Bleeding during pregnancy from varices occurs in a third to half of affected women and is the major cause of maternal mortality (Tan, 2008).

Maternal prognosis is largely dependent on whether there is variceal hemorrhage. Mortality
rates are higher if varices are associated with cirrhosis compared with rates for varices without cirrhosis—18 versus 2 percent, respectively. Perinatal mortality rates are high in women with varices and are worse if cirrhosis caused the varices.

Management

Treatment is the same as for nonpregnant patients. Preventatively, all patients with cirrhosis, including pregnant women, should undergo screening endoscopy for identification of variceal dilatation (Tan, 2008). Beta-blocking drugs such as propranolol are given to reduce portal pressure and hence the bleeding risk (Groszmann, 2005).

For acute bleeding, endoscopic band ligation is preferred to sclerotherapy, as it avoids any potential risks of injecting sclerotherapeutic chemicals (Tan, 2008). Zeeman and Moise (1999) described a pregnant woman who underwent prophylactic banding at 15, 26, and 31 weeks’ gestation to prevent bleeding. Acute medical management for bleeding varices verified by endoscopy includes intravenous vasopressin or octreotide and somatostatin (Chung, 2005). Balloon tamponade using a triple-lumen tube placed into the esophagus and stomach to compress bleeding varices can be lifesaving if endoscopy is not available. The interventional radiology procedure—transjugular intrahepatic portosystemic stent shunting (TIPSS)—can also control bleeding from gastric varices that is unresponsive to other measures (Khan, 2006; Tan, 2008). TIPSS can be done electively in patients with previous variceal hemorrhage.

Acute Acetaminophen Overdose

Nonsteroidal antiinflammatory drugs (NSAIDs) are often used in suicide attempts. In a study from Denmark, Flint and associates (2002) reported that more than half of such attempts by 122 pregnant women were with either acetaminophen or aspirin. In the United States, acetaminophen is much more commonly used during pregnancy, and overdose may lead to hepatocellular necrosis and acute liver failure (Lee, 2008). Massive necrosis causes a cytokine storm and multiorgan dysfunction. Early symptoms of overdose are nausea, vomiting, diaphoresis, malaise, and pallor. After a latent period of 24 to 48 hours, liver failure ensues and usually begins to resolve in 5 days. In a prospective Danish study, only 35 percent of patients who were treated for fulminant hepatic failure spontaneously recovered before being listed for liver transplantation (Schmidt, 2007).

The antidote is N-acetylcysteine, which must be given promptly. The drug is thought to act by increasing glutathione levels, which aid metabolism of the toxic metabolite, N-acetyl-para-benzoquinoneimine. The need for treatment is based on projections of possible plasma hepatotoxic levels as a function of the time from acute ingestion. Many poison control centers use the nomogram established by Rumack and Matthew (1975). A plasma level is measured 4 hours after ingestion, and if the level is > 120 μg/mL, treatment is given. If plasma determinations are not available, empirical treatment is given if the ingested amount exceeded 7.5 g. An oral loading dose of 140 mg/kg of N-acetylcysteine is followed by 17 maintenance doses of 70 mg/kg every 4 hours for 72 hours of total treatment time. Both the oral and an equally efficacious intravenous dosing regimen have been recently reviewed by Hodgman and Garrard (2012). Although the drug reaches therapeutic concentrations in the fetus, any protective effects are unknown (Heard, 2008).

After 14 weeks, the fetus has some cytochrome P450 activity necessary for metabolism of acetaminophen to the toxic metabolite. Riggs and colleagues (1989) reported follow-up data from the Rocky Mountain Poison and Drug Center in 60 such women. The likelihood of maternal and fetal survival was better if the antidote was given soon after overdose. At least one 33-week fetus appears to have died as a direct result of hepatotoxicity 2 days after maternal ingestion. In another
case, Wang and associates (1997) confirmed acetaminophen placental transfer with maternal and cord blood levels that measured 41 μg/mL. Both mother and infant died from hepatorenal failure.

### Focal Nodular Hyperplasia
This is considered a benign lesion of the liver, characterized in most cases by a well-delineated accumulation of normal but disordered hepatocytes that surround a central stellate scar. These usually can be differentiated from hepatic adenomas by MR and CT imaging. Except in the rare situation of unremitting pain, surgery is rarely indicated, and most women remain asymptomatic during pregnancy. Rifai and coworkers (2013) reviewed 20 cases at a single center in Germany. None of the women had complications during pregnancy, and tumor size did not vary significantly before, during, or after pregnancy. Three women had 20-percent tumor growth; in 10 patients, the tumor decreased in size; and the remaining seven were unchanged across pregnancy. Ramirez-Fuentes and associates (2013) studied 44 lesions in 30 women, who each had a minimum of two MR imaging studies 12 months apart. They reported that 80 percent of the lesions were unchanged in size, and most of the remainder decreased in size. They concluded that changes in size were unrelated to pregnancy, oral contraceptive use, or menopause. As noted in Chapter 38 (p. 709), this lesion is not a contraindication to estrogen-containing contraceptives.

### Hepatic Adenoma
This benign neoplasm has a significant risk of rupture-associated hemorrhage, particularly in pregnancy. As discussed above, adenomas can usually be differentiated from focal nodular hyperplasia by MR or CT imaging. Adenomas have a 9:1 predominance among women and are strongly linked with combination oral contraceptive use. The risk of rupture increases with lesion size, and surgery is generally recommended for tumors measuring > 5 cm. From their review, Cobey and Salem (2004) found 27 cases in pregnancy, 23 of which became apparent in the third trimester and puerperium. They found no cases of hemorrhage when the tumor size was < 6.5 cm. In their review, 16 of 27 (60 percent) women with an adenoma presented with tumor rupture that resulted in seven maternal deaths and six fetal deaths. Of note, 13 of 27 women presented within 2 months postpartum, and in half, hemorrhage heralded rupture. Santambrogio and coworkers (2009) provided a case report of a woman with a 12-cm adenoma that ruptured shortly after emergent cesarean for placental abruption and that ultimately prompted liver transplantation.

### Liver Transplantation
According to the Organ Procurement and Transplantation Network (2012), liver transplant patients comprise nearly 18 percent of all proposed waiting organ recipients. Approximately a fourth of these are women of childbearing age. The first human liver transplant was performed 50 years ago, and a recent literature review cited 450 pregnancies in 306 women who had undergone transplantation (Deshpande, 2012). Although their livebirth rate of 80 percent and miscarriage rates compared favorably with those of the general population, there were significantly increased risks of preeclampsia, cesarean delivery, and preterm birth. A fourth of pregnancies were complicated by hypertension, approximately a third resulted in preterm birth, and in 10 percent, there was one or more rejection episodes (Table 55-4). Importantly, 4 percent of mothers had died within a year after delivery, but this rate is comparable with nonpregnant liver transplantation patients.
In pregnant women who have undergone transplantation, close surveillance is mandatory to detect hypertension, renal dysfunction, preeclampsia, and graft rejection. Management considerations, including immunosuppressive therapy, were reviewed by Mastrobattista and Gomez-Lobo (2008) and by McKay and Josephson (2006). Because of increased metabolic clearance, serum levels of some antirejection drugs should be determined. Ethical considerations of pregnancy in transplant recipients were reviewed earlier by Ross (2006).

**GALLBLADDER DISORDERS**

**Cholelithiasis and Cholecystitis**

In the United States, 20 percent of women older than 40 years have gallstones. Most stones contain cholesterol, and its oversecretion into bile is thought to be a major factor in stone formation. Biliary sludge, which may increase during pregnancy, is an important precursor to gallstone formation. The incidence of sonographically identified asymptomatic gallstones in more than 1500 pregnant or postpartum women was 2.5 to 10 percent (Maringhini, 1993; Valdivieso, 1993). Moreover, the cumulative risk of all patients with silent gallstones to require surgery for symptoms or complications is 10 percent at 5 years, 15 percent at 10 years, and 18 percent at 15 years (Greenberger, 2008). For these reasons, prophylactic cholecystectomy is not warranted for asymptomatic stones. For symptomatic gallstone disease, nonsurgical approaches have been used and include oral bile acid therapy with ursodeoxycholic acid and extracorporeal shock wave lithotripsy. There is no experience with these during pregnancy.

Acute cholecystitis usually develops when there is obstruction of the cystic duct. Bacterial infection plays a role in 50 to 85 percent of cases. In more than half of patients with acute cholecystitis, a history of previous right upper quadrant pain from cholelithiasis is elicited. With acute disease, pain is accompanied by anorexia, nausea and vomiting, low-grade fever, and mild leukocytosis. As shown in Figure 55-3, sonography can be used to see stones as small as 2 mm,
Symptomatic gallbladder disorders in young women include acute cholecystitis, biliary colic, and acute pancreatitis. Rarely, a gallbladder undergoes torsion or a neoplasm is found (Kleiss, 2003; Wiseman, 2008). In most symptomatic patients, cholecystectomy is warranted. Although acute cholecystitis responds to medical therapy, contemporary consensus is that early cholecystectomy is indicated (Greenberger, 2008). In acute cases, medical therapy consists of intravenous fluids, antimicrobials, analgesics, and in some instances, nasogastric suction, before surgical therapy. Laparoscopic cholecystectomy has become the preferred treatment for most patients.

Gallbladder Disease During Pregnancy

The incidence of cholecystitis during pregnancy is reported to be approximately 1 in 1000. There is no doubt that pregnancy is “lithogenic.” After the first trimester, the gallbladder fasting volume as well as the residual volume after postprandial emptying are doubled. Incomplete emptying may result in retention of cholesterol crystals, a prerequisite for cholesterol gallstones. Maringhini and colleagues (1993) showed that the incidence of biliary sludge—which can be a forerunner to gallstones—and gallstones in pregnancy are 31 and 2 percent, respectively. Ko and colleagues (2014), however, cited a combined incidence to be lower at about 5 percent. Postpartum, there is frequently regression of sludge, and occasionally gallstones will resorb. Still, after delivery, hospitalization for gallbladder disease within a year remains relatively common. Ko (2006) studied Washington state discharge databases and documented that 0.5 percent of postpartum women were hospitalized within a year for various conditions. Of these 6211 women, 76 had uncomplicated cholecystitis, and 55 underwent cholecystectomy.
Medical versus Surgical Management

Acute cholecystitis during pregnancy or the puerperium is usually associated with gallstones or biliary sludge. Symptomatic cholecystitis is initially managed in a manner similar to that for nonpregnant women. In the past, most favored medical therapy. However, the recurrence rate during the same pregnancy is high, and 25 to 50 percent of women ultimately required cholecystectomy for persistent symptoms. Moreover, if cholecystitis recurs later in gestation, preterm labor is more likely and cholecystectomy technically more difficult.

For these reasons, operative and endoscopic interventions are increasingly favored over conservative measures. Othman and coworkers (2012) showed that women managed conservatively had more pain, more recurrent visits to the emergency department, more hospitalizations, and a higher rate of cesarean delivery. Dhupar and associates (2010) reported more complications with conservative management of gallbladder disease compared with laparoscopic cholecystectomy in pregnancy. These included multiple admissions, prolonged total parenteral nutrition, and unplanned labor induction for worsening gallbladder symptoms.

Cholecystectomy was performed safely in all trimesters. Only one of 19 patients who underwent laparoscopic cholecystectomy had a complication, which did not require further surgery. Date and coworkers (2008) reviewed the literature and found no increased risk of preterm birth or fetal demise for operative compared with conservative management. There was, however, a significantly higher rate of fetal death from gallstone pancreatitis when women were managed conservatively compared with surgical management. There were no perinatal deaths in 20 women undergoing cholecystectomy and in nine undergoing endoscopic retrograde cholangiopancreatography. Management at Parkland Hospital has evolved to a more aggressive surgical approach, especially if there is concomitant biliary pancreatitis as subsequently discussed. During the past two decades, laparoscopic cholecystectomy has evolved as the favored surgical approach and is discussed in Chapter 46 (p. 928).

Endoscopic Retrograde Cholangiopancreatography

Relief from symptomatic biliary duct gallstones during pregnancy has been greatly aided by use of endoscopic retrograde cholangiopancreatography—ERCP (Fogel, 2014; Menees, 2006). The procedure is performed if there is suspected or proven common duct obstruction, usually from stones. Approximately 10 percent of patients with symptomatic stone disease have common duct stones (Greenberger, 2008). ERCP can be modified in many cases so that radiation exposure from fluoroscopy is avoided (Shelton, 2008; Simmons, 2004).

Tang and associates (2009) reported results from 68 ERCP procedures performed in 65 pregnant women at Parkland Hospital. All but two women had gallstones, and sphincterotomy was performed in all but one woman. Common-duct stones were identified in half of these 65 women, and in all but one, the stones were successfully removed. A biliary stent was placed in 22 percent and removed after delivery. Complications were minimal, and post-ERCP pancreatitis developed in 16 percent. Pregnancy outcomes were not different than for the general obstetrical population. As a less invasive approach, magnetic resonance cholangiopancreatography (MRCP) has been reported to have utility in pregnancy, particularly with otherwise unexplained biliary duct dilatation identified sonographically (Oto, 2009). Use of MRCP in this situation identified the cause of the biliary ductal dilatation in four cases and excluded obstructive pathology in the remaining four cases.
**Pancreatic Disorders**

**Pancreatitis**

Acute pancreatic inflammation is triggered by activation of pancreatic trypsinogen followed by autodigestion. It is characterized by cellular membrane disruption and proteolysis, edema, hemorrhage, and necrosis (Fogel, 2014; Whitcomb, 2006). Approximately 20 percent have severe pancreatitis, and mortality rates in these patients reach up to 25 percent (Swaroop, 2004).

In nonpregnant patients, acute pancreatitis is almost equally associated with gallstones and alcohol abuse. During pregnancy, however, cholelithiasis is almost always the predisposing condition. Other causes are hyperlipidemias, usually hypertriglyceridemia; hyperparathyroidism; congenital ductal anomalies; and rarely autoimmune pancreatitis (Crisan, 2008; Finkelberg, 2006). Nonbiliary pancreatitis occasionally develops postoperatively, or it is associated with trauma, drugs, or some viral infections. Certain metabolic conditions, including acute fatty liver of pregnancy and familial hypertriglyceridemia, also predispose to pancreatitis (Nelson, 2013). Acute and chronic pancreatitis have been linked to the more than 1000 mutations of the cystic fibrosis transmembrane conductance regulator gene (Rowntree, 2003).

At Parkland Hospital, with a large Mexican American population, acute pancreatitis complicated approximately 1 in 3300 pregnancies (Ramin, 1995). At Brigham and Women’s Hospital, with a more diversely ethnic population, Hernandez and colleagues (2007) reported an incidence of 1 in 4450. In a multiple-institution Midwestern three-state review of more than 305,000 pregnancies, Eddy and associates (2008) found the incidence of acute pancreatitis to be 1 in 3450.

**Diagnosis**

Acute pancreatitis is characterized by mild to incapacitating epigastric pain, nausea and vomiting, and abdominal distention. Patients are usually in distress and have low-grade fever, tachycardia, hypotension, and abdominal tenderness. As many as 10 percent have systemic inflammatory response syndrome, which causes endothelial activation and can lead to acute respiratory distress syndrome (Chap. 47, p. 943).

Laboratory confirmation is from serum amylase levels three times upper normal values. As shown in Table 55-5, the mean amylase value was approximately 2000 IU/L in 173 pregnant women with pancreatitis, and the mean lipase value approximated 3000 IU/L. Importantly, there is no correlation between the degree of enzyme elevation and disease severity. Indeed, by 48 to 72 hours, amylase levels may return to normal despite other evidence for continuing pancreatitis. Serum lipase activity is also increased and usually remains elevated with continued inflammation. There is usually leukocytosis, and 25 percent of patients have hypocalcemia. Elevated serum bilirubin and aspartate aminotransferase levels may signify gallstone disease.

| TABLE 55-5. Laboratory Values in 173 Pregnant Women with Acute Pancreatitis |
Several prognostic factors may be used to predict disease severity (Whitcomb, 2006). Some of these are respiratory failure, shock, need for massive colloid replacement, hypocalcemia < 8 mg/dL, and dark hemorrhagic fluid removed with paracentesis. If three of the first four features are documented, survival is only 30 percent.

### Management

Medical treatment is the same as that for nonpregnant patients and includes analgesics, intravenous hydration, and measures to decrease pancreatic secretion by interdiction of oral intake. Other than supportive therapy, no particular treatment schemes have improved outcomes (Whitcomb, 2006). In the series by Ramin and colleagues (1995), all 43 affected pregnant women responded to conservative treatment and were hospitalized for a mean of 8.5 days. Nasogastric suction does not improve outcomes of mild to moderate disease, but enteral feeding may be helpful once pain improves and associated ileus resolves. Although we try to avoid parenteral nutrition, in 65 women with acute pancreatitis described by Eddy and coworkers (2008), a fourth had total parenteral nutrition. If there is bacterial superinfection of necrotizing pancreatitis, then antimicrobials are indicated. If common duct stones are found, then ERCP is indicated (Fogel, 2014). For pregnant patients with gallstone pancreatitis, ERCP for removal of common duct stones and papillotomy has been used successfully (Simmons, 2004; Tang, 2009). Cholecystectomy should be considered after inflammation subsides if there is gallbladder disease. Hernandez and associates (2007) reported that half of such women who did not undergo cholecystectomy had recurrent pancreatitis during the same pregnancy. Severe necrotizing pancreatitis can be life threatening, and laparotomy for debridement and drainage may be required (Gosnell, 2001; Robertson, 2006).

Pregnancy outcomes appear to be related to acute pancreatitis severity. Eddy and associates (2008) reported a 30-percent preterm delivery rate, and 11 percent were delivered before 35 weeks’ gestation. There were two pancreatitis-related deaths. Importantly, almost a third of 73 women had recurrent pancreatitis during pregnancy.

### Pancreatic Transplantation
According to the United Network for Organ Sharing, the 5-year graft survival for pancreatic transplantation is 80 percent. Because there is improved survival when a combined pancreas and kidney are grafted for those with type 1 diabetes and renal failure, most transplants include both organs.

Mastrobattista and Gomez-Lobo (2008) reported results from the National Transplantation Pregnancy Registry. Of 44 pregnancies in 73 women following pancreas-kidney transplantation, outcomes have been encouraging, and vaginal delivery has been described. Although the incidence of hypertension, preeclampsia, preterm delivery, and fetal-growth restriction was high, there was only one perinatal death. There were four rejection episodes during pregnancy, which were treated successfully.

Pancreatic islet autotransplantation may be performed to prevent diabetes following pancreatectomy, and at least three successful pregnancies have been described (Jung, 2007).

Pregnant women are susceptible to hematological abnormalities that may affect any woman of childbearing age. These include chronic disorders such as hereditary anemias, immunological thrombocytopenia, and malignancies such as leukemias and lymphomas. Other disorders arise during pregnancy because of pregnancy-induced demands. Two examples are iron deficiency and megaloblastic anemias. Pregnancy may also unmask underlying hematological disorders such as compensated hemolytic anemias caused by hemoglobinopathies or red cell membrane defects. Finally, any hematological disease may first arise during pregnancy. Importantly, pregnancy induces physiological changes that often confuse the diagnosis of these hematological disorders and assessment of their treatment. Several pregnancy-induced hematological changes are discussed in detail in Chapter 4 (p. 55).
Extensive hematological measurements have been made in healthy nonpregnant women. Concentrations of many cellular elements that are normal during pregnancy are listed in the Appendix (p. 1287). The Centers for Disease Control and Prevention (CDC) (1998) defined anemia in iron-supplemented pregnant women using a cutoff of the 5th percentile—11 g/dL in the first and third trimesters, and 10.5 g/dL in the second trimester (Fig. 56-1). An ongoing study of 278 women is currently evaluating the accuracy of an erythrogram and serum ferritin levels for anemia diagnosis and prediction of responsiveness to oral iron (Bresani, 2013).

**FIGURE 56-1** Mean hemoglobin concentrations (black line) and 5th and 95th percentiles (blue lines) for healthy pregnant women taking iron supplements. (Data from the Centers for Disease Control and Prevention, 1989.)

The modest fall in hemoglobin levels during pregnancy is caused by a relatively greater expansion of plasma volume compared with the increase in red cell volume (Chap. 4, p. 55). The disproportion between the rates at which plasma and erythrocytes are added to the maternal circulation is greatest during the second trimester. Late in pregnancy, plasma expansion essentially ceases, while hemoglobin mass continues to increase.

**General Considerations**

The causes of anemia in pregnancy and their frequency are dependent on multiple factors such as geography, ethnicity, nutritional status, preexisting iron status, and prenatal iron supplementation. Other factors are socioeconomic, and anemia is more prevalent among indigent women (American College of Obstetricians and Gynecologists, 2013a). Approximately 25 percent of almost 48,000 Israeli pregnant women had a hemoglobin level < 10 g/dL (Kessous, 2013). Ren and colleagues (2007) found that 22 percent of 88,149 Chinese women were anemic in the first trimester. Of 1000 Indian women, half were anemic at some point, and 40 percent were throughout pregnancy (Kumar, 2013). The importance of prenatal iron therapy is illustrated by the study of Taylor and associates (1982), who reported that hemoglobin levels at term averaged 12.7 g/dL among women who took supplemental iron compared with 11.2 g/dL for those who did not. Bodnar and coworkers (2001)
studied a cohort of 59,248 pregnancies and found a postpartum anemia prevalence of 27 percent that correlated both with prenatal anemia and hemorrhage at delivery.

The etiologies of the more common anemias encountered in pregnancy are listed in Table 56-1. The specific cause of anemia is important when evaluating effects on pregnancy outcome. For example, maternal and perinatal outcomes are seldom affected by moderate iron deficiency anemia, yet they are altered markedly in women with sickle-cell anemia.

**Effects on Pregnancy Outcomes**

Most studies of anemia during pregnancy describe large populations. As indicated, these likely deal with nutritional anemias, specifically those due to iron deficiency. Klebanoff and associates (1991) studied nearly 27,000 women and found a slightly increased risk of preterm birth with midtrimester anemia. Ren and colleagues (2007) found that a low first-trimester hemoglobin concentration increased the risk of low birthweight, preterm birth, and small-for-gestational age infants. In a study from Tanzania, Kidanto and coworkers (2009) reported that the incidence of preterm delivery and low birthweight was increased as the severity of anemia increased. They did not, however, take into account the cause(s) of anemia, which was diagnosed in almost 80 percent of their obstetrical population. Kumar and colleagues (2013) studied 1000 Indian women and also found that second- and third-trimester anemia was associated with preterm birth and low birthweight. Chang and associates (2013) followed 850 children born to women classified as iron deficient in the third trimester. Children without iron supplementation had lower mental development at 12, 18, and 24 months of age, suggesting that prenatal iron deficiency is associated with mental development. Tran and associates (2014) reported similar findings from a Vietnamese study.

A seemingly paradoxical finding is that healthy pregnant women with a higher hemoglobin concentration are also at increased risk for adverse perinatal outcomes (von Tempelhoff, 2008). This may result from lower than average plasma volume expansion of pregnancy concurrent with normal red cell mass increase. Murphy and coworkers (1986) described more than 54,000 singleton pregnancies in the Cardiff Birth Survey and reported excessive perinatal morbidity with
high maternal hemoglobin concentrations. Scanlon and associates (2000) studied the relationship between maternal hemoglobin levels and preterm or growth-restricted infants in 173,031 pregnancies. Women whose hemoglobin concentration was three standard deviations above the mean at 12 or 18 weeks’ gestation had 1.3- to 1.8-fold increases in the incidence of fetal-growth restriction. These findings have led some to the illogical conclusion that withholding iron supplementation to cause iron deficiency anemia will improve pregnancy outcomes (Ziaei, 2007).

Iron Deficiency Anemia

The two most common causes of anemia during pregnancy and the puerperium are iron deficiency and acute blood loss. The CDC (1989) estimated that as many as 8 million American women of childbearing age were iron deficient. In a study of more than 1300 women, 21 percent had third-trimester anemia with 16 percent due to iron deficiency anemia (Vandevijvere, 2013). In a typical singleton gestation, the maternal need for iron averages close to 1000 mg. Of this, 300 mg is for the fetus and placenta; 500 mg for maternal hemoglobin mass expansion; and 200 mg that is shed normally through the gut, urine, and skin. The total amount of 1000 mg considerably exceeds the iron stores of most women and results in iron deficiency anemia unless iron supplementation is given.

Iron deficiency is often manifested by an appreciable drop in hemoglobin concentration. In the third trimester, additional iron is needed to augment maternal hemoglobin and for transport to the fetus. Because the amount of iron diverted to the fetus is similar in a normal and in an iron-deficient mother, the newborn infant of a severely anemic mother does not suffer from iron deficiency anemia. As discussed in Chapter 33 (p. 643), neonatal iron stores are related to maternal iron status and to timing of cord clamping.

Diagnosis

Classic morphological evidence of iron deficiency anemia—erythrocyte hypochromia and microcytosis—is less prominent in the pregnant woman compared with that in the nonpregnant woman. Moderate iron deficiency anemia during pregnancy usually is not accompanied by obvious morphological changes in erythrocytes. Serum ferritin levels, however, are lower than normal, and there is no stainable bone marrow iron. Iron deficiency anemia during pregnancy is the consequence primarily of expansion of plasma volume without normal expansion of maternal hemoglobin mass.

The initial evaluation of a pregnant woman with moderate anemia should include measurements of hemoglobin, hematocrit, and red cell indices; careful examination of a peripheral blood smear; a sickle-cell preparation if the woman is of African origin; and measurement of serum iron or ferritin levels, or both. Expected values in pregnancy are found in the Appendix (p. 1287). Serum ferritin levels normally decline during pregnancy (Goldenberg, 1996). Levels less than 10 to 15 mg/L confirm iron deficiency anemia (American College of Obstetricians and Gynecologists 2013a). Pragmatically, the diagnosis of iron deficiency in moderately anemic pregnant women usually is presumptive and based largely on exclusion.

When pregnant women with moderate iron deficiency anemia are given adequate iron therapy, a hematological response is detected by an elevated reticulocyte count. The rate of increase of hemoglobin concentration or hematocrit is typically slower than in nonpregnant women due to the increasing and larger blood volumes during pregnancy.

Treatment
Regardless of anemia status, daily oral supplementation with 30 to 60 mg of elemental iron and 400 \( \mu \)g of folic acid is recommended in pregnancy (Peña-Rosas, 2012; World Health Organization, 2012). Anemia resolution and restitution of iron stores can be accomplished with simple iron compounds—ferrous sulfate, fumarate, or gluconate—that provide about 200 mg daily of elemental iron. If a woman cannot or will not take oral iron preparations, then parenteral therapy is given. Although both are administered intravenously, ferrous sucrose has been shown to be safer than iron-dextran (American College of Obstetricians and Gynecologists, 2013a). There are equivalent increases in hemoglobin levels in women treated with either oral or parenteral iron therapy (Bayouneu, 2002; Sharma, 2004).

### Anemia from Acute Blood Loss

In early pregnancy, anemia caused by acute blood loss is common with abortion, ectopic pregnancy, and hydatidiform mole. Anemia is much more common postpartum from obstetrical hemorrhage. Massive hemorrhage demands immediate treatment as described in Chapter 41 (p. 814). If a moderately anemic woman—defined by a hemoglobin value of approximately 7 g/dL—is hemodynamically stable, is able to ambulate without adverse symptoms, and is not septic, then blood transfusions are not indicated. Instead, iron therapy is given for at least 3 months (Krafft, 2005). In a randomized trial, Van Wyck and colleagues (2007) reported that intravenous ferric carboxymaltose given weekly was as effective as thrice-daily oral ferrous sulfate tablets for hemoglobin regeneration for postpartum anemia.

### Anemia Associated with Chronic Disease

Weakness, weight loss, and pallor have been recognized since antiquity as characteristics of chronic disease. Various disorders, such as chronic renal failure, cancer and chemotherapy, human immunodeficiency virus (HIV) infection, and chronic inflammation, result in moderate and sometimes severe anemia, usually with slightly hypochromic and microcytic erythrocytes. It is the second most common form of anemia worldwide (Weiss, 2005).

In nonpregnant patients with chronic inflammatory diseases, the hemoglobin concentration is rarely < 7 g/dL; bone marrow cellular morphology is not altered; and serum iron concentrations are decreased. However, ferritin levels usually are elevated. The low levels of iron are mediated by hepcidin, a polypeptide produced in the liver that participates in iron balance and transport (Weiss, 2005). These anemias share similar features that include alterations in reticuloendothelial function, iron metabolism, and decreased erythropoiesis (Cullis, 2013).

### Pregnancy

Women with chronic disorders may develop anemia for the first time during pregnancy. In those with preexisting anemia, it may be intensified as plasma volume expands disproportionately to red cell mass expansion. Causes include chronic renal insufficiency, inflammatory bowel disease, and connective-tissue disorders. Others are granulomatous infections, malignant neoplasms, rheumatoid arthritis, and chronic suppurative conditions.

Of these, chronic renal insufficiency is the most common disorder that we have encountered as a cause of anemia during pregnancy. Some cases are accompanied by erythropoietin deficiency. As discussed in Chapter 53 (p. 1060), during pregnancy in women with mild chronic renal insufficiency, the degree of red cell mass expansion is inversely related to renal impairment. At the same time, plasma volume expansion usually is normal, and thus anemia is intensified.
Anemia often accompanies acute pyelonephritis but is due to acute endotoxin-mediated erythrocyte destruction. With normal erythropoietin production, red cell mass is restored as pregnancy progresses (Cavenee, 1994; Dotters-Katz, 2013).

Treatment

Adequate iron stores must be ensured. Recombinant erythropoietin has been used successfully to treat chronic anemia (Weiss, 2005). In pregnancies complicated by chronic renal insufficiency, recombinant erythropoietin is usually considered when the hematocrit approximates 20 percent (Ramin, 2006). Cyganek and coworkers (2011) described good results in five pregnant renal transplant recipients treated with human recombinant erythropoietin. One worrisome side effect is hypertension, which is already prevalent in women with renal disease. In addition, Casadevall and colleagues (2002) reported pure red cell aplasia and antierthropoietin antibodies in 13 nonpregnant patients given recombinant human erythropoietin. Numerous additional cases have been reported. However, because of changes in manufacturing and new regulations, it is an infrequent toxicity today (McKoy, 2008).

Megaloblastic Anemia

These anemias are characterized by blood and bone-marrow abnormalities from impaired DNA synthesis. Worldwide, the prevalence of megaloblastic anemia during pregnancy varies considerably. In the United States, it is rare.

Folic Acid Deficiency

In the United States, megaloblastic anemia beginning during pregnancy almost always results from folic acid deficiency. In the past, this condition was referred to as pernicious anemia of pregnancy. It usually is found in women who do not consume fresh green leafy vegetables, legumes, or animal protein. As folate deficiency and anemia worsen, anorexia often becomes intense and further aggravates the dietary deficiency. In some instances, excessive ethanol ingestion either causes or contributes to folate deficiency.

In nonpregnant women, the folic acid requirement is 50 to 100 μg/day. During pregnancy, requirements are increased, and 400 μg/day is recommended (Chap. 9, p. 181). The earliest biochemical evidence is low plasma folic acid concentrations (Appendix, p. 1287). Early morphological changes usually include neutrophils that are hypersegmented and newly formed erythrocytes that are macrocytic. With preexisting iron deficiency, macrocytic erythrocytes cannot be detected by measurement of the mean corpuscular volume. Careful examination of a peripheral blood smear, however, usually demonstrates some macrocytes. As the anemia becomes more intense, peripheral nucleated erythrocytes appear, and bone marrow examination discloses megaloblastic erythropoiesis. Anemia may then become severe, and thrombocytopenia, leukopenia, or both may develop. The fetus and placenta extract folate from maternal circulation so effectively that the fetus is not anemic despite severe maternal anemia. There have been instances in which newborn hemoglobin levels were 18 g/dL or more, whereas maternal values were as low as 3.6 g/dL (Pritchard, 1970). A Cochrane review by Lassi and associates (2013) evaluated the effectiveness of oral prenatal folic acid supplementation alone or with other micronutrients versus no folic acid. There was no conclusive evidence of supplement benefit for pregnancy outcomes that included preterm birth and perinatal mortality. There was, however, increased mean birthweight and a significant reduction in the incidence of megaloblastic anemia.
Treatment. Folic acid is given along with iron, and a nutritious diet is encouraged. As little as 1 mg of folic acid administered orally once daily produces a striking hematological response. By 4 to 7 days after beginning folic acid treatment, the reticulocyte count is increased, and leukopenia and thrombocytopenia are corrected.

Prevention. A diet sufficient in folic acid prevents megaloblastic anemia. The role of folate deficiency in the genesis of neural-tube defects has been well studied (Chap. 14, p. 283). Since the early 1990s, nutritional experts and the American College of Obstetricians and Gynecologists (2013c) have recommended that all women of childbearing age consume at least 400 μg of folic acid daily. More folic acid is given in circumstances in which requirements are increased. These include multifetal pregnancy, hemolytic anemia, Crohn disease, alcoholism, and inflammatory skin disorders. There is evidence that women who previously have had infants with neural-tube defects have a lower recurrence rate if a daily 4-mg folic acid supplement is given preconceptionally and throughout early pregnancy.

Vitamin B₁₂ Deficiency
During pregnancy, vitamin B₁₂ levels are lower than nonpregnant values because of decreased levels of binding proteins that include haptocorrin—transcobalamins I and III—and transcobalamin II (Morkbak, 2007). During pregnancy, megaloblastic anemia is rare from deficiency of vitamin B₁₂, that is, cyanocobalamin. The typical example is Addisonian pernicious anemia, which results from absent intrinsic factor that is requisite for dietary vitamin B₁₂ absorption. This autoimmune disorder usually has its onset after age 40 years (Stabler, 2013).

In our limited experience, vitamin B₁₂ deficiency in pregnancy is more likely encountered following gastric resection. Those who have undergone total gastrectomy require 1000 μg of vitamin B₁₂ given intramuscularly each month. Those with a partial gastrectomy usually do not need supplementation, but adequate serum vitamin B₁₂ levels should be ensured during pregnancy (Appendix, p. 1290). Other causes of megaloblastic anemia from vitamin B₁₂ deficiency include Crohn disease, ileal resection, and bacterial overgrowth in the small bowel (Stabler, 2013).

Hemolytic Anemia
There are several conditions in which accelerated erythrocyte destruction is stimulated by a congenital red cell abnormality or by antibodies directed against red cell membrane proteins. The cause may also go unproven. In some cases, hemolysis may be the primary disorder—some examples include sickle-cell disease and hereditary spherocytosis. In other cases, hemolysis develops secondary to an underlying disorder—examples include lupus erythematosus and the preeclampsia syndrome.

Autoimmune Hemolysis
The cause of aberrant antibody production in this uncommon condition is unknown. Typically, both the direct and indirect antiglobulin (Coombs) tests are positive. Anemias caused by these factors may be due to warm-active autoantibodies (80 to 90 percent), cold-active antibodies, or a combination. These syndromes also may be classified as primary (idiopathic) or secondary due to underlying diseases or other factors. Examples of the latter include lymphomas and leukemias, connective-tissue diseases, infections, chronic inflammatory diseases, and drug-induced antibodies...
Cold-agglutinin disease may be induced by infectious etiologies such as *Mycoplasma pneumoniae* or Epstein-Barr viral mononucleosis (Dhingra, 2007). Hemolysis and positive antiglobulin test results may be the consequence of either IgM or IgG antierythrocyte antibodies. Spherocytosis and reticulocytosis are characteristic of the peripheral blood smear. When there is concomitant thrombocytopenia, it is termed Evans syndrome (Wright, 2013).

During pregnancy, there may be marked acceleration of hemolysis. This usually responds to glucocorticoids, and treatment is given with prednisone, 1 mg/kg given orally each day, or its equivalent. Coincidental thrombocytopenia usually is corrected by therapy. Transfusion of red cells is complicated by antierythrocyte antibodies, but warming the donor cells to body temperature may decrease their destruction by cold agglutinins.

**Drug-Induced Hemolysis**

These hemolytic anemias must be differentiated from other causes of autoimmune hemolysis. In most cases, hemolysis is mild, it resolves with drug withdrawal, and recurrence is prevented by avoidance of the drug. One mechanism is by hemolysis induced through drug-mediated immunological injury to red cells. The drug may act as a high-affinity hapten when bound to a red cell protein to which antidrug antibodies attach—for example, IgM antipenicillin or anticephalosporin antibodies. Some other drugs act as low-affinity haptons and adhere to cell membrane proteins—examples include probenecid, quinidine, rifampin, and thiopental. A more common mechanism for drug-induced hemolysis is related to a congenital erythrocyte enzymatic defect. An example is *glucose-6-phosphate dehydrogenase (G6PD) deficiency*, which is common in African American women (p. 1106).

Drug-induced hemolysis is usually chronic and mild to moderate, but occasionally there is severe acute hemolysis. For example, Garratty and coworkers (1999) described seven women with severe Coombs-positive hemolysis stimulated by cefotetan given as prophylaxis for obstetrical procedures. Alpha-methyldopa can cause similar hemolysis (Grigoriadis, 2013). Moreover, maternal hemolysis has been reported after intravenous immune globulin (IVIG) given for fetal and neonatal alloimmune thrombocytopenia (Rink, 2013). As treatment, response to glucocorticoids may be suboptimal, but withdrawal of the offending drug frequently halts the hemolysis.

**Pregnancy-Induced Hemolysis**

In some cases, unexplained severe hemolytic anemia develops during early pregnancy and resolves within months postpartum. There is no evidence of an immune mechanism or intraerythrocytic or extraerythrocytic defects (Starksen, 1983). Because the fetus-infant also may demonstrate transient hemolysis, an immunological cause is suspected. Maternal corticosteroid treatment is often—but not always—effective (Kumar, 2001). We have cared for a woman who during each pregnancy developed intense severe hemolysis with anemia that was controlled by prednisone. Her fetuses were not affected, and in all instances, hemolysis abated spontaneously after delivery.

**Paroxysmal Nocturnal Hemoglobinuria**

Although commonly regarded as a hemolytic anemia, this hemopoietic stem cell disorder is characterized by formation of defective platelets, granulocytes, and erythrocytes. Paroxysmal nocturnal hemoglobinuria is acquired and arises from one abnormal clone of cells, much like a neoplasm (Nguyen, 2006). One mutated X-linked gene responsible for this condition is termed
PIG-A because it codes for phosphatidylinositol glycan protein A. Resultant abnormal anchor proteins of the erythrocyte and granulocyte membrane make these cells unusually susceptible to lysis by complement (Provan, 2000). The most serious complication is thrombosis, which is heightened in the hypercoagulable state of pregnancy.

Chronic hemolysis has an insidious onset, and its severity ranges from mild to lethal. Hemoglobinuria develops at irregular intervals and is not necessarily nocturnal. Hemolysis may be initiated by transfusions, infections, or surgery. Almost 40 percent of patients suffer venous thromboses and may also experience renal failure, hypertension, and Budd-Chiari syndrome. Because of the thrombotic risk, prophylactic anticoagulation is recommended (Parker, 2005). Median survival after diagnosis is 10 years, and bone marrow transplantation is the definitive treatment. Successful treatment of nonpregnant patients has been reported with eculizumab, an antibody that inhibits complement activation (Hillmen, 2006; Parker, 2009). Kelly and colleagues (2010) described seven pregnant women exposed to eculizumab with successful outcomes.

During pregnancy, paroxysmal nocturnal hemoglobinuria can be serious and unpredictable. Complications have been reported in up to three fourths of affected women, and the maternal mortality rate is 10 to 20 percent (De Gramont, 1987). Complications more often develop postpartum, and half of affected women develop venous thrombosis during the puerperium (Fieni, 2006; Greene, 1983; Ray, 2000). In one report of 27 pregnancies in 22 women, the maternal mortality rate was 8 percent and related to postpartum thrombosis (de Guibert, 2011).

Severe Preeclampsia and Eclampsia
Fragmentation or microangiopathic hemolysis with thrombocytopenia is relatively common with severe preeclampsia and eclampsia (Kenny, 2014; Pritchard, 1976). Mild degrees are likely present in most cases of severe preeclampsia and may be referred to as HELLP syndrome—hemolysis, elevated liver enzymes, and low platelet count (Chap. 40, p. 742).

Acute Fatty Liver of Pregnancy
This syndrome is associated with moderate to severe hemolytic anemia (Nelson, 2013). It is discussed further in Chapter 55 (p. 1086).

Bacterial Toxins
The most fulminant acquired hemolytic anemia encountered during pregnancy is caused by the exotoxin of Clostridium perfringens or by group A β-hemolytic streptococcus (Chap. 47, p. 949). Endotoxin of gram-negative bacteria, that is, lipopolysaccharide—especially with bacteremia from severe pyelonephritis—may be accompanied by hemolysis and mild to moderate anemia (Cox, 1991).

Inherited Erythrocyte Membrane Defects
The normal erythrocyte is a biconcave disc. Its shape allows numerous cycles of reversible deformations as the erythrocyte withstands arterial shearing forces and negotiates through splenic slits half the width of its cross-sectional diameter. Several genes encode expression of erythrocyte structural membrane proteins or intraerythrocytic enzymes. Various mutations of these genes may result in inherited membrane defects or enzyme deficiencies that destabilize the lipid bilayer. The loss of lipids from the erythrocyte membrane causes a surface area deficiency and poorly deformable cells that undergo hemolysis. Anemia severity depends on the degree of rigidity or decreased distensibility. Erythrocyte morphology similarly is dependent on these factors, and these
disorders are usually named after the most dominant red-cell shape characteristic of the disorder. Three examples are *hereditary spherocytosis, pyropoikilocytosis,* and *ovalocytosis.*

**Hereditary Spherocytosis.** Hemolytic anemias that comprise this group of inherited membrane defects are probably the most common identified in pregnant women. Mutations are usually an autosomally dominant, variably penetrant *spectrin* deficiency. Others are autosomally recessive or de novo gene mutations that result from deficiency of *ankyrin, protein 4.2, moderate band 3,* or combinations of these (Gallagher, 2010; Yawata, 2000). Clinically, varying degrees of anemia and jaundice result from hemolysis. Diagnosis is confirmed by identification of spherocytes on peripheral smear, reticulocytosis, and increased osmotic fragility (Fig. 56-2).

**FIGURE 56-2** Scanning electron micrograph showing (A) normal-appearing erythrocytes from a heterozygous carrier of recessive spherocytosis, and (B) from her daughter, a homozygote with severe anemia. (From Agre, 1989, with permission.)

Spherocytic anemias may be associated with the so-called *crisis* that is characterized by severe anemia from accelerated hemolysis, and it develops in patients with an enlarged spleen. Infection can also accelerate hemolysis or suppress erythropoiesis to worsen anemia. An example of the latter is infection with parvovirus B19 (Chap. 64, p. 1244). In severe cases, splenectomy reduces hemolysis, anemia, and jaundice.

**Pregnancy.** In general, women with inherited red-cell membrane defects do well during pregnancy. Folic acid supplementation is given to sustain erythropoiesis. Pregnancy outcomes in women with hereditary spherocytosis cared for at Parkland Hospital were reported by Maberry and associates (1992). Twenty-three women with 50 pregnancies were described. In late pregnancy, these women had hematocrits ranging from 23 to 41 volume percent—mean 31. Their reticulocyte count ranged from 1 to 23 percent. Eight women miscarried. Four of 42 infants were born preterm, but none were growth restricted. Infection in four women intensified hemolysis, and three of these required transfusions. Similar results were reported by Pajor and coworkers (1993) in 19 pregnancies in eight women.

Because these disorders are inherited, the newborn may be affected. Celkan and Alhaj (2008) report prenatal diagnosis via cordocentesis at 18 weeks’ gestation and testing for osmotic fragility. Those with hereditary spherocytosis may manifest hyperbilirubinemia and anemia shortly after birth.
Erythrocyte Enzyme Deficiencies

An intraerythrocytic deficiency of enzymes that permit anaerobic glucose metabolism may cause hereditary nonspherocytic anemia. Most of these mutations are autosomal recessive traits, and pyruvate kinase deficiency is probably the most clinically significant. Another is X-linked glucose-6-phosphate dehydrogenase (G6PD) deficiency (Puig, 2013). Other rare enzyme abnormalities may cause varying degrees of chronic hemolysis. As discussed on page 1105, most episodes of severe anemia with enzyme deficiencies are induced by drugs or infections. During pregnancy, oxidant drugs are avoided, infections are treated promptly, and iron and folic acid are given.

Pyruvate kinase deficiency is associated with variable anemia and hypertensive complications (Wax, 2007). Due to recurrent transfusions in homozygous carriers, iron overload is frequent, and associated myocardial dysfunction should be monitored (Dolan, 2002). The fetus that is homozygous for this mutation may develop hydrops fetalis from anemia and heart failure (Chap. 15, p. 315). Gilsanz and colleagues (1993) used funipuncture to diagnose fetal anemia and pyruvate kinase deficiency.

Glucose-6-phosphate dehydrogenase deficiency is complex because there are more than 400 known enzyme variants. The most common are caused by a base substitution that leads to an amino acid replacement and a broad range of phenotypic severity (Beutler, 1991; Puig, 2013). In the homozygous or A variant, both X chromosomes are affected, and erythrocytes are markedly deficient in G6PD activity. Approximately 2 percent of African American women are affected. The heterozygous variant that is found in 10 to 15 percent of African American women may confer some degree of protection against malaria (Mockenhaupt, 2003). In both instances, random X-chromosome inactivation—lyonization—results in a variable deficiency of enzyme activity.

During pregnancy, infections or drugs can induce hemolysis in both heterozygous and homozygous women, and the severity is related to enzyme activity. Anemia is usually episodic, although some variants induce chronic nonspherocytic hemolysis. Because young erythrocytes contain more enzyme activity than older erythrocytes, in the absence of bone marrow depression, anemia ultimately stabilizes and is corrected soon after the inciting cause is eliminated. Newborn screening for G6PD deficiency is not recommended by the American College of Medical Genetics (2013) as discussed in Chapter 32 (Table 32-3, p. 632).

Aplastic and Hypoplastic Anemia

Although rarely encountered during pregnancy, aplastic anemia is a grave complication. It is characterized by pancytopenia and markedly hypocellular bone marrow (Young, 2008). There are multiple etiologies, and at least one is linked to autoimmune diseases (Stalder, 2009). The inciting cause can be identified in approximately a third of cases. These include drugs and other chemicals, infection, irradiation, leukemia, immunological disorders, and inherited conditions such as Fanconi anemia and Diamond-Blackfan syndrome (Green, 2009; Lipton, 2009). The functional defect appears to be a marked decrease in committed marrow stem cells.

Hematopoietic stem-cell transplantation is optimal therapy in a young patient (Young, 2008). Immunosuppressive therapy is given. In some nonresponders, eltrombopag has been used successfully (Olnes, 2012). Definitive treatment is bone marrow transplantation, and approximately three fourths of patients have a good response with long-term survival when treated with antithymocyte globulin and cyclosporine (Rosenfeld, 2003). There is a potential for transplantation with umbilical cord blood-derived stem cells (Moise, 2005; Pinto, 2008). Previous blood transfusions and even pregnancy enhance the risk of graft rejection, which is the most
common serious complication, causing two thirds of deaths within the first 2 years (Socié, 1999).

**Pregnancy**

Hypoplastic or aplastic anemia complicating pregnancy is rare. In most cases, the diagnosis precedes conception, or the condition develops during pregnancy as a chance occurrence. That said, there are a few well-documented cases of *pregnancy-induced hypoplastic anemia* (Bourantas, 1997; Choudhry, 2002). We have cared for a few such women in whom hypoplastic anemia was first identified during a pregnancy. Anemia and other cytopenias improved or remitted following delivery or pregnancy termination. In some cases, recurrence in a subsequent pregnancy was documented.

*Diamond-Blackfan anemia* is a rare form of pure red-cell hypoplasia, and approximately 40 percent are familial and have autosomal dominant inheritance (Orfali, 2004). There is usually a good response to glucocorticoid therapy. However, continuous treatment is necessary, and most become at least partially transfusion dependent (Vlachos, 2008). In 64 pregnancies complicated by this syndrome, Faivre and associates (2006) reported that two thirds had complications related to placental vascular etiologies that included miscarriage, preeclampsia, preterm birth, stillbirth, or growth-restricted newborn.

*Gaucher disease* is an autosomally recessive lysosomal enzyme deficiency characterized by deficient acid β-glucosidase activity. It involves multiple systems, including bone marrow. Affected women have anemia and thrombocytopenia that is usually worsened by pregnancy (Granovsky-Grisaru, 1995). Elstein and colleagues (1997) described six pregnant women whose disease improved when they were given alglucerase enzyme replacement. Imiglucerase therapy, which is human recombinant enzyme replacement therapy, has been available since 1994. European guidelines recommend treatment in pregnancy, whereas the Food and Drug Administration states it may be given in pregnancy with “clear indications” (Granovsky-Grisaru, 2011).

The major risks to pregnant woman with hypoplastic anemia are hemorrhage and infection. Management depends on gestational age, disease severity, and whether treatment has been given. Supportive care includes continuous infection surveillance and prompt antimicrobial therapy. Granulocyte transfusions are given only during infections. Red cells are transfused to improve symptomatic anemia and routinely to maintain the hematocrit at or above 20 volume percent. Platelet transfusions may be needed to control hemorrhage. Even when thrombocytopenia is intense, the risk of severe hemorrhage can be minimized by vaginal rather than cesarean delivery. Maternal mortality rates reported since 1960 have averaged nearly 50 percent (Choudhry, 2002). Better outcomes are reported with more recent series (Kwon, 2006).

**Pregnancy after Bone Marrow Transplantation**

There have been several reports of successful pregnancies in women who have undergone bone marrow transplantation (Borgna-Pignatti, 1996; Eliyahu, 1994). In their review, Sanders and coworkers (1996) reported 72 pregnancies in 41 women who had undergone transplantation. In the 52 pregnancies resulting in a liveborn infant, almost half were complicated by preterm delivery or hypertension. Our experiences with a few of these women indicate that they have normal pregnancy-augmented erythropoiesis and total blood volume expansion.
Secondary Polycythemia

Excessive erythrocytosis during pregnancy is usually related to chronic hypoxia from maternal congenital cardiac disease or a chronic pulmonary disorder. Unusually heavy cigarette smoking can cause polycythemia. We have encountered otherwise healthy pregnant women who were heavy smokers, had chronic bronchitis, and had hematocrits ranging from 55 to 60 volume percent! Brewer and colleagues (1992) described a woman with persistent erythrocytosis associated with a placental site tumor. If polycythemia is severe, the probability of a successful pregnancy outcome is low.

Polycythemia Vera

This is a primary myeloproliferative hemopoietic stem cell disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic precursors. It is uncommon and likely an acquired genetic disorder of stem cells (Spivak, 2008). Virtually all patients have either a \( JAK2V617F \) or a \( JAK2 \) exon 12 gene mutation (Harrison, 2009). Serum erythropoietin level measurement is helpful to differentiate polycythemia vera—low values—from secondary erythrocytosis—high values. Symptoms are related to increased blood viscosity, and thrombotic complications are common. Fetal loss has been reported to be high in women with polycythemia vera, and pregnancy outcome may be improved with aspirin therapy (Griesshammer, 2006; Robinson, 2005; Tefferi, 2000).

HEMOGLOBINOPATHIES

Sickle-Cell Hemoglobinopathies

Hemoglobin A is the most common hemoglobin tetramer and consists of two \( \alpha \) - and two \( \beta \) -chains. In contrast, sickle hemoglobin (hemoglobin S) originates from a single \( \beta \) -chain substitution of glutamic acid by valine, which stems from an A-for-T substitution at codon 6 of the \( \beta \) -globin gene. Hemoglobinopathies that can result in clinical features of the sickle-cell syndrome include sickle-cell anemia—Hb SS; sickle cell-hemoglobin C disease—Hb SC; sickle cell-\( \beta \)-thalassemia disease—either Hb S/\( \beta^0 \) or Hb S/\( \beta^+ \); and sickle-cell E disease—Hb SE (Stuart, 2004). All are also associated with increased maternal and perinatal morbidity and mortality.

Inheritance

Sickle-cell anemia originates from the inheritance of the gene for S hemoglobin from each parent. In the United States, 1 of 12 African Americans has sickle-cell trait, which results from inheritance of one gene for hemoglobin S and one for normal hemoglobin A. The computed incidence of sickle-cell anemia among African Americans is 1 in 576 (\( 1/12 \times 1/12 \times 1/4 = 1/576 \)). But, the disease is less common in adults and therefore during pregnancy because of earlier mortality, especially during early childhood.

Hemoglobin C originates from a single \( \beta \) -chain substitution of glutamic acid by lysine at codon 6 of the \( \beta \) -globin gene. Approximately 1 in 40 African Americans has the gene for hemoglobin C. Thus, the theoretical incidence for coinheritance of the gene for hemoglobin S and an allelic gene for hemoglobin C in an African American child is about 1 in 2000 (\( 1/12 \times 1/40 \times 1/4 \)). \( \beta \)-Thalassemia minor is approximately 1 in 40, thus S-\( \beta \)-thalassemia also is found in approximately 1
Pathophysiology
Red cells with hemoglobin S undergo sickling when they are deoxygenated, and the hemoglobin aggregates. Constant sickling and unsickling cause membrane damage, and the cell may become irreversibly sickled. Events that slow erythrocyte transit through the microcirculation contribute to vasoocclusion. These include endothelial cell adhesion, erythrocytic dehydration, and vasomotor dysregulation. Clinically, the hallmarks of sickling episodes are periods during which there is ischemia and infarction in various organs. These produce clinical symptoms, predominately pain, which is often severe—the sickle-cell crisis. There may be aplastic, megaloblastic, sequestration, and hemolytic crises.

Chronic and acute changes from sickling include bony abnormalities such as osteonecrosis of femoral and humeral heads, renal medullary damage, autosplenectomy in homozygous SS patients and splenomegaly in other variants, hepatomegaly, ventricular hypertrophy, pulmonary infarctions, pulmonary hypertension, cerebrovascular accidents, leg ulcers, and a propensity for infection and sepsis (Driscoll, 2003; Gladwin, 2004; Stuart, 2004). Of increasing importance is acquisition of pulmonary hypertension, which can be demonstrated in 20 percent of adults with SS hemoglobin (Gladwin, 2008). Depending on its severity, this complication increases the relative risk for death from four- to 11-fold. Another emerging problem with improved survival is chronic sickle-cell disease nephropathy (Maigne, 2010). The median age at death for women is 48 years. Even so, Serjeant and associates (2009) described a cohort of 102 patients followed since birth in which 40 were still alive at 60 to 87 years!

Treatment
Good supportive care is essential to prevent mortality in patients with sickle-cell syndromes. Specific therapies are evolving, and many are still experimental (Stuart, 2004). One treatment is hemoglobin F induction given for both sickling and thalassemia syndromes. These drugs stimulate gamma-chain synthesis. This increases hemoglobin F (fetal hemoglobin), which inhibits hemoglobin S polymerization. One inducing agent, hydroxyurea, when given to patients with moderate to severe disease, increases hemoglobin F production and mitigates erythrocyte membrane damage. This reduces the number of clinical sickling episodes (Platt, 2008). It is not known yet if hydroxyurea increases long-term patient survival (Brawley, 2008). Hydroxyurea is teratogenic in animals, although a preliminary 17-year surveillance of antenatally exposed children was reassuring (Ballas, 2009; Briggs, 2011; Italia, 2010).

Various forms of hemopoietic cell transplantation are emerging as “cures” for sickle-cell syndromes and severe thalassemias (Hsieh, 2009). Oringanje and coworkers (2009) performed a Cochrane Review and found that only observational studies have been reported. Bone marrow transplantation, as discussed on page 1107, has 5-year survival rates that exceed 90 percent (Dalle, 2013). Cord-blood stem-cell transplantation from related donors has also shown great promise (Shenoy, 2013). One intriguing treatment uses cells taken for prenatal diagnosis from a fetus destined to have sickle-cell anemia. Research suggests these cells can be conditioned to produce hemoglobin A and used for replacement after birth (Ye, 2009).

Pregnancy and Sickle-Cell Syndromes
Pregnancy is a serious burden to women with any of the major sickle hemoglobinopathies, particularly those with hemoglobin SS disease. Two large studies define this relationship. The
first, by Villers and colleagues (2008), included 17,952 births delivered of women with sickle-cell syndromes from 2000 through 2003. The second study, by Chakravarty and associates (2008), was from 2002 through 2004 and included 4352 pregnancies. A more recent cohort study of 1526 women was reported by Boulet and coworkers (2013). Common obstetrical and medical complications and their relative risks from these studies are shown in Table 56-2. Added to these are findings of Chakravarty and associates (2008), who reported significantly increased risks for renal failure, gestational hypertension, and fetal-growth restriction.

Data from Boulet, 2013; Villers, 2008.

Maternal morbidity common in pregnancy includes ischemic necrosis of multiple organs, especially bone marrow, that causes episodes of severe pain. Pyelonephritis, pneumonia, and other pulmonary complications are frequent. The acute chest syndrome is manifest by the radiological appearance of a new pulmonary infiltrate accompanied by fever and respiratory symptoms. There are four precipitants of this—infection, marrow emboli, thromboembolism, and atelectasis (Medoff, 2005). Of these, infection causes approximately half of cases and results from typical bacteria and viruses. When the chest syndrome develops, the mean duration of hospitalization is 10.5 days. Mechanical ventilation is required in approximately 15 percent, and the mortality rate is
about 3 percent (Gladwin, 2008).

Despite these complications, the maternal mortality rate has decreased. And although improved, perinatal morbidity and mortality rates remain formidable (Yu, 2009). Some perinatal outcomes reported since 2000 are shown in Table 56-3. In addition to increased risks for preterm birth shown in Table 56-2, the frequency of fetal-growth restriction and perinatal mortality are daunting.

### Hemoglobin SC

In nonpregnant women, morbidity and mortality rates from SC disease are appreciably lower than those from sickle-cell anemia. Indeed, fewer than half of women with SC disease have symptoms before pregnancy. In our experiences, affected pregnant and puerperal women suffer attacks of severe bone pain and episodes of pulmonary infarction and embolization—acute chest syndrome—more commonly compared with when they are not pregnant (Cunningham, 1983). It is arguable whether SC disease has a maternal mortality rate equivalent to that of hemoglobin SS disease (Pritchard, 1973; Serjeant, 2005). In the reports shown in Table 56-3, the perinatal mortality rate is somewhat greater than that of the general obstetrical population, but nowhere as great as with
Management During Pregnancy

Women with sickle-cell hemoglobinopathies require close prenatal observation. These women maintain hemoglobin mass by intense hemopoiesis to compensate for the markedly shortened erythrocyte life span. Thus, any factor that impairs erythropoiesis or increases red cell destruction or both aggravates the anemia. Prenatal folic acid supplementation with 4 mg daily is needed to support the rapid red blood cell turnover (American College of Obstetricians and Gynecologists 2013b).

One danger is that a symptomatic woman may categorically be considered to be suffering from a sickle-cell crisis. As a result, serious obstetrical or medical problems that cause pain, anemia, or both may be overlooked. Some examples are ectopic pregnancy, placental abruption, pyelonephritis, or appendicitis. Thus, the term “sickle-cell crisis” importantly should be applied only after all other possible causes of pain or fever or worsening anemia have been excluded. Pain with sickle-cell syndromes is caused by intense sequestration of sickled erythrocytes and infarction in various organs. These episodes may develop acutely, especially late in pregnancy, during labor and delivery, and early in the puerperium. Because bone marrow is frequently involved, intense bone pain is common.

A system for care of these women has been appropriately stressed by Rees and colleagues (2003). Marti-Carvajal and coworkers (2009) performed a Cochrane review and reported that no randomized trials have evaluated treatment during pregnancy. At minimum, intravenous fluids are given and opioids administered promptly for severe pain. Oxygen via nasal cannula may decrease the intensity of sickling at the capillary level. We have found that red cell transfusions after the onset of severe pain do not dramatically improve the intensity of the current pain crisis and may not shorten its duration. Conversely, as discussed later, prophylactic transfusions almost always prevent further vasoocclusive episodes and pain crises. Recent reports suggest benefits from epidural analgesia used for severe sickle-cell crisis in nonlaboring obstetrical patients (Verstraete, 2012; Winder, 2011). During the past few years, we have encountered several affected women who apparently are habituated to narcotics given chronically to alleviate sickle-cell pain. It is problematic that such women complain of “sickling pain” even when they have effectively undergone exchange transfusion with normal AA-hemoglobin-containing donor red cells.

Rates of covert bacteriuria and acute pyelonephritis are increased substantively, and screening and treatment for bacteriuria are essential. If pyelonephritis develops, sickle cells are extremely susceptible to bacterial endotoxin, which can cause dramatic and rapid red cell destruction while simultaneously suppressing erythropoiesis. Pneumonia, especially due to *Streptococcus pneumoniae*, is common. The CDC (2013a) recommends the following vaccines for those with sickle-cell disease and all asplenic patients: polyvalent pneumococcal, *Haemophilus influenzae* type B, and meningococcal vaccines.

Pulmonary complications are often encountered. Acute chest syndrome is characterized by pleuritic chest pain, fever, cough, lung infiltrates, and hypoxia, and usually also by bone and joint pain (Vichinsky, 2000). The spectrum of its pathology includes infection, infarction, pulmonary sequestration, and fat embolization from bone marrow. At least for nonpregnant adults, some recommend rapid simple or exchange transfusions to remove the “trigger” for acute chest syndromes (Gladwin, 2008). In a cohort study of nonpregnant patients, Turner and colleagues (2009) reported that there were no increased benefits of exchange versus simple transfusions, and the former were associated with fourfold increased blood usage. Recurrent episodes of acute chest
syndrome may lead to restrictive chronic lung disease or arteriolar vasculopathy and pulmonary hypertension.

Pregnant women with sickle-cell anemia usually have some degree of cardiac dysfunction from ventricular hypertrophy. There is increased preload, decreased afterload, normal ejection fraction, and a high cardiac output. Chronic hypertension worsens this pattern (Gandhi, 2000). During pregnancy, the basal hemodynamic state characterized by high cardiac output and increased blood volume is augmented (Veille, 1994). Although most women tolerate pregnancy without problems, complications such as severe preeclampsia or serious infections may result in ventricular failure (Cunningham, 1986). As discussed in Chapter 49 (p. 986), heart failure caused by pulmonary hypertension must also be considered (Chakravarty, 2008; Stuart, 2004).

In the review of 4352 pregnancies in women with sickle-cell syndromes noted earlier, Chakravarty and associates (2008) reported significantly increased pregnancy complications compared with the total population of 11.2 million women. Compared with controls, women with sickling disorders had a 63-percent rate of non-delivery-related admissions. They had a 1.8-fold increased incidence of hypertensive disorders—19 percent; a 2.9-fold increased rate of fetal-growth restriction—6 percent; and a 1.7-fold increased cesarean delivery rate—45 percent.

Prophylactic Red Cell Transfusions. There are several clinical situations for which prophylactic transfusions have been shown to decrease morbidity from sickle-cell syndromes. For example, chronic transfusion therapy prevents strokes in high-risk children. However, there are no randomized trials of such therapy to prevent pulmonary hypertension and chronic sickle-cell lung disease (Cho, 2014). Preoperative transfusions improved some postoperative outcomes (Howard, 2013). During pregnancy, the most dramatic impact of prophylactic transfusions has been on maternal morbidity. In an observational 10-year prospective study at Parkland Hospital, we offered prophylactic transfusions to all pregnant women with sickle-cell syndromes. Transfusions were given throughout pregnancy to maintain the hematocrit above 25 volume percent and the portion of hemoglobin S below 60 percent (Cunningham, 1979). There was minimal maternal morbidity, and erythropoiesis suppression was not problematic. Their outcomes were compared with historical controls who were not routinely transfused. Morbidity and hospitalizations were significantly reduced in the transfused group (Cunningham, 1983). Others have reported similar data (Grossetti, 2009; Howard, 1995). Still, adverse perinatal outcomes are prevalent (Ngô, 2010).

In a multicenter trial, Koshy and coworkers (1988) randomly assigned 72 pregnant women with sickle-cell syndrome to prophylactic or indicated transfusions. They reported a significant decline in the incidence of painful sickle-cell crises with prophylactic transfusions but no differences in perinatal outcomes. Because of risks inherent with blood administration, they concluded that prophylactic transfusions were not necessary.

There is no doubt that morbidity from multiple transfusions is significant. Up to 10 percent of women had a delayed hemolytic transfusion reaction, and infections are major concerns (Garratty, 1997). From our experiences from Parkland Hospital cited above, we found the incidence of red cell alloimmunization to be 3 percent per unit of blood transfused (Cox, 1988). Similarly, in 12 studies reviewed by Garratty (1997), alloimmunization developed in a fourth of women undergoing chronic transfusions. According to Kacker and colleagues (2014), it not cost effective to extensively match blood donors for these women. Finally, although worrisome, we found no evidence of transfusional iron overload, hemochromatosis, or chronic hepatitis in liver biopsies performed in 40 women transfused during pregnancy (Yeomans, 1990).
pregnancy remain controversial (American College of Obstetricians and Gynecologists, 2013b). Similar conclusions were reached after a Cochrane Database analysis (Okusayna, 2013). Current consensus is that their use should be individualized. For example, some clinicians recommend prophylactic transfusions for women with either frequent vasoocclusive episodes or poor obstetrical outcomes (Castro, 2003).

**Fetal Assessment.** Because of the high incidence of fetal-growth restriction and perinatal mortality, serial fetal assessment is necessary. According to the American College of Obstetricians and Gynecologists (2013b), a plan for serial sonographic examinations and antepartum fetal surveillance is reasonable. Anyaegbunam and colleagues (1991) evaluated fetal well-being during 39 sickling crises in 24 women. Almost 60 percent had nonreactive stress tests, which became reactive with crisis resolution, and all had an increased uterine artery systolic-diastolic (S/D) ratio. At the same time, there were no changes in umbilical artery S/D ratios (Chap. 10, p. 219). These investigators concluded that transient effects of sickle-cell crisis do not compromise umbilical, and hence fetal, blood flow. At Parkland Hospital, we serially assess these women with sonography for fetal growth and amnionic fluid volume changes. Nonstress or contraction stress tests are not done routinely unless complications such as fetal-growth restriction develop or fetal movement is reported to be diminished.

**Labor and Delivery.** Management is essentially identical to that for women with cardiac disease (Chap. 49, p. 978). Women should be kept comfortable but not oversedated. Labor epidural analgesia is ideal, and conduction analgesia seems preferable for operative delivery (Camous, 2008). Compatible blood should be available. If a difficult vaginal or cesarean delivery is contemplated, and the hematocrit is < 20 volume percent, then packed erythrocyte transfusions are administered. There is no categorical contraindication to vaginal delivery, and cesarean delivery is reserved for obstetrical indications (Rogers, 2010). Circulatory overload and pulmonary edema from ventricular failure should be avoided.

**Contraception and Sterilization**
Because of chronic debility, complications caused by pregnancy, and the predictably shortened life span of women with sickle-cell anemia, contraception and possibly sterilization are important considerations. Many clinicians do not recommend combined hormonal pills because of potential adverse vascular and thrombotic effects. After a systematic review, however, it was concluded that there was no increase in complications with their use in women with sickle-cell syndromes (Haddad, 2012). The CDC (2013b) regards the contraceptive pill, patch, and ring along with the copper intrauterine device (IUD) as having “advantages that generally outweigh theoretical or proven risks.” All progestin-only methods may be used without restrictions. Because progesterone has been long known to prevent painful sickle-cell crises, low-dose oral progestins or progesterone injections or implants seem ideal. In one study, de Abood and associates (1997) reported significantly fewer and less intense pain crises in women given depot medroxyprogesterone intramuscularly.

**Sickle-Cell Trait**
The heterozygous inheritance of the gene for hemoglobin S results in sickle-cell trait, or AS hemoglobin. Hemoglobin A is most abundant, and the amount of hemoglobin S averages approximately 30 percent in each red cell. The frequency of sickle-cell trait among African Americans averages 8 percent. There is evidence that carriers have occasional hematuria, renal
papillary necrosis, and hyposthenuria (Tsaras, 2009). And although controversial, we believe that sickle-cell trait is not associated with increased rates of abortion, perinatal mortality, low birthweight, or pregnancy-induced hypertension (Pritchard, 1973; Tita, 2007; Tuck, 1983). One unquestioned relationship is the twofold increased incidence of asymptomatic bacteriuria and urinary infection. Sickle-cell trait therefore should not be considered a deterrent to pregnancy on the basis of increased maternal risks.

Preliminary findings from a cohort study by Austin and coworkers (2009) suggested that African American women with sickle trait may have a higher incidence of venous thromboembolism when using hormonal contraceptives compared with women without the trait. However, more data are needed before these effective contraceptive methods are withheld from trait-positive women.

Inheritance is a concern for the infant of a mother with sickle-cell trait whenever the father carries a gene for abnormal hemoglobins that include S, C, and D or for β-thalassemia trait. Prenatal diagnosis through amniocentesis, chorionic villus sampling (CVS), or preimplantation genetic evaluation is available (Chap. 14, p. 297).

### Hemoglobin C and C-β-Thalassemia

Approximately 2 percent of African Americans are heterozygous for hemoglobin C, but even if homozygous, hemoglobin C is innocuous (Nagel, 2003). Neither cause severe anemia or adverse pregnancy outcomes. However, when co-inherited with sickle-cell trait, hemoglobin SC is the second most common serious sickle-cell syndrome.

Pregnancy and homozygous hemoglobin CC disease or hemoglobin C-β-thalassemia are relatively benign associations. Maberry and colleagues (1990) reported our experiences from Parkland Hospital as shown in Table 56-4. Other than mild to moderate anemia, pregnancy outcomes were not different compared with those of the general obstetrical population. When severe anemia is identified, iron or folic acid deficiency or some other superimposed cause should be suspected. Supplementation with folic acid and iron is indicated.

Data from Maberry, 1990.
Hemoglobin E

Although it is uncommon in the United States, hemoglobin E is the second most frequent hemoglobin variant worldwide. Hemoglobin E results from a single β-chain substitution of lysine for glutamic acid at codon 26. The hemoglobin is particularly susceptible to oxidative stress. The heterozygous E trait is common in Southeast Asia. Hurst and coworkers (1983) identified homozygous hemoglobin E, hemoglobin E plus β-thalassemia, or hemoglobin E trait in 36 percent of Cambodians and 25 percent of Laotians. In addition, α- and β-thalassemia traits were prevalent in all groups.

Homzygous hemoglobin EE is associated with little or no anemia, hypochromia, marked microcytosis, or erythrocyte targeting. In our limited experience, pregnant women do not appear to be at increased risk. Conversely, doubly heterozygous hemoglobin E-β-thalassemia is a common cause of childhood anemia in Southeast Asia (Fucharoen, 2000). In a cohort study of 54 women with singleton pregnancies, Luwan and associates (2009) reported a threefold increased risk of preterm birth and fetal-growth restriction in affected women. It is unclear if hemoglobin SE disease is as ominous during pregnancy as hemoglobin SC or S-β-thalassemia disease (Ramahi 1988).

Hemoglobinopathy in the Newborn

Infants with homozygous SS, SC, and CC disease can be identified accurately at birth by cord blood electrophoresis. The United States Preventive Services Task Force recommends that all newborn infants be tested for sickle-cell disease (Lin, 2007). In most states, such screening is mandated by law and performed routinely (Chap. 32, p. 632). Screening for sickle hemoglobinopathies leads to clearly decreased mortality rates in children with sickle-cell disease identified at birth.

Prenatal Diagnosis

There are many tests to detect sickle-cell disease prenatally. Most are DNA based and use CVS samples or amniotic fluid specimens (American College of Obstetricians and Gynecologists 2013b). Several mutations that encode hemoglobin S and other abnormal hemoglobins can be detected by targeted mutation analysis as well as polymerase chain reaction-based techniques (Chap. 13, p. 277).

THALASSEMIAS SYNDROMES

Hundreds of mutations have been described for genes that control production of the normal hemoglobins. Some of these mutations impair synthesis of one or more of the normal globin peptide chains and may result in a clinical syndrome characterized by varying degrees of ineffective erythropoiesis, hemolysis, and anemia. Thalassemias are classified according to the globin chain that is deficient. The two major forms involve impaired production or instability of α-peptide chains—causing α-thalassemia, or of β-chains—causing β-thalassemia. These may form from point mutations, deletions, or translocations involving the α- or non-α-globin gene. The estimated prevalence for thalassemia trait is 16 percent in Southern European, 10 percent in Thai, and 3 to 8 percent in Indian and Chinese populations (Leung, 2012).
Alpha Thalassemias

Because there are four α-globin genes, the inheritance of α-thalassemia is more complicated than for β-thalassemia (Weatherall, 2010). Possible genotypes and phenotypes arising from these mutations are shown in Table 56-5. For each, a close correlation has been established between clinical severity and the degree of α-globin chains synthesis impairment. In most populations, the α-globin chain “cluster” or gene loci are doubled on chromosome 16. Thus, the normal genotype for diploid cells can be expressed as αα/αα. There are two main groups of α-thalassemia determinants: α<sup>0</sup>-thalassemia is characterized by the deletion of both loci from one chromosome (––/αα), whereas α<sup>+</sup>-thalassemia is characterized by the loss of a single locus from one allele (–α/αα heterozygote) or a loss from each allele alleles (–α–α homozygote).

<sup>a</sup>More common in African Americans.
<sup>b</sup>More common in Asian Americans.

There are two major phenotypes. The deletion of all four α-globin chain genes (––/––) characterizes homozygous α-thalassemia. Because α-chains are contained in fetal hemoglobin, the fetus is affected. With none of the four genes expressed, there are no α-globin chains, and instead, hemoglobin Bart (γ<sub>4</sub>) and hemoglobin H (β<sub>4</sub>) are formed as abnormal tetramers (Chap. 7, p. 137).

Frequency

The relative frequency of α-thalassemia minor, hemoglobin H disease, and hemoglobin Bart disease varies remarkably among racial groups. All of these variants are encountered in Asians. In those of African descent, although α-thalassemia minor has a frequency of approximately 2 percent, hemoglobin H disease is rare and hemoglobin Bart disease is unreported. This is because Asians usually have α<sup>0</sup>-thalassemia minor inherited with both gene deletions typically from the same chromosome (––/αα), whereas blacks usually have α<sup>+</sup>-thalassemia minor in which one gene is deleted from each chromosome (–α–α). The α-thalassemia syndromes appear sporadically in other racial and ethnic groups. Diagnosis of β-thalassemia minor and α-thalassemia major in the fetus can be accomplished by DNA analysis using molecular techniques (American College of Obstetricians and Gynecologists, 2013b). Fetal diagnosis of hemoglobin Bart has been described
using capillary electrophoresis or high-performance liquid chromatography (HPLC) techniques (Sirichotiyakul, 2009; Srivorakun, 2009). Molecular genetic testing for HBA1 and HBA2 identifies 90 percent of deletions and 10 percent of point mutations in affected individuals (Galanello, 2011b).

**Pregnancy**

Important obstetrical aspects of some α-thalassemia syndromes depend on the number of gene deletions in a given woman. The silent carrier state with one gene deletion is of no consequence. Deletion of two genes resulting in α-thalassemia minor is characterized by minimal to moderate hypochromic microcytic anemia. This is due to either the α0- or the α+-thalassemia trait, and thus genotypes may be –α/–α or –/αα. Differentiation is possible only by DNA analysis (Weatherall, 2000a,b). Because there are no other clinical abnormalities with either α-thalassemia minor, it often goes unrecognized and is usually of no maternal consequence. The fetus with these forms of thalassemia minor will have hemoglobin Bart at birth, but as its levels drop, it is not replaced by hemoglobin H. Red cells are hypochromic and microcytic, and the hemoglobin concentration is normal to slightly depressed.

**Hemoglobin H disease** (β4) results from the compound heterozygous state for α0- plus α+-thalassemia with deletion of three of four alpha genes (—/–α). With only one functional α-globin gene per diploid genome, the newborn will have abnormal red cells containing a mixture of hemoglobin Bart (γ4), hemoglobin H (β4), and hemoglobin A. The neonate appears normal but soon develops hemolytic anemia as most of the hemoglobin Bart is replaced by hemoglobin H. Anemia is moderate to severe, and it usually worsens during pregnancy.

Inheritance of all four abnormal alpha genes causes homozygous α-thalassemia with predominant production of hemoglobin Bart, which has an appreciably increased affinity for oxygen. This is incompatible with extended survival, and stillbirths caused by the homozygous condition are especially common in Southeast Asia. Hsieh and colleagues (1989) reported that blood obtained by funipuncture from 20 hydropic fetuses contained 65 to 98 percent Bart hemoglobin. Either these fetuses are stillborn, or they die very soon after birth and have the typical features of nonimmune hydrops fetalis shown in Figure 16-4 (p. 330).

Lam and associates (1999) reported that sonographic measurement of the fetal cardiothoracic ratio at 12 to 13 weeks’ gestation was 100-percent sensitive and specific for identifying affected fetuses. Sonographic evaluation of the myocardial performance index—the Tei index—in the first half of pregnancy has been evaluated. Changes predating hydrops are seen in affected fetuses (Luewan, 2013). Severe anemia can be detected using Doppler velocimetry of the middle cerebral artery (Chap. 10, p. 221). Although a successful case of hemopoietic cell transplantation with a fetal “cure” has been described, this remains experimental (Galanello, 2011a; Yi, 2009).

**Beta Thalassemias**

The β-thalassemias are the consequences of impaired β-globin chain production or α-chain instability. Genes that encode control of β-globin synthesis are in the δγβ-gene “cluster” located on chromosome 11 (Fig. 7-10, p. 138). More than 150 point mutations in the β-globin gene have been described (Weatherall, 2010). Most are single-nucleotide substitutions that produce transcriptional or translational defects, RNA splicing or modification, or frameshifts that result in highly unstable hemoglobins. Thus, deletional and nondeletional mutations affect β-globin RNA. In β-thalassemia there is decreased β-chain production, and excess α-chains precipitate to cause cell membrane...
damage. Other forms of β-thalassemias are caused by α-chain instability (Kihm, 2002). Because of the variety of genetic defects and their combinations with genes that code for globin chain synthesis, these are collectively referred to as thalassemia syndromes (Weatherall, 2010).

The heterozygous trait is β-thalassemia minor, and those most commonly encountered have elevated hemoglobin A2 levels. This hemoglobin is composed of two α- and two δ-globin chains, and concentrations are usually more than 3.5 percent. Hemoglobin F—composed of two α- and two γ-globin chains—also usually has increased concentrations of more than 2 percent. Some patients with heterozygous β-thalassemia minor do not have anemia, and others have mild to moderate anemia characterized by hypochromia and microcytosis.

Homozygous β-thalassemia—also called β-thalassemia major or Cooley anemia—is a serious and frequently fatal disorder. There is intense hemolysis and severe anemia. Many patients become transfusion dependent, and the subsequent iron load, along with abnormally increased gastrointestinal iron absorption, leads to hemochromatosis, which is fatal in many cases. A heterozygous form of β-thalassemia that clinically manifests as thalassemia intermedia produces moderate anemia.

Pregnancy
There are few problems that arise during pregnancy in women with β-thalassemia minor who have mild anemia. Iron and folate supplements are given. In some women, anemia will worsen because normal plasma volume expansion may be accompanied by slightly subnormal erythropoiesis.

Thalassemia major and some of the other severe forms were uncommonly encountered during pregnancy before the advent of transfusion and iron chelation therapy. With such management, there were 63 pregnancies reported without serious complications (Aessopos, 1999; Daskalakis, 1998; Kumar, 1997). Pregnancy is considered advisable if there is normal maternal cardiac function. Transfusions are given throughout pregnancy to maintain the hemoglobin concentration at 10 g/dL. This is coupled with surveillance of fetal growth (American College of Obstetricians and Gynecologists, 2013b; Sheiner, 2004).

Prenatal Diagnosis
Because β-thalassemia major is caused by numerous mutations, prenatal diagnosis is difficult. For a given individual, targeted mutation analysis is done that requires prior identification of that familial mutation. These are done using CVS and other techniques discussed in Chapter 14 (p. 300). Noninvasive testing of circulating fetal nucleic acids in maternal plasma for the diagnosis of β-thalassemia has been described (Galbiati, 2012; Leung, 2012).

PLATELET DISORDERS

Thrombocytopenia
Various platelet abnormalities may precede pregnancy, may develop during pregnancy coincidentally, or may be induced by pregnancy. Abnormally low platelet counts are relatively common in the pregnant woman and have various causes. These disorders may be inherited or idiopathic, acute or chronic in onset, and either primary or associated with other disorders. For example, thrombocytopenia in obstetrics is seen often with severe preeclampsia syndrome; massive hemorrhage with transfusions; consumptive coagulopathy from placental abruption, sepsis
syndrome, or amniotic-fluid embolism; hemolytic anemias; systemic lupus erythematosus and antiphospholipid antibody syndrome; or hypoplastic or aplastic anemia. Other causes include viral infections, exposure to various drugs, and allergic reactions (Aster, 2007; Diz-Küçükkäya, 2010). Thrombocytopenia defined as < 150,000/μL platelets occurs in 6 to 15 percent of pregnant women, and 75 percent of these cases stem from gestational thrombocytopenia (Boehlen, 2006).

Burrows and Kelton (1993) reported that 6.6 percent of 15,471 pregnant women had a platelet count < 150,000/μL, and in 1.2 percent, it was < 100,000/μL. They reported that almost 75 percent of 1027 women whose platelet counts were < 150,000/μL were found to have normal-variant incidental thrombocytopenia. Of the remainder, 21 percent had a hypertensive disorder of pregnancy, and 4 percent had an immunological disorder. A platelet count of < 80,000/μL should trigger an evaluation for etiologies other than incidental or gestational thrombocytopenia, which is unlikely to have a platelet count of < 50,000/μL (Gernsheimer, 2013).

Gestational Thrombocytopenia

Normal pregnancy may be accompanied by a physiological decrease in platelet concentration (Appendix, p. 1287). This is usually evident in the third trimester and is thought to be predominantly due to hemodilution. However, the increased splenic mass characteristic of normal pregnancy may be contributory (Maymon, 2006). Most evidence shows that platelet life span is unchanged in normal pregnancy (Kenny, 2014). Thus, some degree of gestational thrombocytopenia is considered normal. Obviously, the definition used for thrombocytopenia is important. In their review, Rouse and coworkers (1998) cited an incidence of 4 to 7 percent for gestational thrombocytopenia, defined by platelet counts < 150,000/μL.

Inherited Thrombocytopenias

The Bernard-Soulier syndrome is characterized by lack of platelet membrane glycoprotein (GPIb/IX), which causes severe dysfunction. Maternal antibodies against fetal GPIb/IX antigen can cause alloimmune fetal thrombocytopenia. Peng and colleagues (1991) described an affected woman who during four pregnancies had episodes of postpartum hemorrhage, gastrointestinal hemorrhage, and fetal thrombocytopenia. Fujimori and associates (1999) described a similarly affected woman whose neonate died from thrombocytopenic intracranial hemorrhage. A systematic review of 30 pregnancies in 18 women reported a 33-percent rate of primary postpartum hemorrhage, gastrointestinal hemorrhage, and half of women with bleeding required blood transfusion. The reviewers also noted six cases of neonatal alloimmune thrombocytopenia and two perinatal deaths (Peitsidis, 2010). Close monitoring through pregnancy and 6 weeks postpartum is critical due to the possibility of life-threatening hemorrhage (Prabu, 2006).

Chatwani and coworkers (1992) reported a woman with autosomally dominant May-Hegglin anomaly whose infant was not affected. This condition is characterized by thrombocytopenia, giant platelets, and leukocyte inclusions. Urato and Repke (1998) also described such a woman who was delivered vaginally. Despite a platelet count of 16,000/μL, she did not bleed excessively. The neonate inherited the anomaly, but also had no bleeding despite a platelet count of 35,000/μL. Fayyad and colleagues (2002) managed three pregnancies in a woman with May-Hegglin anomaly. In the first, the mother had a term cesarean delivery of an unaffected infant; in the second, she had a fetal demise with multiple placental infarcts; and in the third, she received low-dose aspirin (75 mg/d) and gave birth to an unaffected infant.

Immune Thrombocytopenic Purpura
The primary form—also termed idiopathic thrombocytopenic purpura (ITP)—is usually caused by a cluster of IgG antibodies directed against one or more platelet glycoproteins (Schwartz, 2007). Antibody-coated platelets are destroyed prematurely in the reticuloendothelial system, especially the spleen. Although this is not proven, the disorder is probably mediated by autoantibodies directed at platelet-associated immunoglobulins—PAIgG, PAIgM, and PAIgA. In adults, ITP most often is a chronic disease that rarely resolves spontaneously.

Secondary forms of chronic thrombocytopenia appear in association with systemic lupus erythematosus, lymphomas, leukemias, and several systemic diseases. Approximately 2 percent of thrombocytopenic patients have positive serological tests for lupus, and in some cases there are high levels of anticardiolipin antibodies. Perhaps 10 percent of HIV-positive patients will have associated thrombocytopenia (Scaradavou, 2002).

**Diagnosis and Management.** Only a few adults with primary ITP recover spontaneously, and for those who do not, platelet counts usually range from 10,000 to 100,000/μL (George, 2010). There is no irrefutable evidence that pregnancy increases the risk of relapse in women with previously diagnosed ITP or worsens thrombocytopenia in women with active disease. That said, it is certainly not unusual for women who have been in clinical remission for several years to have recurrent thrombocytopenia during pregnancy. Although this may be from closer surveillance, hyperestrogenemia has also been suggested as a cause.

Therapy is considered if the platelet count is less than 30,000 to 50,000/μL (George, 2010). Primary treatment includes IVIG or corticosteroids (Neunert, 2011). Prednisone, 1 mg/kg daily, is given to suppress the phagocytic activity of the splenic monocyte-macrophage system. IVIG given in a total dose of 2 g/kg during 2 to 5 days is also usually effective.

In pregnant women with no response to corticosteroid or IVIG therapy, open or laparoscopic splenectomy may be effective. In late pregnancy, surgery is technically more difficult, and cesarean delivery may be necessary for exposure. Intravenous anti-D IgG, 50 to 75 μg/kg, has been described for treatment of resistant ITP in D-positive patients with a spleen (Konkle, 2008). There usually is improvement by 1 to 3 days, with a peak at approximately 8 days (Sieunarine, 2007). Cytotoxic agents are typically avoided in pregnancy due to teratogenicity risks. Azathioprine and rituximab, however, which are used in nonpregnant ITP, have been used for other conditions in pregnancy. Finally, the thrombopoietin agonist romiplostim has improved responses (Imbach, 2011; Kuter, 2010).

**Fetal and Neonatal Effects.** Platelet-associated IgG antibodies cross the placenta and may cause thrombocytopenia in the fetus-neonate. Fetal death from hemorrhage occurs occasionally (Webert, 2003). The severely thrombocytopenic fetus is at increased risk for intracranial hemorrhage with labor and delivery. This fortunately is unusual. Payne and associates (1997) reviewed studies of maternal ITP published since 1973 and added their experiences with 55 cases. Of 601 newborns, 12 percent had severe thrombocytopenia defined as a platelet count < 50,000/μL. Six infants had intracranial hemorrhage, and in three, their initial platelet count was > 50,000/μL. This is consistent with a study of 127 pregnancies in women with ITP in which 10 to 15 percent of neonates were found to have transient ITP (Koyama, 2012).

Considerable attention has been directed at identifying the fetus with potentially dangerous thrombocytopenia. All investigators have concurred that there is not a strong correlation between fetal and maternal platelet counts (George, 2009; Payne, 1997). Because of this, there have been attempts to quantify the relationships among maternal IgG free platelet antibody levels, platelet-associated antibody levels, and fetal platelet count. Again, however, there is little concurrence.
Investigators have also examined the association between the specific maternal cause of thrombocytopenia and risk of a thrombocytopenic fetus. Four causes investigated include gestational thrombocytopenia, hypertension-associated thrombocytopenia, ITP, and alloimmune thrombocytopenia. Burrows and Kelton (1993) reported neonatal umbilical cord platelet counts of < 50,000/μL in 19 of 15,932 consecutive newborns (0.12 percent). Of all of these pregnancies, only one of 756 mothers with gestational thrombocytopenia had an affected infant. Of 1414 hypertensive women with thrombocytopenia, five infants had thrombocytopenia. In contrast, of 46 mothers with ITP, four infants had thrombocytopenia. Finally, alloimmune thrombocytopenia was associated with profound thrombocytopenia and cord platelet counts < 20,000/μL. One of these fetuses died, and two others had intracranial hemorrhage.

Detection of Fetal Thrombocytopenia. Because there are no clinical characteristics or laboratory tests that accurately predict fetal platelet count, direct fetal blood sampling is necessary. Scott and coworkers (1983) obtained intrapartum scalp blood samples and recommended cesarean delivery for fetuses with platelet counts < 50,000/μL. Daffos and colleagues (1985) reported that percutaneous umbilical cord blood sampling (PUBS) had a high complication rate (Chap. 14, p. 300). Conversely, using PUBS, Berry and associates (1997) reported no complications but found a high negative predictive value of low platelet counts. Payne and coworkers (1997) summarized six studies in which fetal blood sampling was done for platelet estimation. Of the total of 195 fetuses, severe neonatal thrombocytopenia—defined as < 50,000/μL—was found in 7 percent. However, there were serious complications from cordocentesis in 4.6 percent. Because of the low incidence of severe neonatal thrombocytopenia and morbidity, fetal platelet determinations and cesarean delivery are not recommended for women with ITP (Neunert, 2011).

Neonatal Alloimmune Thrombocytopenia (NAIT). Disparity between maternal and fetal platelet antigens can stimulate maternal production of antiplatelet antibodies. Such platelet alloimmunization is identical to that caused by red cell antigens (Chap. 15, p. 313).

Thrombocytosis

Also called thrombocythemia, thrombocytosis generally is defined as persistent platelet counts > 450,000/μL. Common causes of secondary or reactive thrombocytosis are iron deficiency, infection, inflammatory diseases, and malignant tumors (Deutsch, 2013). Platelet counts seldom exceed 800,000/μL in these secondary disorders, and prognosis depends on the underlying disease. On the other hand, primary or essential thrombocytosis accounts for most cases in which platelet counts exceed 1 million/μL. It is a clonal disorder frequently due to an acquired mutation in the JAK2 gene (Beer, 2010). Thrombocytosis usually is asymptomatic, but arterial and venous thromboses may develop (Rabinerson, 2007). These cases must be differentiated from the sticky platelet syndrome, which is also associated with thromboses (Rac, 2011). Cortelazzo and colleagues (1995) reported that myelosuppression with hydroxyurea for nonpregnant patients with essential thrombocytosis decreased thrombotic episodes from 24 to 4 percent compared with rates in untreated controls.

Normal pregnancies have been described in women whose mean platelet counts were > 1.25 million/μL (Beard, 1991; Randi, 1994). Others report more adverse outcomes. Niittyvuopio and associates (2004) described 40 pregnancies in 16 women with essential thrombocythemia. Almost
half had a spontaneous abortion, fetal demise, or preeclampsia. In 63 pregnancies in 36 women cared for at the Mayo Clinic, a third had a spontaneous miscarriage, but other pregnancy complications were uncommon (Gangat, 2009). In this observational study, aspirin therapy was associated with a significantly lower abortion rate than that in untreated women—1 versus 75 percent, respectively.

Suggested treatments for thrombocytosis during pregnancy include aspirin, low-molecular-weight heparin, and interferon-α (Finazzi, 2012). Interferon-α therapy during pregnancy was successful in 11 women in the review by Delage and coworkers (1996). One of these women had transient blindness at midpregnancy when her platelet count was 2.3 million/μL. Thrombocytapheresis and interferon-α were used to maintain platelet counts at approximately 1 million/μL until delivery.

Thrombotic Microangiopathies

Although not a proven primary platelet disorder, there almost always is some degree of thrombocytopenia with the thrombotic microangiopathies. Their similarities to the HELLP syndrome allude to their obstetrical ramifications (George, 2013). Moschcowitz (1925) originally described *thrombotic thrombocytopenic purpura (TTP)* by the pentad of thrombocytopenia, fever, neurological abnormalities, renal impairment, and hemolytic anemia. Gasser and colleagues (1955) later described the similar *hemolytic uremic syndrome (HUS)*, which had more profound renal involvement and fewer neurological aberrations. Scully and associates (2012) provided guidelines for the diagnosis and management of thrombotic microangiopathic hemolytic anemias. The syndromes have an incidence of 2 to 6 per million persons per year (Miller, 2004).

Etiopathogenesis

Different causes likely account for the variable findings within these syndromes. Clinically, however, they frequently are indistinguishable in adults. Most cases of TTP are thought to be caused by a plasma deficiency of or antibodies to a von Willebrand factor-cleaving protease termed *ADAMTS-13 (ADAM metallopeptidase with thrombospondin type 1 motif, 13)* (Ganesan, 2011; Sadler, 2010). Conversely, HUS is usually due to endothelial damage incited by viral or bacterial infections and is seen primarily in children (Ardissino, 2013; George, 2013).

The general consensus is that intravascular platelet aggregation stimulates a cascade of events leading to end-organ failure. Although there is endothelial activation and damage, it is unclear whether this is a consequence or a cause. Elevated levels of unusually large multimers of von Willebrand factor are identified with active TTP. The *ADAMTS13* gene encodes the endothelium-derived protease responsible for cleaving von Willebrand factor—vWF (Sadler, 2010). Defects in this gene result in various clinical presentations of thrombotic microangiopathy (Camilleri, 2007; Moake, 2002, 2004). In another scheme, antibodies raised against ADAMTS-13 neutralize its action to cleave vWF multimers during an acute episode. The end result is microthrombi of hyaline material consisting of platelets and small amounts of fibrin develop within arterioles and capillaries. When sufficient in number or size, these aggregates produce ischemia or infarctions in various organs.

Clinical and Laboratory Manifestations

Thrombotic microangiopathies are characterized by thrombocytopenia, fragmentation hemolysis, and variable organ dysfunction. Neurological symptoms develop in up to 50 percent and include headache, altered consciousness, convulsions, fever, or stroke. Because renal involvement is
common, TTP and HUS are difficult to separate clinically. Renal failure is thought to be more severe with the HUS, and in half of the cases, dialysis is required.

Thrombocytopenia is usually severe, but fortunately, even with very low platelet counts, spontaneous severe hemorrhage is uncommon. Microangiopathic hemolysis is associated with moderate to marked anemia, and erythrocyte transfusions are frequently necessary. The blood smear is characterized by erythrocyte fragmentation with schizocytosis. Reticulocytes and nucleated red blood cells are increased, lactate dehydrogenase (LDH) levels are high, and haptoglobin concentrations are decreased. Consumptive coagulopathy, although common, is usually subtle and clinically insignificant.

**Treatment**

The cornerstone of treatment is plasmapheresis with fresh-frozen plasma replacement. Plasma exchange removes inhibitors and replaces the *ADAMTS-13* enzyme (George, 2010; Michael, 2009; Sadler, 2010). This has remarkably improved outcomes with these formerly fatal syndromes. Red cell transfusions are imperative for life-threatening anemia. If there are neurological abnormalities or rapid clinical deterioration, then plasmapheresis and plasma exchange can be performed twice daily. These are usually continued until the platelet count is > 150,000/μL. Unfortunately, relapses are common (Sadler, 2010). Additionally, there may be long-term sequelae such as renal impairment (Dashe, 1998).

**Pregnancy**

As shown in the Appendix (p. 1288), ADAMTS-13 enzyme activity decreases across pregnancy by as much as 50 percent (Sánchez-Luceros, 2004). Levels are decreased even further with the preeclampsia syndrome (Chap. 40, p. 731). This is consonant with prevailing opinions that TTP is more commonly seen during pregnancy. The Parkland Hospital experiences were described by Dashe and coworkers (1998), who identified 11 pregnancies complicated by these syndromes among nearly 275,000 obstetrical patients—a frequency of 1 in 25,000.

It seems likely that the disparately higher incidence in pregnancy reported by others is because of inclusion of women with severe preeclampsia and eclampsia (Hsu, 1995; Magann, 1994). There are differences that allow appropriate diagnosis (Table 56-6). For example, moderate to severe hemolysis is a rather constant feature of thrombotic microangiopathies. This is seldom severe with the preeclampsia syndrome, even when complicated by HELLP syndrome (Chap. 40, p. 742). And, although there is deposition of hyaline microthrombi within the liver with thrombotic microangiopathy, hepatocellular necrosis with elevated serum hepatic aminotransferase levels characteristic of preeclampsia is not a common feature (Ganesan, 2011; Sadler, 2010). Importantly, whereas delivery is imperative to reverse the preeclampsia syndrome in women with the HELLP syndrome, there is no evidence that thrombotic microangiopathy is improved by delivery (Dashe, 1998; Letsky, 2000). Finally, microangiopathic syndromes are usually recurrent and unassociated with pregnancy. For example, seven of 11 women described by Dashe and colleagues (1998) had recurrent disease either when not pregnant or within the first trimester of a subsequent pregnancy. George (2009) reported recurrent TTP in only five of 36 subsequent pregnancies.

Unless the diagnosis is unequivocally one of these thrombotic microangiopathies, rather than severe preeclampsia, the response to pregnancy termination should be evaluated before resorting to plasmapheresis and exchange transfusion, massive-dose glucocorticoid therapy, or other therapy. Unfortunately, recall that determination of ADAMTS-13 enzyme activity may be difficult to interpret if not within the already lower range for normal pregnancy. With HELLP syndrome, enzyme activity levels are much lower and similar to those reported with microangiopathies (Franchini, 2007). It cannot be overemphasized that plasmapheresis is not indicated for preeclampsia-eclampsia complicated by hemolysis and thrombocytopenia.

During the past two decades, and coincidental with plasmapheresis and plasma exchange, maternal survival rates from thrombotic microangiopathy have improved dramatically (Dashe, 1998). Although previously fatal in up to half of mothers, with such treatment, Egerman and coworkers (1996) reported two maternal and three fetal deaths in 11 pregnancies. Hunt and associates (2013) reported that TTP accounted for 1 percent of maternal deaths in the United Kingdom from 2003 to 2008. Finally, a case of sudden maternal death from TTP has been described (Yamamoto, 2013).

### Long-Term Prognosis

Women who are diagnosed with thrombotic microangiopathy during pregnancy are at risk for serious long-term complications. The Parkland experiences included a mean 9-year surveillance period (Dashe, 1998). These women had multiple recurrences; renal disease requiring dialysis,

*Includes thrombotic thrombocytopenia purpura (TTP) and hemolytic uremic syndrome (HUS).

ADAMTS13 = ADAM metalloprotease with thrombospondin type 1 motif, 13; AST = aspartate aminotransferase; ALT = alanine aminotransferase; def. = deficiency; DIC = disseminated intravascular coagulation; HELLP = hemolysis, elevated liver enzymes, and low platelets; Mod. = moderate.
transplantation, or both; severe hypertension; and transfusion-acquired infectious diseases. Two women died remote from pregnancy—one from dialysis complications and one from transfusion-acquired HIV infection. Similar observations were reported by Egerman and colleagues (1996).

There have been reports of persistent cognitive defects and physical disabilities in nonpregnant women who have recovered from thrombotic microangiopathies (Kennedy, 2009; Lewis, 2009). Interestingly, these cognitive defects are very similar to those found in long-term surveillance studies of women who had eclampsia. Aukes (2009, 2012) and Wiegman (2012) and their associates from The Netherlands have documented cognitive and visual defects years following an eclamptic episode as further discussed in Chapter 40 (p. 770).

INHERITED COAGULATION DEFECTS

Hemophilias A and B

Obstetrical hemorrhage may infrequently be the consequence of an inherited defect of a protein that controls coagulation. As examples, both types of hemophilia may be involved. These are dependent on plasma factor levels and are categorized as mild—levels of 6 to 30 percent; moderate—2 to 5 percent; or severe—less than 1 percent (Mannucci, 2001).

Hemophilia A is an X-linked recessively transmitted disease characterized by a marked deficiency of small component antihemophilic factor (factor VIII). It is rare among women compared with men, in whom the heterozygous state is responsible for the disease. Heterozygous women have diminished factor VIII levels, but almost invariably, the homozygous state is the requisite for hemophilia A. In a few instances, it appears in women spontaneously from a newly mutant gene. Pregnancy-associated acquired hemophilia A from antibodies may result in severe morbidity from bleeding (Tengborn, 2012).

Christmas disease or hemophilia B is caused by severe deficiency of factor IX and has genetic and clinical features similar to those of hemophilia A.

Pregnancy

The obstetrical bleeding risk with these is directly related to factor VIII or factor IX levels. Affected women have a range of activity that is determined by random X-chromosome inactivation—lyonization—although activity is expected to average 50 percent (Letsky, 2000). If levels fall below 10 to 20 percent, there is a risk of hemorrhage. If levels fall to near zero, the risks are substantial. Pregnancy does afford some protection, however, because both of these clotting factors increase appreciably during normal pregnancy (Appendix, p. 1288). Treatment with desmopressin may also stimulate factor VIII release. Risks are further reduced by avoiding lacerations, minimizing episiotomy use, and maximizing postpartum uterine contractions. Operative vaginal deliveries should be avoided (Ljung, 1994).

There are few published experiences during pregnancy in women with hemophilia complications. Kadir and coworkers (1997) reported that 20 percent of carriers had postpartum hemorrhage, and in two, it was massive. Guy and associates (1992) reviewed five pregnancies in women with hemophilia B, and in all, outcomes were favorable. They recommended factor IX administration if levels are below 10 percent. Desmopressin has been shown in selected cases to reduce obstetrical bleeding complications (Trigg, 2012).

If a male fetus has hemophilia, the risk of hemorrhage increases after delivery in the neonate.
This is especially true if circumcision is attempted.

**Inheritance**

If a mother has hemophilia A or B, all of her sons will have the disease, and all of her daughters will be carriers. If she is a carrier, half of her sons will inherit the disease, and half of her daughters will be carriers. Prenatal diagnosis of hemophilia is possible in some families using CVS (Chap. 14, p. 300). Preimplantation genetic diagnosis for hemophilia was reviewed by Lavery (2009).

**Factor VIII or IX Inhibitors**

Rarely, antibodies directed against factor VIII or IX are acquired and may lead to life-threatening hemorrhage. Patients with hemophilia A or B, because of prior treatment with factor VIII or IX, more commonly develop such antibodies. In contrast, acquisition of these antibodies in nonhemophiliacs is extraordinary. That said, this phenomenon has been identified rarely in women during the puerperium (Santoro, 2009). The prominent clinical feature is severe, protracted, repetitive hemorrhage from the reproductive tract starting a week or so after an apparently uncomplicated delivery (Reece, 1988). The activated partial thromboplastin time is markedly prolonged. Treatment has included multiple transfusions of whole blood and plasma; huge doses of cryoprecipitate; large volumes of an admixture of activated coagulation factors, including porcine factor VIII; immunosuppressive therapy; and attempts at various surgical procedures, especially curettage and hysterectomy. Another treatment involves bypassing factor VIII or IX by the use of activated forms of factors VII, IX, and X. A recombinant activated factor VII (NovoSeven) stop bleeding in up to 75 percent of patients with these inhibitors (Mannucci, 2001). As discussed in Chapter 41 (p. 817), NovoSeven has also been used in nonhemophiliac patients in cases of intractable obstetrical hemorrhage caused by uterine atony and by dilutional effects of multiple transfusions.

**Von Willebrand Disease**

There are at least 20 heterogeneous clinical disorders involving aberrations of factor VIII complex and platelet dysfunction—collectively termed *von Willebrand disease* (vWD). These abnormalities are the most commonly inherited bleeding disorders, and their prevalence is as high as 1 to 2 percent (Mannucci, 2004; Pacheco, 2010). Most von Willebrand variants are inherited as autosomal dominant traits, and types I and II are the most common. Type III, which is the most severe, is a recessive trait (Nichols, 2008).

Although far less common than inherited von Willebrand disease, acquired disorders have been described. These are stimulated by underlying conditions such as benign and malignant hematological diseases, solid tumors, autoimmune disorders, and medications such as ciprofloxacin (Shau, 2002). Although most cases of acquired vWD develop after age 50 years, some have been reported in pregnant women (Lipkind, 2005).

**Pathogenesis**

The *von Willebrand factor* is a series of large plasma multimeric glycoproteins that form part of the factor VIII complex. It is essential for normal platelet adhesion to subendothelial collagen and formation of a primary hemostatic plug at the site of blood vessel injury. It also plays a major role in stabilizing the coagulant properties of factor VIII. The procoagulant component is the
antihemophilic factor or factor VIII, which is a glycoprotein synthesized by the liver. Conversely, von Willebrand precursor, which is present in platelets and plasma, is synthesized by endothelium and megakaryocytes under the control of autosomal genes on chromosome 12. The von Willebrand factor antigen (vWF:Ag) is the antigenic determinant measured by immunoassays.

Clinical Presentation

Symptomatic patients usually present with bleeding suggestive of a chronic coagulation disorder. The classic autosomal dominant form usually causes symptoms in the heterozygous state. The less common but clinically more severe autosomal recessive form is manifest when inherited from both parents, who typically demonstrate little or no disease. Type I, which accounts for 75 percent of von Willebrand variants, is characterized by easy bruising; epistaxis; mucosal hemorrhage; and excessive bleeding with trauma, including surgery. Its laboratory features are usually a prolonged bleeding time, prolonged partial thromboplastin time, decreased vWF antigen levels, decreased factor VIII immunological and coagulation-promoting activity, and inability of platelets from an affected person to react to various stimuli.

Pregnancy

During normal pregnancy, maternal levels of both factor VIII and vWF antigen increase substantially (Appendix, p. 1288). Because of this, pregnant women with vWD often develop normal levels of factor VIII coagulant activity and vWF antigen, although the bleeding time still may be prolonged. If factor VIII activity is very low or if there is bleeding, treatment is recommended. Desmopressin by infusion may transiently increase factor VIII and vWF levels especially in patients with type I disease (Kujovich, 2005; Mannucci, 2004). With significant bleeding, 15 or 20 units of cryoprecipitate are given every 12 hours. Alternatively, factor VIII concentrates may be given that contain high-molecular-weight vWF multimers (Alfamune, Hemate-P). These concentrates are highly purified and are heat treated to destroy HIV. Lubetsky and colleagues (1999) described continuous infusion with Hemate-P in a woman during a vaginal delivery. According to Chi and coworkers (2009), conduction analgesia can be given safely if coagulation defects have normalized or if hemostatic agents are given prophylactically.

Pregnancy outcomes in women with von Willebrand disease are generally good, but postpartum hemorrhage is encountered in up to 50 percent of cases. Of 38 cases summarized by Conti and associates (1986), bleeding was reported with abortion, with delivery, or in the puerperium in a fourth. Greer and colleagues (1991) noted that eight of 14 pregnancies were complicated by postpartum hemorrhage. Kadir and coworkers (1998) reported their experiences with 84 pregnancies. They described a 20-percent incidence of immediate postpartum hemorrhage and another 20-percent incidence of late hemorrhage. Most cases were associated with low vWF levels in untreated women, and none given treatment peripartum had hemorrhage. In our experiences, levels of coagulant factors within the normal range do not always protect against such bleeding.

Inheritance

Although most patients with von Willebrand disease have heterozygous variants and associated minor bleeding complications, the disease can be severe. Moreover, homozygous offspring develop a serious clotting dysfunction. CVS with DNA analysis to detect the missing genes has been described. Some authorities recommend cesarean delivery to avoid trauma to a possibly affected fetus if the mother has severe disease.
Other Factor Deficiencies

In general, the activity of most procoagulant factors increases across pregnancy (Appendix, p. 1288). In addition to the hemophilias, there are other inherited deficiencies of these factors that may cause a coagulopathy.

**Factor VII deficiency** is a rare autosomal recessive disorder. Levels of this factor normally increase during pregnancy, but these may rise only mildly in women with factor VII deficiency (Fadel, 1989). A systematic review of 94 births found no difference in postpartum hemorrhage rates with or without prophylaxis with recombinant factor VIIa (Baumann Kreuziger, 2013).

**Factor X or Stuart-Prower factor** deficiency is rare and is inherited as an autosomal recessive trait. Factor X levels typically rise by 50 percent during normal pregnancy. Konje and colleagues (1994) described a woman who had 2-percent factor activity. She was given prophylactic treatment with plasma-derived factor X, which raised her plasma levels to 37 percent. Despite this, she suffered an intrapartum placental abruption. Bofill and coworkers (1996) gave intrapartum fresh-frozen plasma to a woman with less than 1-percent factor X activity. She delivered spontaneously without incident. Beksaç and associates (2010) described a woman with severe factor X deficiency who was successfully managed with prophylactic prothrombin complex concentrate. Nance and colleagues (2012) reported on 24 pregnancies, of which 18 resulted in a healthy baby. However, the authors found a 2.5-fold increased risk of preterm birth.

**Factor XI—plasma thromboplastin antecedent—deficiency** is inherited as an autosomal trait. It is manifest as severe disease in homozygotes but only as a minor defect in heterozygotes. It is most prevalent in Ashkenazi Jews and is rarely seen in pregnancy. Musclow and coworkers (1987) reported 41 deliveries in 17 affected women, and none required transfusion. They also described a woman who developed a spontaneous hemarthrosis at 39 weeks. Kadir and associates (1998) analyzed 29 pregnancies in 11 affected women. None of these had factor XI level increases; 15 percent had immediate postpartum hemorrhage; and another 25 percent had delayed hemorrhage. In 105 pregnancies from 33 affected women, Myers and colleagues (2007) reported an uneventful pregnancy and delivery in 70 percent. They recommended peripartum treatment with factor XI concentrate if cesarean delivery is performed and advised against epidural analgesia unless factor XI is given. From their review, Martin-Salces and associates (2010) found that there was poor correlation between factor XI levels and bleeding in women with severe deficiency.

**Factor XII deficiency** is another autosomal recessive disorder that rarely complicates pregnancy. An increased incidence of thromboembolism is encountered in nonpregnant patients with this deficiency. Lao and coworkers (1991) reported an affected pregnant woman in whom placental abruption developed at 26 weeks’ gestation.

**Factor XIII deficiency** is an autosomal recessive trait and may be associated with maternal intracranial hemorrhage (Letsky, 2000). In their review, Kadir and associates (2009) cited an increased risk of recurrent miscarriage and placental abruption. It has also been reported to cause umbilical cord bleeding (Odame, 2014). Treatment is fresh frozen plasma. Naderi and colleagues (2012) described 17 successful pregnancies in women receiving weekly prophylaxis with FXIII concentrate.

Fibrinogen abnormalities—either qualitative or quantitative—also may cause coagulation abnormalities. Autosomally inherited abnormalities usually involve the formation of a functionally defective fibrinogen—commonly referred to as dysfibrinogenemia (Edwards, 2000). Familial hypofibrinogenemia and sometimes afibrinogenemia are infrequent recessive disorders. In some cases, both are found—hypodysfibrinogenemia (Deering, 2003). Our experience suggests that hypofibrinogenemia represents a heterozygous autosomal dominant state. Typically, the thrombin-
clottable protein level in these patients ranges from 80 to 110 mg/dL when nonpregnant, and this increases by 40 or 50 percent in normal pregnancy. Those pregnancy complications that give rise to acquired hypofibrinogenemia, for example, placental abruption, are more common with fibrinogen deficiency. Trehan and Fergusson (1991) and Funai and coworkers (1997) described successful outcomes in two affected women in whom fibrinogen or plasma infusions were given weekly or biweekly throughout pregnancy.

Conduction Analgesia with Bleeding Disorders

Most serious bleeding disorders would logically preclude the use of epidural or spinal analgesia for labor or delivery. If the bleeding disorder is controlled, however, conduction analgesia may be considered. Chi and colleagues (2009) reviewed intrapartum outcomes in 80 pregnancies in 63 women with an inherited bleeding disorder. These included those with factor XI deficiency, hemophilia carrier status, von Willebrand disease, platelet disorders, or a deficiency of factor VII, XI, or X. Regional block was used in 41. Of these, 35 had spontaneously normalized hemostatic dysfunction, and others were given prophylactic replacement therapy. The reviewers encountered no unusual complications and concluded that such practices were safe. Singh and associates (2009) reviewed 13 women with factor XI deficiency. Nine received neuraxial analgesia without complications, but only after fresh-frozen plasma was given to most to correct the activated partial thromboplastin time.

THROMBOPHILIAS

Several important regulatory proteins inhibit clotting. There are physiological antithrombotic proteins that act as inhibitors at strategic sites in the coagulation cascade to maintain blood fluidity. Inherited deficiencies of these inhibitory proteins are caused by gene mutations. Because they may be associated with recurrent thromboembolism, they are collectively referred to as thrombophilias. Because these deficiencies may be associated with thromboembolism, they are discussed in Chapter 52 (p. 1029), and they have been recently reviewed by the American College of Obstetricians and Gynecologists (2013d).

According to the National Center for Health Statistics (2013), the number of adults diagnosed with diabetes in the United States has tripled from 6.9 million in 1991 to 20.9 million in 2011. Astoundingly, the Centers for Disease Control and Prevention (2010) have estimated that the number of Americans with diabetes will range from 1 in 3 to 1 in 5 by 2050. Reasons for this rise include an aging population more likely to develop type 2 diabetes, increases in minority groups at particular risk for type 2 diabetes, and dramatic increases in obesity—also referred to as diabesity. This term reflects the strong relationship of diabetes with the current obesity epidemic in the United States and underlines the critical need for diet and lifestyle interventions to change the trajectory of both.

There is keen interest in events that precede diabetes, and this includes the uterine environment, where early imprinting is believed to have effects later in life (Saudek, 2002). For example, in utero exposure to maternal hyperglycemia leads to fetal hyperinsulinemia, causing an increase in fetal fat cells. This leads to obesity and insulin resistance in childhood (Feig, 2002). This in turn leads to impaired glucose tolerance and diabetes in adulthood. This cycle of fetal exposure to diabetes leading to childhood obesity and glucose intolerance has been reported in Pima Indians and a heterogeneous Chicago population (Silverman, 1995).
In nonpregnant individuals, the type of diabetes is based on its presumed etiopathogenesis and its pathophysiological manifestations. Absolute insulin deficiency characterizes type 1 diabetes. In contrast, defective insulin secretion, insulin resistance, or increased glucose production characterizes type 2 diabetes (Table 57-1). Both types are generally preceded by a period of abnormal glucose homeostasis. The terms insulin-dependent diabetes mellitus (IDDM) and noninsulin-dependent diabetes mellitus (NIDDM) are now obsolete. Pancreatic β-cell destruction can begin at any age, but type 1 diabetes is clinically apparent most often before age 30. Type 2 diabetes usually develops with advancing age but is increasingly identified in younger obese adolescents.

### Classification During Pregnancy

Diabetes is the most common medical complication of pregnancy. Women can be separated into those who were known to have diabetes before pregnancy—pregestational or overt, and those diagnosed during pregnancy—gestational diabetes. The incidence of diabetes complicating pregnancy increased approximately 40 percent between 1989 and 2004 (Getahun, 2008). In 2006, slightly more than 179,000—4.2 percent—of American women had pregnancies coexistent with some form of diabetes (Martin, 2009). African American, Native American, Asian, and Hispanic women are at higher risk for gestational diabetes compared with white women (Ferrara, 2007). The increasing incidence of gestational diabetes during the past 15 years, shown in Figure 57-1, is reminiscent of similar statistics for obesity (Chap. 48, p. 961).
White Classification in Pregnancy

Until the mid-1990s, the classification by Priscilla White for diabetic pregnant women was the linchpin of management. Today, the White classification is used less frequently, but its role remains important. And because most currently cited literature contains data from these older classifications, the one previously recommended by the American College of Obstetricians and Gynecologists (1986) is provided in Table 57-2.

| Table 57-2. Classification Scheme Used from 1986 through 1994 for Diabetes Complicating Pregnancy |
Beginning several years ago, the American College of Obstetricians and Gynecologists (2012, 2013) no longer recommended the White classification. Instead, the current focus is whether diabetes antedates pregnancy or is first diagnosed during pregnancy. Many now recommend adoption of the classification proposed by the American Diabetes Association (ADA), as shown in Table 57-3.

<sup>a</sup>When diagnosed during pregnancy: proteinuria ≥ 500 mg/24 hr before 20 weeks’ gestation.

The increasing prevalence of type 2 diabetes in general, and in younger people in particular, has
led to an increasing number of affected pregnancies (Ferrara, 2007). In Los Angeles County, Baraban and coworkers (2008) reported that the age-adjusted prevalence tripled from 14.5 cases per 1000 women in 1991 to 47.9 cases per 1000 in 2003. Thus, the number of pregnant women with diabetes that was undiagnosed before pregnancy is increasing. Many women found to have gestational diabetes are likely to have type 2 diabetes that has previously gone undiagnosed (Feig, 2002). In fact, 5 to 10 percent of women with gestational diabetes are found to have diabetes immediately after pregnancy.

**Diagnosis**

Women with high plasma glucose levels, glucosuria, and ketoacidosis present no problem in diagnosis. Similarly, women with a random plasma glucose level > 200 mg/dL plus classic signs and symptoms such as polydipsia, polyuria, and unexplained weight loss or those with a fasting glucose level exceeding 125 mg/dL are considered by the ADA (2012) to have overt diabetes. Women with only minimal metabolic derangement may be more difficult to identify. To diagnose overt diabetes in pregnancy, The International Association of Diabetes and Pregnancy Study Groups (IADPSG) Consensus Panel (2010) recommends threshold values for fasting or random plasma glucose and glycosylated hemoglobin (A1c) levels at prenatal care initiation (Table 57-4). There was no consensus on whether such testing should be universal or limited to those women classified as high risk. Regardless, the tentative diagnosis of overt diabetes during pregnancy based on these thresholds should be confirmed postpartum. Risk factors for impaired carbohydrate metabolism in pregnant women include a strong familial history of diabetes, prior delivery of a large newborn, persistent glucosuria, or unexplained fetal losses.

*Apply to women without known diabetes antedating pregnancy. The decision to perform blood testing for evaluation of glycemia on all pregnant women or only on women with characteristics indicating a high risk for diabetes is based on the background frequency of abnormal glucose metabolism in the population and on local circumstances. Modified from International Association of Diabetes and Pregnancy Study Groups Consensus Panel, 2010.*
Impact on Pregnancy

With pregestational—or overt—diabetes, the embryo, fetus, and mother frequently experience serious complications directly attributable to diabetes. The likelihood of successful outcomes with overt diabetes is related somewhat to the degree of glycemic control, but more importantly, to the degree of underlying cardiovascular or renal disease. Thus, advancing stages of the White classification, seen in Table 57-2, are inversely related to favorable pregnancy outcomes. As an example shown in Table 57-5, data from Yang and associates (2006) chronicles the deleterious pregnancy outcomes of overt diabetes. These maternal and fetal complications are described in the following sections.

### Fetal Effects

**Spontaneous Abortion.** Several studies have shown that early miscarriage is associated with poor glycemic control. In 215 women with type 1 diabetes enrolled for prenatal care before 9 weeks’ gestation, 24 percent had an early pregnancy loss (Rosenn, 1994). Only those whose initial glycohemoglobin \( \text{A}_{1c} \) concentrations were > 12 percent or whose preprandial glucose concentrations were persistently > 120 mg/dL were at increased risk. In another analysis of 127 Spanish women with pregestational diabetes, poor glycemic control, defined by glycohemoglobin \( \text{A}_{1c} \) concentrations > 7 percent, was associated with a threefold increase in the spontaneous abortion rate (Galindo, 2006).

**Preterm Delivery.** Overt diabetes is an undisputed risk factor for preterm birth. Eidem and associates (2011) analyzed 1307 births in women with pregestational type 1 diabetes from the Norwegian Medical Birth Registry. More than 26 percent were delivered preterm compared with 6.8 percent in the general obstetrical population. Moreover, almost 60 percent were indicated preterm births, that is, due to obstetrical or medical complications. In the Canadian study shown in
Table 57-5, the incidence of preterm birth was 28 percent—a fivefold increase compared with that of their normal population.

**Malformations.** The incidence of major malformations in women with type 1 diabetes is doubled and approximates 5 percent (Eidem, 2010; Sheffield, 2002). These account for almost half of perinatal deaths in diabetic pregnancies. A twofold increased risk of major congenital defects in Norwegian women with pregestational type 1 diabetes included cardiovascular malformations that accounted for more than half of the anomalies (Table 57-6). In the National Birth Defects Prevention Study, the risk of an isolated cardiac defect was fourfold higher in women with pregestational diabetes compared with the twofold increased risk of noncardiac defects (Correa, 2008). The caudal regression sequence is a rare malformation frequently associated with maternal diabetes (Garne, 2012).

CNS = central nervous system.
Data from Eidem, 2010.

Poorly controlled diabetes, both preconceptionally and early in pregnancy, is thought to underlie this increased severe-malformation risk. As shown in Figure 57-2, Galindo and colleagues (2006) demonstrated a clear correlation between increased maternal glycohemoglobin A1c at first prenatal visit and major malformations. Eriksson (2009) concluded that the etiology was multifactorial. At least three interrelated molecular chain reactions have been linked to maternal hyperglycemia and can potentially explain the mechanism behind poor glycemic control and increased risk for major malformations (Reece, 2012). These include alterations in cellular lipid metabolism, excess production of toxic superoxide radicals, and activation of programmed cell death. For example, Morgan and associates (2008) demonstrated that hyperglycemia-induced oxidative stress inhibited migration of cardiac neural-crest cells in embryos of diabetic mice.
**Altered Fetal Growth.** Diminished growth may result from congenital malformations or from substrate deprivation due to advanced maternal vascular disease. However, fetal overgrowth is more typical of pregestational diabetes. Maternal hyperglycemia prompts fetal hyperinsulinemia, particularly during the second half of gestation. This in turn stimulates excessive somatic growth or macrosomia. Except for the brain, most fetal organs are affected by the macrosomia that characterizes the fetus of a diabetic woman. Such infants are described as being anthropometrically different from other large-for-gestational age (LGA) infants (Durnwald, 2004; McFarland, 2000). Specifically, those whose mothers are diabetic have excessive fat deposition on the shoulders and trunk, which predisposes to shoulder dystocia or cesarean delivery (Fig. 57-3).
The incidence of macrosomia rises significantly when mean maternal blood glucose concentrations chronically exceed 130 mg/dL (Hay, 2012). Hammoud and coworkers (2013) reported that the macrosomia rates for Nordic women with type 1, type 2, or gestational diabetes were 35 percent, 28 percent, and 24 percent, respectively. As shown in Figure 57-4, the birthweight distribution of neonates of diabetic mothers is skewed toward consistently heavier birthweights compared with that of normal pregnancies.
In the study by Hammoud and colleagues (2013), fetal growth profiles from 897 sonographic examinations in 244 women with diabetes were compared with 843 examinations in 145 control women. The abdominal circumference evolved differently in the diabetic groups. Analysis of head circumference/abdominal circumference (HC/AC) ratios shows that this disproportionate growth occurs mainly in diabetic pregnancies that ultimately yield macrosomic newborns (Fig. 57-5). These findings comport with the observation that virtually all neonates of diabetic mothers are growth promoted. Ben-Haroush and associates (2007) analyzed fetal sonographic measurements between 29 and 34 weeks’ gestation in 423 diabetic pregnancies and found that accelerated fetal growth was particularly evident in women with poor glycemic control.
FIGURE 57-5 Comparison of sonographic fetal anatomic measurements by gestational age and subdivided according to presence or absence of macrosomia among women with various types of diabetes types and controls. A. Abdominal circumference measurements. B. Head circumference (HC)/Abdominal circumference (AC) ratio. DM = diabetes mellitus; GDM = gestational diabetes mellitus. (Redrawn from Hammoud, 2013, with permission.)

Unexplained Fetal Demise. The risk of fetal death is three to four times higher in women with type 1 diabetes compared with that of the general obstetrical population (Eidem, 2011). Stillbirth without an identifiable cause is a phenomenon relatively limited to pregnancies complicated by overt diabetes. These stillbirths are “unexplained” because common factors such as obvious placental insufficiency, abruption, fetal-growth restriction, or oligohydramnios are not identified. These infants are typically LGA and die before labor, usually after 35 weeks’ gestation or later (Garner, 1995).

These unexplained stillbirths are associated with poor glycemic control. Lauenborg and
coworkers (2003) identified suboptimal glycemic control in two thirds of unexplained stillbirths between 1990 and 2000. Also, fetuses of diabetic mothers often have elevated lactic acid levels. Salvesen and colleagues (1992, 1993) analyzed fetal blood samples and reported that mean umbilical venous blood pH was lower in diabetic pregnancies and was significantly related to fetal insulin levels. Such findings support the hypothesis that hyperglycemia-mediated chronic aberrations in oxygen and fetal metabolite transport may underlie these unexplained fetal deaths (Pedersen, 1977). However, the exact mechanisms by which uncontrolled hyperglycemia leads to elevated lactic acid levels and fetal acidosis remain unclear.

Explicable stillbirths due to placental insufficiency also occur with increased frequency in women with overt diabetes, usually in association with severe preeclampsia. In a retrospective analysis of more than 500,000 singleton deliveries, Yanit and associates (2012) found that the fetal death risk was sevenfold higher in women with hypertension and pregestational diabetes compared with the threefold increased risk associated with diabetes alone. Stillbirth is also increased in women with advanced diabetes and vascular complications. Maternal ketoacidosis can also cause fetal death.

**Hydramnios.** Diabetic pregnancies are often complicated by excess amniotic fluid. According to Idris and coworkers (2010), 18 percent of 314 women with pregestational diabetes were identified with hydramnios, defined as an amniotic fluid index (AFI) greater than 24 cm in the third trimester. A likely—albeit unproven—explanation is that fetal hyperglycemia causes polyuria (Chap. 11, p. 234). In a study from Parkland Hospital, Dashe and colleagues (2000) found that the AFI parallels the amniotic fluid glucose level among women with diabetes. This finding suggests that the hydramnios associated with diabetes is a result of increased amniotic fluid glucose concentration. Further support for this hypothesis was provided by Vink and associates (2006), who linked poor maternal glucose control to macrosomia and hydramnios. In their retrospective analysis of diabetic pregnancies, Idris and coworkers (2010) also found that women with elevated glycohemoglobin A₁c values in the third trimester were more likely to have hydramnios.

**Neonatal Effects.** Before tests of fetal health and maturity became available, delivery before term was deliberately selected for women with diabetes to avoid unexplained fetal death. Although this practice has been abandoned, there is still an increased frequency of preterm delivery in women with diabetes. Most are due to advanced diabetes with superimposed preeclampsia. Thankfully, modern neonatal care has largely eliminated neonatal deaths due to immaturity. Conversely, neonatal morbidity due to preterm birth continues to be a serious consequence.

**Respiratory Distress Syndrome.** Historically, newborns of diabetic mothers were thought to be at increased risk for respiratory distress from delayed lung maturation. Subsequent observations challenged this concept, and gestational age rather than overt diabetes is likely the most significant factor associated with respiratory distress syndrome. Indeed, in their analysis of 19,399 very-low-birthweight neonates delivered between 24 and 33 weeks’ gestation, Bental and colleagues (2011) were unable to demonstrate an increased rate of respiratory distress syndrome in newborns of diabetic mothers. This is discussed further in Chapter 33 (p. 637).

**Hypoglycemia.** Newborns of a diabetic mother experience a rapid drop in plasma glucose concentration after delivery. This is attributed to hyperplasia of the fetal β-islet cells induced by chronic maternal hyperglycemia. Low glucose concentrations—defined as < 45 mg/dL—are particularly common in newborns of women with unstable glucose concentrations during labor (Persson, 2009). In a recent analysis of prenatal outcomes during a 20-year period in Finnist
women with type 1 diabetes, the incidence of neonatal hypoglycemia declined significantly over time (Klemetti, 2012). The authors attributed this to frequent blood glucose measurements and active early feeding practices in such neonates. Prompt recognition and treatment of the hypoglycemic newborn minimizes adverse sequelae.

**Hypocalcemia.** Defined as a total serum calcium concentration < 8 mg/dL in term newborns, hypocalcemia is one of the potential metabolic derangements in neonates of diabetic mothers. Its cause has not been explained. Theories include aberrations in magnesium–calcium economy, asphyxia, and preterm birth. In a randomized study by DeMarini and associates (1994), 137 pregnant women with type 1 diabetes were managed with strict versus customary glucose control. Almost a third of neonates in the customary control group developed hypocalcemia compared with only 18 percent of those in the strict control group.

**Hyperbilirubinemia and Polycythemia.** The pathogenesis of hyperbilirubinemia in neonates of diabetic mothers is uncertain. A major contributing factor is newborn polycythemia, which increases the bilirubin load (Chap. 33, p. 643). Polycythemia is thought to be a fetal response to relative hypoxia. According to Hay (2012), the sources of this fetal hypoxia are hyperglycemia-mediated increases in maternal affinity for oxygen and fetal oxygen consumption. Together with insulin-like growth factors, this hypoxia leads to increased fetal erythropoietin levels and red cell production. Venous hematocrits of 65 to 70 volume percent have been observed in up to 40 percent of these newborns (Salvesen, 1992). Renal vein thrombosis is reported to result from polycythemia.

**Cardiomyopathy.** Infants of diabetic pregnancies may have hypertrophic cardiomyopathy that primarily affects the interventricular septum (Rolo, 2011). In severe cases, this cardiomyopathy may lead to obstructive cardiac failure. Russell and coworkers (2008) performed serial echocardiograms on fetuses of 26 women with pregestational diabetes. In the first trimester, fetal diastolic dysfunction was evident compared with that of nondiabetic controls. In the third trimester, the fetal interventricular septum and right ventricular wall were thicker in fetuses of diabetic mothers. The authors concluded that cardiac dysfunction precedes these structural changes. Fortunately, most affected newborns are asymptomatic following birth, and hypertrophy resolves in the months after delivery. Relief from maternal hyperglycemia is presumed to promote this resolution (Hornberger, 2006). Conversely, fetal cardiomyopathy may progress to adult cardiac disease.

**Long-Term Cognitive Development.** Intrauterine metabolic conditions have long been linked to neurodevelopment in offspring. This may also be true in children of diabetic mothers. Despite rigorous antepartum management, Rizzo and colleagues (1995) found numerous correlations between maternal glycemia and intellectual performance in children up to age 11 years in 139 offspring of diabetic women. In a study of more than 700,000 Swedish-born men, the intelligence quotient of those whose mothers had diabetes during pregnancy averaged 1 to 2 points lower (Fraser, 2014). DeBoer and associates (2005) demonstrated impaired memory performance in infants of diabetic mothers at age 1 year. Finally, results from the Childhood Autism Risks from Genetics and the Environment (CHARGE) study indicated that autism spectrum disorders or developmental delay were more common in children of diabetic women (Krakowiak, 2012). Although interpreting effects of the intrauterine environment on neurodevelopment is certainly confounded by postnatal events, emerging data at least support a link between maternal diabetes, glycemic control, and neurocognitive outcome.
Inheritance of Diabetes. The risk of developing type 1 diabetes if either parent is affected is 3 to 4 percent. Type 2 diabetes has a much stronger genetic component. If both parents have type 2 diabetes, the risk of developing it approaches 40 percent. McKinney and coworkers (1999) studied 196 children with type 1 diabetes and found that older maternal age and maternal type 1 diabetes are important risk factors. Plagemann and colleagues (2002) have implicated breast feeding by diabetic mothers in the genesis of childhood diabetes. Conversely, breast feeding has also been associated with a reduced risk of type 2 diabetes (Owen, 2006). The Trial to Reduce Insulin-dependent Diabetes Mellitus in the Genetically At Risk (TRIGR) was designed to analyze hydrolyzed formula use, rather than breast milk, to reduce rates of type 1 diabetes in at-risk children by age 10. This study will be complete in 2017 (Knip, 2011).

Maternal Effects

Diabetes and pregnancy interact significantly such that maternal welfare can be seriously jeopardized. With the possible exception of diabetic retinopathy, however, the long-term course of diabetes is not affected by pregnancy.

Maternal death is uncommon, but rates in women with diabetes are still increased. In an analysis of 972 women with type 1 diabetes, Leinonen and associates (2001) reported a maternal mortality rate of 0.5 percent. Deaths resulted from diabetic ketoacidosis, hypoglycemia, hypertension, and infection. Especially morbid is ischemic heart disease. Pombar and coworkers (1995) reviewed 17 women with coronary artery disease—class H diabetes—and reported that only half survived pregnancy.

Preeclampsia. Hypertension that is induced or exacerbated by pregnancy is the complication that most often forces preterm delivery in diabetic women. The incidence of chronic and gestational hypertension—and especially preeclampsia—is remarkably increased in diabetic mothers. In the study cited earlier by Yanit and colleagues (2012), preeclampsia developed three to four times more often in women with overt diabetes. Moreover, those diabetics with coexistent chronic hypertension were almost 12 times more likely to develop preeclampsia. Special risk factors for preeclampsia include any vascular complication and preexisting proteinuria, with or without chronic hypertension. As shown in Figure 57-6, women with type 1 diabetes who are in more advanced White classes of overt diabetes increasingly developed preeclampsia. This increasing risk with duration of diabetes may be related to oxidative stress, which plays a key role in the pathogenesis of diabetic complications and preeclampsia. With this in mind, the Diabetes and Preeclampsia Intervention Trial (DAPIT) randomly assigned 762 women with type 1 diabetes to antioxidant vitamin C and E supplementation or placebo in the first half of pregnancy (McCance, 2010). There were no differences in preeclampsia rates except in a few women with a low antioxidant status at baseline. Temple and coworkers (2006) prospectively studied hemoglobin A\textsubscript{1c} levels at 24 weeks’ gestation in 290 women with type 1 diabetes and found that preeclampsia was related to glucose control. Management of preeclampsia is discussed in Chapter 40 (p. 749).
Diabetic Nephropathy. Diabetes is the leading cause of end-stage renal disease in the United States (Chap. 53, p. 1060). Clinically detectable nephropathy begins with microalbuminuria—30 to 300 mg/24 hours. This may manifest as early as 5 years after diabetes onset. Macroalbuminuria—more than 300 mg/24 hours—develops in patients destined to have end-stage renal disease. Hypertension almost invariably develops during this period, and renal failure ensues typically in the next 5 to 10 years. The incidence of overt proteinuria is nearly 30 percent in individuals with type 1 diabetes and ranges from 4 to 20 percent in those with type 2 diabetes (Reutens, 2013). Progression from microalbuminuria is not inexorable, and regression is common. Presumably from improved glucose control, the incidence of nephropathy in individuals with type 1 diabetes has declined in the past few decades. Investigators for the Diabetes Control and Complications Trial (2002) reported that there was a 25-percent decrease in the rate of nephropathy for each 10-percent decrease in hemoglobin A$_1c$ levels.

Approximately 5 percent of pregnant women with diabetes already have renal involvement. Approximately 40 percent of these will develop preeclampsia (Vidaeff, 2008). High rates are also illustrated in Figure 57-6. However, this may not be the case with microproteinuria. In one analysis of 460 women, How and colleagues (2004) found no association between preeclampsia and microproteinuria. Nevertheless, they found that chronic hypertension with overt diabetic nephropathy increased the risk of preeclampsia to 60 percent.

In general, pregnancy does not appear to worsen diabetic nephropathy. In their prospective study of 43 women with diabetes, Young and associates (2012) could not demonstrate diabetic nephropathy progression through 12 months after delivery. Most of these women had only mild renal impairment. Conversely, pregnancy in women with moderate to severe renal impairment may accelerate progression of their disease (Vidaeff, 2008). As in women with glomerulopathies, hypertension or substantial proteinuria before or during pregnancy is a major predictive factor for progression to renal failure in women with diabetic nephropathy (Chap. 53, p. 1062).

Diabetic Retinopathy. Retinal vasculopathy is a highly specific complication of both type 1 and type 2 diabetes. In the United States, diabetic retinopathy is the most important cause of visual
impairment in persons younger than age 60 years (Frank, 2004). The first and most common visible lesions are small microaneurysms followed by blot hemorrhages that form when erythrocytes escape from the aneurysms. These areas leak serous fluid that creates hard exudates. Such features are termed benign or background or nonproliferative retinopathy. With increasingly severe retinopathy, the abnormal vessels of background eye disease become occluded, leading to retinal ischemia and infarctions that appear as cotton wool exudates. These are considered preproliferative retinopathy. In response to ischemia, there is neovascularization on the retinal surface and out into the vitreous cavity. Vision is obscured when there is hemorrhage. Laser photocoagulation before hemorrhage, as shown in Figure 57-7, reduces the rate of visual loss progression and blindness by half. The procedure is performed during pregnancy when indicated.
Vestgaard and coworkers (2010) reported that almost two thirds of 102 pregnant women with type 1 diabetes examined by 8 weeks' gestation had background retinal changes, proliferative retinopathy, or macular edema. A fourth of these women developed progression of retinopathy in at least one eye. The same group of investigators evaluated 80 type 2 diabetics and identified
retinopathy, mostly mild, in 14 percent during early pregnancy. Progression was identified in only 14 percent (Rasmussen, 2010). This complication is believed to be a rare example of a long-term adverse effect of pregnancy. However, in a prospective postpartum 5-year surveillance of 59 type 1 diabetic women, Arun and Taylor (2008) found that baseline retinopathy was the only independent risk factor for progression.

Other risk factors that have been associated with progression of retinopathy include hypertension, higher levels of insulin-like growth factor-I, and macular edema identified in early pregnancy (Bargiota, 2011; Mathiesen, 2012; Ringholm, 2011; Vestgaard, 2010). The National Institute for Health and Clinical Excellence (2008) established guidelines recommending that pregnant women with preexisting diabetes should routinely be offered retinal assessment after the first prenatal visit. Currently, most agree that laser photocoagulation and good glycemic control during pregnancy minimize the potential for deleterious effects of pregnancy.

Ironically, “acute” rigorous metabolic control during pregnancy has been linked to acute worsening of retinopathy. In a study of 201 women with retinopathy, McElvy and associates (2001) found that almost 30 percent suffered eye disease progression during pregnancy despite intensive glucose control. That said, Wang and coworkers (1993) have observed that retinopathy worsened during the critical months of rigorous glucose control, but long term, deterioration of eye disease slowed. In their study mentioned above, Arun and Taylor (2008) found that only four women required laser photocoagulation during pregnancy, and none required laser in the next 5 years.

Diabetic Neuropathy. Peripheral symmetrical sensorimotor diabetic neuropathy is uncommon in pregnant women. But a form of this, known as diabetic gastropathy, is troublesome during pregnancy. It causes nausea and vomiting, nutritional problems, and difficulty with glucose control. Women with gastroparesis should be advised that this complication is associated with a high risk of morbidity and poor perinatal outcome (Kitzmiller, 2008). Treatment with metoclopramide and H₂-receptor antagonists is sometimes successful. Hyperemesis gravidarum is further discussed in Chapter 54 (p. 1070).

Diabetic Ketoacidosis. This serious complication develops in approximately 1 percent of diabetic pregnancies (Hawthorne, 2011). It is most often encountered in women with type 1 diabetes. It is increasingly being reported in women with type 2 or even those with gestational diabetes (Sibai, 2014). Diabetic ketoacidosis (DKA) may develop with hyperemesis gravidarum, β-mimetic drugs given for tocolysis, infection, and corticosteroids given to induce fetal lung maturation. DKA results from an insulin deficiency combined with an excess in counter-regulatory hormones such as glucagon. This leads to gluconeogenesis and ketone body formation. The ketone body β-hydroxybutyrate is synthesized at a much greater rate than acetoacetate, which is preferentially detected by commonly used ketosis detection methodologies. Therefore, serum or plasma assays for β-hydroxybutyrate more accurately reflect true ketone body levels.

The incidence of fetal loss can be as high as 20 percent with DKA. Noncompliance is a prominent factor, and this and ketoacidosis were historically considered prognostically bad signs in pregnancy (Pedersen, 1974). Pregnant women usually develop ketoacidosis at lower blood glucose thresholds than when nonpregnant. In a study from China, the mean glucose level for pregnant women with DKA was 293 mg/dL compared with 495 mg/dL for nonpregnant women (Guo, 2008). Chico and associates (2008) reported ketoacidosis in a pregnant woman whose plasma glucose was only 87 mg/dL.

One management protocol for diabetic ketoacidosis is shown in Table 57-7. An important
cornerstone of management is vigorous rehydration with crystalloid solutions of normal saline or Ringer lactate.

**Infections.** Almost all types of infections are increased in diabetic pregnancies. Stamler and coworkers (1990) reported that almost 80 percent of women with type 1 diabetes develop at least one infection during pregnancy compared with only 25 percent in those without diabetes. Common infections include *Candida* vulvovaginitis, urinary and respiratory tract infections, and puerperal pelvic sepsis. In their population-based study of almost 200,000 pregnancies, Sheiner and colleagues (2009) found a twofold increased risk of asymptomatic bacteruria in women with diabetes. Similarly, Alvarez and associates (2010) reported positive urine cultures in a fourth of diabetic women compared with 10 percent of nondiabetic pregnant women. In a 2-year analysis of pyelonephritis at Parkland Hospital, 5 percent of women with diabetes developed pyelonephritis compared with 1.3 percent of the nondiabetic population (Hill, 2005). Fortunately, these latter infections can be minimized by screening and eradication of asymptomatic bacteriuria (Chap. 53, p. 1053). Takoudes and colleagues (2004) found that pregestational diabetes is associated with a two- to threefold increase in wound complications after cesarean delivery.
Management of Diabetes in Pregnancy

Because of the relationship between pregnancy complications and maternal glycemic control, efforts to achieve glucose targets are typically more aggressive during pregnancy. Management preferably should begin before pregnancy and include specific goals during each trimester.

Preconceptional Care

To minimize early pregnancy loss and congenital malformations in offspring of diabetic mothers, optimal medical care and education are recommended before conception (Chap. 8, p. 157). Unfortunately, nearly half of pregnancies in the United States are unplanned, and many diabetic women frequently begin pregnancy with suboptimal glucose control (Finer, 2011; Kim, 2005).

The ADA has defined optimal preconceptional glucose control using insulin to include self-monitored preprandial glucose levels of 70 to 100 mg/dL, peak postprandial values of 100 to 129 mg/dL, and mean daily glucose concentrations < 110 mg/dL (Kitzmiller, 2008). Glycosylated hemoglobin measurement, which reflects an average of circulating glucose for the past 4 to 8 weeks, is useful to assess early metabolic control. The ADA (2012) defines optimal values to be < 7 percent. In their prospective population-based study of 933 pregnant women with type 1 diabetes, Jensen and colleagues (2010) found the risk of congenital malformations was not demonstrably higher with glycosylated hemoglobin levels < 6.9 percent compared with that in more than 70,000 nondiabetic controls. They also identified a substantial fourfold increased risk for malformations at levels > 10 percent.

If indicated, evaluation and treatment for diabetic complications such as retinopathy or nephropathy should also be instituted before pregnancy. Finally, folate, 400 μg/day orally is given periconceptionally and during early pregnancy to decrease the risk of neural-tube defects.

First Trimester

Careful monitoring of glucose control is essential. For this reason, many clinicians hospitalize overtly diabetic women during early pregnancy to initiate an individualized glucose control program and offer education. It also provides an opportunity to assess the extent of diabetic vascular complications and precisely establish gestational age.

Insulin Treatment

The overtly diabetic pregnant woman is best treated with insulin. Although oral hypoglycemic agents have been used successfully for gestational diabetes (p. 1141), these agents are not currently recommended for overt diabetes except for limited and individualized use (American College of Obstetricians and Gynecologists, 2012). Maternal glycemic control can usually be achieved with multiple daily insulin injections and adjustment of dietary intake. The action profiles of commonly used short- and long-term insulins are shown in Table 57-8.

| TABLE 57-8. Action Profiles of Commonly Used Insulins |
Subcutaneous insulin infusion by a calibrated pump may be used during pregnancy. However, as demonstrated in a Cochrane Database review by Farrar and associates (2007), there is scarce robust evidence for specific salutary pregnancy effects. In a metaanalysis of six small randomized trials comparing insulin pumps to multiple daily injections of insulin, there were no significant differences in LGA birthweight, maternal hypoglycemia, or retinopathy progression (Mukhopadhyay, 2007). Notably, more women using insulin pumps developed ketoacidosis. Roeder and colleagues (2012) noted with insulin pump use in women with type 1 diabetes that total daily doses declined in the first trimester but later increased by more than threefold. Postprandial glucose excursions accounted for most increases. Women who use an insulin pump must be highly motivated and compliant to minimize the risk of nocturnal hypoglycemia (Gabbe, 2003).

**Monitoring.** Self-monitoring of capillary glucose levels using a glucometer is recommended because this involves the woman in her own care. Glucose goals recommended during pregnancy are shown in Table 57-9. Advances in noninvasive glucose monitoring will undoubtedly render intermittent capillary glucose monitoring obsolete. Subcutaneous continuous glucose monitoring devices reveal that pregnant women with diabetes experience significant periods of daytime hyperglycemia and nocturnal hypoglycemia that are undetected by traditional monitoring (Combs, 2012). In one randomized trial of 71 women, those with periodic supplemental access to continuous glucose data had lower glycosylated hemoglobin levels—5.8 versus 6.4 percent—and delivered fewer overgrown newborns (Murphy, 2008). To date however, there have been no trials evaluating the impact of *personal* continuous monitoring devices that give immediate feedback to pregnant women. Such glucose monitoring systems, coupled with a continuous insulin pump, offer the potential of an “artificial pancreas” to avoid undetected hypo- or hyperglycemia during pregnancy.
Diet. Nutritional planning includes appropriate weight gain through carbohydrate and caloric modifications based on height, weight, and degree of glucose intolerance (American Diabetes Association, 2012; Bantle, 2008). The mix of carbohydrate, protein, and fat is adjusted to meet the metabolic goals and individual patient preferences, but a 175-g minimum of carbohydrate per day should be provided. Carbohydrate should be distributed throughout the day in three small- to moderate-sized meals and two to four snacks (Bantle, 2008). Weight loss is not recommended, but modest caloric restriction may be appropriate for overweight or obese women. An ideal dietary composition is 55 percent carbohydrate, 20 percent protein, and 25 percent fat, of which < 10 percent is saturated fat.

Hypoglycemia. Diabetes tends to be unstable in the first trimester. Hellmuth and associates (2000) reported that 37 percent of 43 women with type 1 diabetes had maternal hypoglycemia during the first trimester, and the average duration was more than 2 hours. Similarly, Chen and coworkers (2007) identified hypoglycemic events—blood glucose < 40 mg/dL—in 37 of 60 women with type 1 diabetes. A fourth of these were considered severe because the women were unable to treat their own symptoms. Rosenn and colleagues (1994) noted that maternal hypoglycemia had a peak incidence between 10 and 15 weeks’ gestation. Caution is recommended when attempting euglycemia in women with recurrent episodes of hypoglycemia.

We have reported that good pregnancy outcomes can be achieved in women with mean preprandial plasma glucose values up to 143 mg/dL (Leveno, 1979). In women with diabetes who are not pregnant, the Diabetes Control and Complications Trial Research Group (1993) found that similar glucose values delayed and slowed diabetic retinopathy, nephropathy, and neuropathy. Thus, women with overt diabetes who have glucose values considerably above those defined as normal both during and after pregnancy can expect good outcomes.

Second Trimester

Maternal serum alpha-fetoprotein determination at 16 to 20 weeks’ gestation is used in association with targeted sonographic examination at 18 to 20 weeks to detect neural-tube defects and other anomalies (Chap. 14, p. 284). Maternal alpha-fetoprotein levels may be lower in diabetic pregnancies, and interpretation is altered accordingly. Because the incidence of congenital cardiac anomalies is five times greater in mothers with diabetes, fetal echocardiography is an important part of second-trimester sonographic evaluation (Fouda, 2013). Despite advances in ultrasound technology, however, Dashe and associates (2009) cautioned that detection of fetal anomalies in obese diabetic women is more difficult than in similarly sized women without diabetes.

Regarding second-trimester glucose control, euglycemia with self-monitoring continues to be
the goal in management. After the first-trimester instability, a stable period ensues. This is followed by an increased insulin requirement. Recall that Roeder and coworkers (2012) identified a threefold increase in total daily insulin after the first trimester in women using an insulin pump. This is due to the increased peripheral resistance to insulin described in Chapter 4 (p. 53).

**Third Trimester and Delivery**

During the last several decades, the threat of late-pregnancy fetal death in women with diabetes has prompted recommendations for various fetal surveillance programs beginning in the third trimester. Such protocols include fetal movement counting, periodic fetal heart rate monitoring, intermittent biophysical profile evaluation, and contraction stress testing (Chap. 17, p. 335). None of these techniques has been subjected to prospective randomized clinical trials, and their primary value seems related to their low false-negative rates. The American College of Obstetricians and Gynecologists (2012) suggests initiating such testing at 32 to 34 weeks’ gestation.

At Parkland Hospital, women with diabetes are seen in a specialized obstetrical complications clinic every 2 weeks. During these visits, glycemic control is evaluated and insulin adjusted. They are routinely instructed to perform fetal kick counts beginning early in the third trimester. At 34 weeks, admission is offered to all insulin-treated women. While in the hospital, they continue daily fetal movement counts and undergo fetal heart rate monitoring three times a week. Delivery is planned for 38 weeks.

Labor induction may be attempted when the fetus is not excessively large and the cervix is considered favorable (Chap. 26, p. 523). Cesarean delivery at or near term has frequently been used to avoid traumatic birth of a large infant in a woman with diabetes. In women with more advanced diabetes, especially those with vascular disease, the reduced likelihood of successful labor induction remote from term has also contributed to an increased cesarean delivery rate. In a nested case-control study of 209 women with type 1 diabetes, Lepercq and colleagues (2010) reported a 70-percent cesarean delivery rate overall. Two thirds of these were delivered without labor. Both maternal body mass index (BMI) > 25 kg/m² and low Bishop score were independently associated with cesarean delivery for those in labor. In another study, a glycohemoglobin level > 6.4 percent at delivery was independently associated with urgent cesarean delivery. This suggests that tighter glycemic control during the third trimester might reduce late fetal compromise and cesarean delivery for fetal indications (Miallhe, 2013). The cesarean delivery rate for women with overt diabetes has remained at approximately 80 percent for the past 35 years at Parkland Hospital.

Reducing or withholding the dose of long-acting insulin given on the day of delivery is recommended. Regular insulin should be used to meet most or all of the insulin needs of the mother during this time, because insulin requirements typically drop markedly after delivery. We have found that continuous insulin infusion by calibrated intravenous pump is most satisfactory (Table 57-10). Throughout labor and after delivery, the woman should be adequately hydrated intravenously and given glucose in sufficient amounts to maintain normoglycemia. Capillary or plasma glucose levels should be checked frequently, especially during active labor, and regular insulin should be administered accordingly.

**TABLE 57-10. Insulin Management During Labor and Delivery**

- Usual dose of intermediate-acting insulin is given at bedtime.
- Morning dose of insulin is withheld.
- Intravenous infusion of normal saline is begun.
Once active labor begins or glucose levels decrease to < 70 mg/dL, the infusion is changed from saline to 5-percent dextrose and delivered at a rate of 100–150 mL/hr (2.5 mg/kg/min) to achieve a glucose level of approximately 100 mg/dL.

Glucose levels are checked hourly using a bedside meter allowing for adjustment in the insulin or glucose infusion rate.

Regular (short-acting) insulin is administered by intravenous infusion at a rate of 1.25 U/hr if glucose levels exceed 100 mg/dL.

Puerperium

Often, women may require virtually no insulin for the first 24 hours or so postpartum. Subsequently, insulin requirements may fluctuate markedly during the next few days. Infection must be promptly detected and treated.

Counseling in the puerperium should include a discussion of birth control. Available options are discussed in Chapter 38 (p. 695). Effective contraception is especially important in women with overt diabetes to allow optimal glucose control before subsequent conceptions.

GESTATIONAL DIABETES

In the United States, 5 to 6 percent of pregnancies—almost 250,000 women—are affected annually by various forms of gestational diabetes. Worldwide, its prevalence differs according to race, ethnicity, age, and body composition and by screening and diagnostic criteria. There continue to be several controversies pertaining to the diagnosis and treatment of gestational diabetes. Accordingly, a National Institutes of Health (NIH) Consensus Development Conference (2013 was convened. Coincidental with publication of the Conference findings, the American College of Obstetricians and Gynecologists (2013) also updated its recommendations. These two authoritative sources provide an up-to-date analysis of the issues surrounding this diagnosis and bolster the approach to identifying and treating women with gestational diabetes, as described subsequently.

The word gestational implies that diabetes is induced by pregnancy—ostensibly because of exaggerated physiological changes in glucose metabolism (Chap. 4, p. 53). Gestational diabetes is defined as carbohydrate intolerance of variable severity with onset or first recognition during pregnancy (American College of Obstetricians and Gynecologists, 2013). This definition applies whether or not insulin is used for treatment and undoubtedly includes some women with previously unrecognized overt diabetes. In their analysis of more than 1500 nonpregnant adults as part of National Health and Nutrition Examinations Survey (NHANES) IV, Karve and Hayward (2010) estimated that only 4.8 percent of individuals with impaired fasting glucose or glucose intolerance were aware of their diagnosis.
Use of the term *gestational diabetes* has been encouraged to communicate the need for increased surveillance and to stimulate women to seek further testing postpartum. The most important perinatal correlate is excessive fetal growth, which may result in both maternal and fetal birth trauma. The likelihood of fetal death with appropriately treated gestational diabetes is not different from that in the general population. Importantly, more than half of women with gestational diabetes ultimately develop overt diabetes in the ensuing 20 years. And, as discussed on page 1125, evidence is mounting for long-range complications that include obesity and diabetes in their offspring.

### Screening and Diagnosis

Despite more than 40 years of research, there is still no agreement regarding optimal gestational diabetes screening. The difficulty in achieving consensus is underscored by the controversy following publication of the single-step approach espoused by the IADPSG Consensus Panel (2010) (Table 57-11). This strategy was greatly influenced by results of the Hypoglycemia and Pregnancy Outcomes (HAPO) Study described later. Although the ADA adopted this new scheme, the American College of Obstetricians and Gynecologists (2013) declined to endorse the single 75-gram oral glucose tolerance test. Instead, the College continues to recommend a two-step approach to screen and diagnose gestational diabetes. Similarly, the NIH Consensus Development Conference in 2013 concluded that evidence is insufficient to adopt a one-step approach.

<td></td>
</tr>
</tbody>
</table>

<sup>a</sup>One or more of these values from a 75-g OGTT must be equaled or exceeded for the diagnosis of gestational diabetes.

<sup>b</sup>In addition, 1.7% of participants in the initial cohort were unblinded because of fasting plasma glucose levels > 5.8 mmol/L (105 mg/dL) or 2-hr OGTT values > 11.1 mmol/L (200 mg/dL), bringing the total to 17.8%. OGTT = oral glucose tolerance test.

The recommended two-step approach begins with either universal or risk-based selective screening using a 50-g, 1-hour oral glucose challenge test. Participants in the Fifth International Workshop Conferences on Gestational Diabetes endorsed use of *selective screening* criteria...
Universal screening is also acceptable. Gabbe and associates (2004) surveyed practicing obstetricians and reported that 96 percent used universal screening. Screening should be performed between 24 and 28 weeks’ gestation in those women not known to have glucose intolerance earlier in pregnancy. This 50-g screening test is followed by a diagnostic 100-g, 3-hour oral glucose tolerance test (OGTT) if screening results meet or exceed a predetermined plasma glucose concentration.

OGTT = oral glucose tolerance test.
Modified from Metzger, 2007.

For the 50-g screen, the plasma glucose level is measured 1 hour after a 50-g oral glucose load without regard to the time of day or time of last meal. In a recent review, the pooled sensitivity for a threshold of 140 mg/dL ranged from 74 to 83 percent depending on 100-g thresholds used for diagnosis (van Leeuwen, 2012). Sensitivity estimates for a 50-g screen threshold of 135 mg/dL improved only slightly to 78 to 85 percent. Importantly, specificity dropped from a range of 72 to 85 percent for 140 mg/dL to 65 to 81 percent for a threshold of 135 mg/dL. That said, the American College of Obstetricians and Gynecologists (2013) recommends using either 135 or 140 mg/dL as the 50-g screen threshold. At Parkland Hospital, we continue to use 140 mg/dL.

Justification for screening and treatment of women with gestational diabetes was strengthened by the study by Crowther and coworkers (2005). They assigned 1000 women with gestational...
diabetes between 24 and 34 weeks’ gestation to receive dietary advice with blood glucose monitoring plus insulin therapy—the intervention group—or to undergo routine prenatal care. Women were diagnosed as having gestational diabetes if their blood glucose was < 100 mg/dL after an overnight fast and was between 140 and 198 mg/dL 2 hours after ingesting a 75-g glucose solution. Women in the intervention group had a significantly reduced risk of a composite adverse outcome that included perinatal death, shoulder dystocia, fetal bone fracture, and fetal nerve palsy. Macrosomia defined by birthweight ≥ 4000 g complicated 10 percent of deliveries in the intervention group compared with 21 percent in the routine prenatal care group. Cesarean delivery rates were almost identical in the two study groups.

Slightly different results were reported by the Maternal-Fetal Medicine Units Network randomized trial of 958 women (Landon, 2009). Dietary counseling plus glucose monitoring was compared with standard obstetrical care in women with mild gestational diabetes to reduce perinatal morbidity rates. Mild gestational diabetes was identified in women with fasting glucose levels < 95 mg/dL. They reported no differences in rates of composite morbidity that included stillbirth; neonatal hypoglycemia, hyperinsulinemia, and hyperbilirubinemia; and birth trauma. Importantly, secondary analyses demonstrated a 50-percent reduction in macrosomia, fewer cesarean deliveries, and a significant decrease in shoulder dystocia rates—1.5 versus 4 percent—in treated versus control women.

Based largely on these two studies, the U.S. Preventive Services Task Force (2013) now recommends universal screening in low-risk women after 24 weeks’ gestation. However, the Task Force concluded that evidence is insufficient to assess the balance of benefits versus harms of screening before 24 weeks. From the foregoing, there obviously is not international agreement as to the optimal glucose tolerance test to identify gestational diabetes. The World Health Organization (1998) and now the American Diabetes Association (2013) recommend the 75-g 2-hour oral glucose tolerance test. In the United States, however, the 100-g, 3-hour OGTT test performed after an overnight fast is recommended by the American College of Obstetricians and Gynecologists (2013). Criteria for interpretation of the 100-g diagnostic glucose tolerance test are shown in Table 57-13. Also shown are the criteria for the 75-g test most often used outside the United States.

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study

This was a 7-year international epidemiological study of 23,325 pregnant women at 15 centers in nine countries (HAPO Study Cooperative Research Group, 2008). The investigation analyzed the association of various levels of glucose intolerance during the third trimester with adverse infant outcomes in women with gestational diabetes. Between 24 and 32 weeks’ gestation, the general population of pregnant women underwent 75-g oral glucose tolerance testing after overnight fasting. Blood glucose levels were measured fasting and then 1 and 2 hours after glucose ingestion. Caregivers were blinded to results except for women whose glucose levels exceeded values that required treatment and removal from the study. Glucose values at each of these three time points were stratified into seven categories (Fig. 57-8). Values were then correlated with rates for birthweight > 90th percentile (LGA), primary cesarean delivery, clinical neonatal hypoglycemia, and cord-serum C-peptide levels > 90th percentile. C-peptide is a measurable by-product created during insulin production. Odds of each outcome were calculated using the lowest category—for example, fasting plasma glucose < 75 mg/dL—as the referent group. Their findings in general supported the supposition that increasing plasma glucose levels at each epoch were associated with increasing adverse outcomes.

The test should be performed in the morning after an overnight fast of at least 8 hr but not more than 14 hr and after at least 3 days of unrestricted diet (≥ 150 g/d) and physical activity. The subject should remain seated and should not smoke during the test.

Two or more of the venous plasma glucose concentrations listed must be met or exceeded for a positive diagnosis.

Data from Metzger, 2007.
In an editorial accompanying publication of the HAPO trial, Ecker and Greene (2008) pose the question: “Given the results of the HAPO study, should we lower our threshold for the diagnosis and treatment of gestational diabetes?” It was adjudged that it will be difficult to show that treating lesser degrees of carbohydrate intolerance—as suggested in the HAPO study—would provide any meaningful improvements in clinical outcomes. Thus Ecker and Greene (2008) concluded, and we agree, that changes in criteria are not justified until clinical trials prove benefits. Most recently, this position was endorsed by the 2013 NIH Consensus Development Conference.

International Association of Diabetes and Pregnancy Study Group

The IADPSG sponsored a workshop conference on the diagnosis and classification of gestational diabetes in 2008. After reviewing the results of the HAPO study, a panel was appointed to develop recommendations for the diagnosis and classification of hyperglycemia during pregnancy. This panel allowed for the diagnosis of overt diabetes during pregnancy as shown in Table 57-4. It also recommended a single-step approach to the diagnosis of gestational diabetes using the 75-g, 2-hour OGTT. Thresholds for fasting, 1-, and 2-hour values based on mean glucose concentrations from the entire HAPO study cohort were considered. These thresholds were derived using an arbitrary 1.75 odds ratio of outcomes such as LGA birthweight and cord serum C-peptide levels ≥ 90th percentile. Only one of these thresholds would need to be met or exceeded to make the
diagnosis of gestational diabetes (see Table 57-11).

It is estimated that implementation of these recommendations would increase the prevalence of gestational diabetes in the United States to 17.8 percent! Said another way, the number of women with mild gestational diabetes would increase almost threefold with no evidence of treatment benefit (Cundy, 2012). Despite these significant drawbacks, the ADA (2013) recommended adopting this new approach based on benefits inferred from trials in women identified using a two-step approach described on page 1138 (Crowther, 2005; Landon, 2009).

National Institutes of Health Consensus Development Conference on Diagnosing Gestational Diabetes Mellitus
Prompted by the IADPSG recommendations (2010) and their adoption by the ADA (2013), an NIH Consensus Development Conference (2013) was convened. This conference included input from a multidisciplinary planning committee, a systematic evidence review by the Agency for Healthcare Research and Quality (AHRQ) Evidence-Based Practice Center, expert testimony, and a nonbiased panel to produce the overall report. The panel concluded that there were potential benefits to worldwide standardization. However, it found insufficient evidence to adopt a one-step diagnostic process such as the one proposed by the IADPSG. Moreover, as mentioned previously after consideration of these findings, the American College of Obstetricians and Gynecologists (2013) continues to recommend a two-step screening and diagnostic approach to gestational diabetes diagnosis. It noted no significant improvements in maternal or perinatal outcomes that would offset the tripling of gestational diabetes incidence that would derive from the one-step approach. We applaud this decision.

Maternal and Fetal Effects
Adverse consequences of gestational diabetes differ from those of pregestational diabetes. Unlike in women with overt diabetes, rates of fetal anomalies do not appear to be substantially increased (Sheffield, 2002). In a study of more than 1 million women from the Swedish Medical Birth Registry, major malformation rates were marginally increased—2.3 versus 1.8 percent (Fadl, 2010). The stillbirth rate was not increased in this study or in an analysis of 130 perinatal deaths in the HAPO study (2008). In contrast, and not unexpectedly, women with elevated fasting glucose levels have increased rates of unexplained stillbirths similar to women with overt diabetes. The ADA (2003) concluded that fasting hyperglycemia > 105 mg/dL may be associated with an increased risk of fetal death during the final 4 to 8 weeks. This increasing risk with progressive maternal hyperglycemia prompted the IADPSG (2010) to emphasize the importance of identifying women with evidence of preexisting diabetes early in pregnancy (see Table 57-4). Similar to women with overt diabetes, adverse maternal effects associated with gestational diabetes include an increased frequency of hypertension and cesarean delivery.

Fetal Macrosomia
The primary effect attributed to gestational diabetes is excessive fetal size or macrosomia that is variably defined and discussed further in Chapter 44 (p. 884). Maternal hyperglycemia prompts fetal hyperinsulinemia, particularly during the second half of pregnancy. This in turn stimulates excessive somatic growth. The perinatal goal is to avoid difficult delivery from macrosomia and concomitant birth trauma associated with shoulder dystocia. In a retrospective analysis of more than 80,000 vaginal deliveries in Chinese women, Cheng and associates (2013) calculated a 76-fold increased risk for shoulder dystocia in newborns weighing ≥ 4200 g compared with the risk in
those weighing < 3500 g. Importantly, however, the odds ratio for shoulder dystocia in women with diabetes was less than 2. Although gestational diabetes is certainly a risk factor, it accounts for only a small number of pregnancies complicated by shoulder dystocia.

The excessive shoulder and trunk fat that commonly characterizes the macrosomic infant of a diabetic mother theoretically predisposes such infants to shoulder dystocia or cesarean delivery (Durnwald, 2004; McFarland, 2000). Landon and colleagues (2011) identified shoulder dystocia in approximately 4 percent of women with mild gestational diabetes compared with < 1 percent of women with a 50-g glucose screen result < 120 mg/dL. In a prospective study of fetal adipose measurements, however, Buhling and coworkers (2012) demonstrated no differences between measurements in 630 offspring of women with gestational diabetes and 142 without diabetes. The authors attributed this negative finding to successful treatment of gestational diabetes.

There is extensive evidence that insulin-like growth factors also play a role in fetal-growth regulation (Chap. 44, p. 872). These proinsulin-like polypeptides are produced by virtually all fetal organs and are potent stimulators of cell differentiation and division. Luo and coworkers (2012) reported that insulin-like growth factor-I strongly correlated with birthweight. The HAPC study investigators also reported dramatic increases of cord-serum C-peptide levels with increasing maternal glucose levels following a 75-g OGTT. C-peptide levels > 90th percentile were found in almost a third of newborns in the highest glucose categories. Other factors implicated in macrosomia include epidermal growth factor, fibroblast growth factor, platelet-derived growth factor, leptin, and adiponectin (Grissa, 2011; Loukovaara, 2004; Mazaki-Tovi, 2005).

**Neonatal Hypoglycemia**

Neonatal hyperinsulinemia may provoke hypoglycemia within minutes of birth. The incidence varies depending on the threshold definition. Cornblath and associates (2000) established a threshold of 35 mg/dL in term newborns. An NIH workshop conference on neonatal hypoglycemia supported use of such operational thresholds but cautioned that these are not strictly evidence-based (Hay, 2009). Newborns described by the HAPO study (2008) had an incidence of clinical neonatal hypoglycemia that increased with increasing maternal OGTT values defined in Figure 57-8. The frequency varied from 1 to 2 percent, but it was as high as 4.6 percent in women with fasting glucose levels ≥ 100 mg/dL. Likewise, cord-blood insulin levels are related to maternal glucose control (Leipold, 2004).

**Maternal Obesity**

In women with gestational diabetes, maternal BMI is an independent and more substantial risk factor for fetal macrosomia than is glucose intolerance (Ehrenberg, 2004; Mission, 2013). Stuebe and colleagues (2012) completed a secondary analysis of women with either untreated mild gestational diabetes or normal glucose tolerance testing results. They found that higher BMI levels were associated with increasing birthweight, regardless of glucose levels. Also, maternal obesity is an important confounding factor in the diagnosis of gestational diabetes. In their metaanalysis, Torloni and coworkers (2009) estimated that the gestational diabetes prevalence increases by approximately 1 percent for every 1 kg/m² increase in BMI. Weight distribution also seems to play a role because the risk of gestational diabetes is increased with truncal obesity. Suresh and colleagues (2012) verified that increased maternal abdominal subcutaneous fat thickness as measured by sonography at 18 to 22 weeks’ gestation correlated with BMI and was a better predictor of gestational diabetes. Martin and associates (2009) reported similar findings for sonographically measured maternal visceral adipose depth. Importantly, excessive gestational
weight gain is commonly identified in women with gestational diabetes and also confers an additive risk for fetal macrosomia (Egan, 2014).

Management

Women with gestational diabetes can be divided into two functional classes using fasting glucose levels. Pharmacological methods are usually recommended if diet modification does not consistently maintain the fasting plasma glucose levels < 95 mg/dL or the 2-hour postprandial plasma glucose < 120 mg/dL (American College of Obstetricians and Gynecologists, 2013). Whether pharmacological treatment should be used in women with lesser degrees of fasting hyperglycemia—105 mg/dL or less before dietary intervention—is unclear. There have been no controlled trials to identify ideal glucose targets for fetal risk prevention. On the other hand, the HAPO study (2008) did demonstrate increased fetal risk at glucose levels below the threshold used for diagnosis of diabetes. The Fifth International Workshop Conference recommended that fasting capillary glucose levels be kept ≤ 95 mg/dL (Metzger, 2007).

In a systematic review, Hartling and colleagues (2013) concluded that treating gestational diabetes resulted in a significantly lower incidence of preeclampsia, shoulder dystocia, and macrosomia. For example, the calculated risk ratio for delivering an infant > 4000 g after treatment was 0.50. These investigators caution that the attributed risk for these outcomes is low, especially when glucose values are only moderately elevated. Importantly, they were unable to demonstrate an effect on neonatal hypoglycemia or future metabolic outcomes in the offspring.

Diabetic Diet

As discussed previously, reports by Crowther (2005) and Landon (2009) and their colleagues describe the benefits of dietary counseling and monitoring in women with gestational diabetes. The ADA recommends individualized nutritional counseling based on height and weight (Bantle, 2008). Nutritional instructions generally include a carbohydrate-controlled diet sufficient to maintain normoglycemia and avoid ketosis. On average, this includes a daily caloric intake of 30 to 35 kcal/kg. Moreno-Castilla and associates (2013) randomly assigned 152 women with gestational diabetes to either a 40- or a 55-percent daily carbohydrate diet and found no difference in insulin levels and pregnancy outcomes. The American College of Obstetricians and Gynecologists (2013) suggests that carbohydrate intake be limited to 40 percent of total calories. The remaining calories are apportioned to give 20 percent as protein and 40 percent as fat.

Although the most appropriate diet for women with gestational diabetes has not been established, the ADA (2003) has suggested that obese women with a BMI > 30 kg/m² may benefit from a 30-percent caloric restriction, which approximates 25 kcal/kg/d. This should be monitored with weekly assessment for ketonuria, which has been linked with impaired psychomotor development in offspring (Rizzo, 1995; Scholte, 2012). That said, Most and Langer (2012) found that insulin was necessary to reduce excess birthweight in offspring of obese women with gestational diabetes.

Exercise

The American College of Obstetricians and Gynecologists (2009) reviewed three randomized trials of exercise in women with gestational diabetes (Avery, 1997; Bung, 1993; Jovanovic-Peterson, 1989). The results suggest that exercise improved cardiorespiratory fitness without improving pregnancy outcome. Importantly, these trials were small and had limited power to show
improvement in outcomes. Dempsey and coworkers (2004) found that physical activity during pregnancy reduced the risk of gestational diabetes. Brankston and associates (2004) reported that resistance exercise diminished the need for insulin therapy in overweight women with gestational diabetes. Conversely, Stafne and colleagues (2012), in a randomized controlled trial in 855 women, observed that a 1-week exercise program during the second half of pregnancy did not prevent gestational diabetes or improve insulin resistance. Importantly, the average BMI at enrollment was 24.8 ± 3.2. The American College of Obstetricians and Gynecologists (2013) recommends a moderate exercise program as part of the treatment plan for women with gestational diabetes.

Glucose Monitoring

Hawkins and colleagues (2008) compared outcomes in 315 women with diet-treated gestational diabetes who used personal glucose monitors with those of 615 gestational diabetics who were also diet-treated but who underwent intermittent fasting glucose evaluation during semi-weekly obstetrical visits. Women using daily blood-glucose self-monitoring had significantly fewer macrosomic infants and gained less weight after diagnosis than women evaluated during clinic visits only. These findings support the common practice of blood-glucose self-monitors for women with diet-treated gestational diabetes.

Postprandial surveillance for gestational diabetes has been shown to be superior to preprandial surveillance. DeVeciana and coworkers (1995) studied 66 pregnant women with gestational diabetes in whom insulin was initiated for fasting hyperglycemia. The women were randomly assigned to glucose surveillance using either preprandial or 1-hour postprandial capillary blood-glucose concentrations. Postprandial surveillance was shown to be superior in that blood-glucose control was significantly improved and was associated with fewer cases of neonatal hypoglycemia—3 versus 21 percent; less macrosomia—12 versus 42 percent; and fewer cesarean deliveries for dystocia—24 versus 39 percent. At Parkland Hospital, we were unable to demonstrate similar findings when we reviewed the impact of changing to postprandial monitoring in women with diet-treated gestational diabetes. We did, however, demonstrate a significant reduction in maternal weight gain per week—0.63 lb/week to 0.45 lb/week—in women managed with a postprandial monitoring schema. The American College of Obstetricians and Gynecologists (2013) recommends four-times daily glucose monitoring performed fasting and either 1 or 2 hours after each meal.

Insulin Treatment

Historically, insulin has been considered standard therapy in women with gestational diabetes when target glucose levels cannot be consistently achieved through nutrition and exercise. It does not cross the placenta, and tight glycemic control can typically be achieved. In a report prepared for the AHRQ, Nicholson and associates (2009) were unable to determine a threshold above which insulin should be initiated. Pharmacological therapy—in this case insulin—is typically added if fasting levels persistently exceed 95 mg/dL in women with gestational diabetes. The American College of Obstetricians and Gynecologists (2013) also recommends that insulin be considered in women with 1-hour postprandial levels that persistently exceed 140 mg/dL or those with 2-hour levels above 120 mg/dL. Importantly, all of these thresholds are extrapolated from recommendations for managing women with overt diabetes.

If insulin is initiated, the starting dose is typically 0.7–1.0 units/kg/day given in divided doses (American College of Obstetricians and Gynecologists, 2013). A combination of intermediate-acting and short-acting insulin may be used, and dose adjustments are based on glucose levels at
particular times of the day. At Parkland Hospital, insulin instruction for these women is accomplished either in a specialized outpatient clinic or during a short hospital stay. As shown in Table 57-8, insulin analogues such as insulin aspart and insulin lispro have a more rapid onset of action than regular insulin and theoretically could be helpful in postprandial glucose management. Experience with these analogues with gestational diabetes is limited, and Singh and coworkers (2008) were unable to demonstrate a benefit compared with conventional insulins.

**Oral Hypoglycemic Agents**

Several studies have attested to the safety and efficacy of gestational diabetes treatment with either glyburide (Micronase) or metformin (Glucophage) (Langer, 2000; Nicholson, 2009; Rowan, 2008). In one study, Langer and colleagues (2000, 2005) randomly assigned 404 women to insulin or glyburide therapy. Near normoglycemic levels were achieved with either regimen, and there were no apparent neonatal complications attributable to glyburide. In a follow-up study, Conway and coworkers (2004) reported that women with fasting glucose levels > 110 mg/dL did not adequately respond to glyburide therapy. Similar results were reported by Chmait (2004) and Kahn (2006) and their associates. At one time, glyburide was thought not to cross the placenta. However, Hebert and colleagues (2008, 2009) sampled 20 paired maternal-cord specimens and found the latter to have glyburide concentrations approximately half that of maternal levels.

**Metformin** treatment for polycystic ovarian disease throughout pregnancy reduced the incidence of gestational diabetes (Glueck, 2004). Because metformin crosses to the fetus, there was reticence to use it in pregnant women (Harborne, 2003). Subsequent studies have helped allay these concerns. Rowan and associates (2008) randomly assigned 751 women with gestational diabetes to metformin or insulin treatment. The primary outcome was a composite of neonatal hypoglycemia, respiratory distress syndrome, phototherapy, birth trauma, 5-minute Apgar score ≤ 7, and preterm birth. Similarities in the composite outcome between metformin and insulin led investigators to conclude that metformin was not associated with adverse perinatal outcomes. It is noteworthy that 46 percent of women in the metformin trial required supplemental insulin compared with only 4 percent of women treated with glyburide (Langer, 2000).

In their systematic review and metaanalysis of oral hypoglycemic agents for gestational diabetes, Nicholson and coworkers (2009) found no evidence of increased adverse maternal or neonatal outcomes with glyburide or metformin compared with insulin. Moore and associates (2010) randomly assigned 149 women with gestational diabetes who did not achieve glycemic control on diet therapy to either glyburide or metformin treatment. More than a third of women in the metformin group required supplemental insulin compared with 16 percent of those treated with glyburide.

Oral hypoglycemic agents are being increasingly used for gestational diabetes, although they have not been approved by the Food and Drug Administration for this indication. A survey of almost 1400 fellows of the American College of Obstetricians and Gynecologists found that 13 percent of respondents were using glyburide as first-line therapy for diet failure in women with gestational diabetes (Gabbe, 2004). The American College of Obstetricians and Gynecologists (2013) acknowledges that both glyburide and metformin are appropriate, as is insulin, for first-line glycemic control in women with gestational diabetes. Because long-term outcomes have not been studied, the committee recommends appropriate counseling when hypoglycemic agents are used.

**Obstetrical Management**

In general, for women with gestational diabetes who do not require insulin, early delivery or other
interventions are seldom required. There is no consensus regarding the value or timing of antepartum fetal testing. It is typically reserved for women with pregestational diabetes because of the increased stillbirth risk. The American College of Obstetricians and Gynecologists (2013) endorses fetal surveillance in women with gestational diabetes and poor glycemic control. At Parkland Hospital, women with gestational diabetes are routinely instructed to perform daily fetal kick counts in the third trimester (Chap. 17, p. 335). Insulin-treated women are offered inpatient admission after 34 weeks’ gestation, and fetal heart rate monitoring is performed three times each week.

Women with gestational diabetes and adequate glycemic control are managed expectantly. Elective labor induction to prevent shoulder dystocia compared with spontaneous labor remains controversial. One randomized trial evaluated induction at 38 weeks in 200 women with insulin-treated diabetes—187 of whom had gestational diabetes. Investigators reported a significantly lower proportion of newborns with a birthweight > 90th percentile in the active induction group—10 versus 23 percent (Kjos, 1993). However, there were no differences in rates of cesarean delivery or shoulder dystocia or in neonatal outcomes. Witkop and colleagues (2009) performed a systematic review and concluded that, in the aggregate, a reduction in fetal macrosomia is likely in women with gestational diabetes who undergo an elective labor induction at term. They also found a limited ability to draw definite conclusions based on available evidence. The American College of Obstetricians and Gynecologists (2013) also has concluded that no evidence-based recommendation can be made regarding delivery timing in women with gestational diabetes. To study this, a large multicenter trial (NCT01058772) expected to enroll 1760 women with gestational diabetes is currently recruiting participants (Maso, 2011).

Elective cesarean delivery to avoid brachial plexus injuries in overgrown fetuses is also an important issue. The American College of Obstetricians and Gynecologists (2013) has suggested that cesarean delivery should be considered in women with gestational diabetes whose fetuses have a sonographically estimated weight ≥ 4500 g. From their systematic review, Garabedian and coworkers (2010) estimated that as many as 588 cesarean deliveries in women with gestational diabetes and an estimated fetal weight of ≥ 4500 g would be necessary to avoid one case of permanent brachial plexus palsy. Effects of such a policy were retrospectively analyzed by Gonen and associates (2000) in a general obstetrical population of more than 16,000 women. Elective cesarean delivery had no significant effect on the incidence of brachial plexus injury.

Postpartum Evaluation

Recommendations for postpartum evaluation are based on the 50-percent likelihood of women with gestational diabetes developing overt diabetes within 20 years (O’Sullivan, 1982). The Fifth International Workshop Conference on Gestational Diabetes recommended that women diagnosed with gestational diabetes undergo evaluation with a 75-g oral glucose tolerance test at 6 to 12 weeks postpartum and other intervals thereafter (Metzger, 2007). These recommendations are shown in Table 57-14 along with the classification scheme of the ADA (2013). Hunt and colleagues (2010) reviewed performance rates of postpartum glucose screening and found that anywhere between 23 and 58 percent of women actually undergo 75-g glucose testing. The American College of Obstetricians and Gynecologists (2013) recommends either a fasting glucose or the 75-g, 2-hour OGTT for the diagnosis of overt diabetes. The ADA (2011) recommends testing at least every 3 years in women with a history of gestational diabetes but normal postpartum glucose screening.
Women with a history of gestational diabetes are also at risk for cardiovascular complications associated with dyslipidemia, hypertension, and abdominal obesity—the metabolic syndrome (Chap. 48, p. 962). In a study of 47,909 parous women, Kessous and coworkers (2013) evaluated subsequent hospitalizations due to cardiovascular morbidity. They found that almost 5000 women with gestational diabetes were 2.6 times more likely to be hospitalized for cardiovascular morbidity. Shah and coworkers (2008) also documented excessive cardiovascular disease by 10 years in women with gestational diabetes. Akinci and associates (2009) reported that a fasting glucose level ≥ 100 mg/dL in the index OGTT was an independent predictor of the metabolic syndrome.

### Recurrent Gestational Diabetes

In subsequent pregnancies, recurrence was documented in 40 percent of 344 primiparous women with gestational diabetes (Holmes, 2010). Obese women were more likely to have impaired glucose tolerance in subsequent pregnancies. Thus, lifestyle behavioral changes, including weight control and exercise between pregnancies, likely would prevent gestational diabetes recurrence (Kim, 2008). Ehrlich and colleagues (2011) found that the loss of at least two BMI units was associated with a lower risk of gestational diabetes in women who were overweight or obese in the first pregnancy. Getahun and coworkers (2010) found that only 4.2 percent of women without gestational diabetes in their first pregnancy were diagnosed with gestational diabetes when screened in a second pregnancy. This compared with 41.3 percent in women with a history of gestational diabetes.

Low-dose hormonal contraceptives may be used safely by women with recent gestational diabetes (Chap. 38, p. 709). The rate of subsequent diabetes in oral contraceptive users is not significantly different from that in those who did not use hormonal contraception (Kerlan, 2010). Importantly, comorbid obesity, hypertension, or dyslipidemia should direct the choice for contraception toward a method without potential cardiovascular consequences. In these instances, the intrauterine device is a good alternative.

There are no endocrine disorders that are unique to pregnancy. However, endocrinopathies seem particularly closely related to pregnancy due to their proclivity for hormone secretion. Indeed, some hormones are secreted in prodigious quantities. This is probably best illustrated by placental lactogen in diabetes, the most common endocrinopathy encountered in pregnancy (Chap. 57, p. 1125). Pregnancy is also interrelated with some endocrinopathies that are at least partially due to autoimmune dysregulation. Clinical manifestations of this result from complex interplay among genetic, environmental, and endogenous factors that activate the immune system against targeted cells within endocrine organs. An extraordinary example of these interactions comes from studies that implicate maternal organ engraftment by fetal cells that were transferred during pregnancy. These cells later provoke antibody production, tissue destruction, and autoimmune endocrinopathies.
Taken in aggregate, these are common in young women and thus frequently managed in pregnancy. There is an intimate relationship between maternal and fetal thyroid function, and drugs that affect the maternal thyroid also affect the fetal gland. Moreover, thyroid autoantibodies have been associated with increased early pregnancy wastage, and uncontrolled thyrotoxicosis and untreated hypothyroidism are both associated with adverse pregnancy outcomes. Finally, there is evidence that autoimmune thyroid disorder severity may be ameliorated during pregnancy, only to be exacerbated postpartum.

**Thyroid Physiology and Pregnancy**

Maternal thyroid changes are substantial, and normally altered gland structure and function are sometimes confused with thyroid abnormalities. These alterations are discussed in detail in Chapter 4 (p. 68), and normal hormone level values are found in the Appendix (p. 1290). First, maternal serum concentrations of thyroid-binding globulin are increased concomitantly with total or bound thyroid hormone levels (Fig. 4-17, p. 69). Second, thyrotropin, also called thyroid-stimulating hormone (TSH), currently plays a central role in screening and diagnosis of many thyroid disorders. Serum TSH levels in early pregnancy decline because of weak TSH-receptor stimulation from massive quantities of human chorionic gonadotropin (hCG) secreted by placental trophoblast. Because TSH does not cross the placenta, it has no direct fetal effects. During the first 12 weeks of gestation, when hCG serum levels are maximal, thyroid hormone secretion is stimulated. The resulting increased serum free thyroxine levels act to suppress hypothalamic thyrotropin-releasing hormone (TRH) and in turn limit pituitary TSH secretion (Fig. 58-1). Accordingly, TRH is undetectable in maternal serum. Conversely, beginning at midpregnancy, TRH becomes detectable in fetal serum, but levels are static and do not increase with advancing gestation.

**FIGURE 58-1** Gestational age-specific values for serum thyroid-stimulating hormone (TSH) levels (black lines) and free thyroxine (T4) levels (blue lines). Data were derived from 17,298 women tested during pregnancy. For each color, the dark solid lines represent the 50th percentile, whereas the upper and lower light lines represent the 2.5th and 97.5th percentiles, respectively. (Data from Casey, 2005; Dashe, 2005.)
Throughout pregnancy, maternal thyroxine is transferred to the fetus (Calvo, 2002). Maternal thyroxine is important for normal fetal brain development, especially before development of fetal thyroid gland function (Bernal, 2007). And even though the fetal gland begins concentrating iodine and synthesizing thyroid hormone after 12 weeks’ gestation, maternal thyroxine contribution remains important. In fact, maternal sources account for 30 percent of thyroxine in fetal serum at term (Thorpe-Beeston, 1991; Vulsma, 1989). Developmental risks associated with maternal hypothyroidism after midpregnancy, however, remain poorly understood (Morreale de Escobar, 2004).

### Autoimmunity and Thyroid Disease

Most thyroid disorders are inextricably linked to autoantibodies against various cell components. Several of these antibodies variably stimulate thyroid function, block function, or cause thyroid inflammation that may lead to follicular cell destruction. Often, these effects overlap or even coexist.

*Thyroid-stimulating autoantibodies*, also called *thyroid-stimulating immunoglobulins (TSIs)*, bind to the TSH receptor and activate it, causing thyroid hyperfunction and growth. Although these antibodies are identified in most patients with classic Graves disease, simultaneous production of *thyroid-stimulating blocking antibodies* may blunt this effect (Weetman, 2000). *Thyroid peroxidase (TPO)* is a thyroid gland enzyme that normally functions in the production of thyroid hormones. *Thyroid peroxidase antibodies*, previously called *thyroid microsomal autoantibodies*, are directed against TPO and have been identified in 5 to 15 percent of all pregnant women (Abbassi-Ghanavati, 2010; Kuijpens, 2001). These antibodies have been associated in some studies with early pregnancy loss and preterm birth (Abramson, 2001; Negro, 2006; Thangaratinam, 2011). Conversely, in a study with more than 1000 TPO antibody-positive pregnant women, there was no increased risk for preterm birth, however, there was an increased risk for placental abruption (Abbassi-Ghanavati, 2010). These women are also at high risk for postpartum thyroid dysfunction and at lifelong risk for permanent thyroid failure (Premawardhana, 2000; Stagnaro-Green, 2011b).
FIGURE 58-2 Incidence in percent of antithyroid peroxidase antibodies in 16,407 women who are normal or euthyroid, in 233 with isolated maternal hypothyroxinemia (IMH), in 598 with subclinical hypothyroidism (SCH), and in 134 with overt hypothyroidism. (Data from Casey, 2007).

Fetal Microchimerism
Autoimmune thyroid disease is much more common in women than in men. One intriguing explanation for this disparity is fetal-to-maternal cell trafficking (Greer, 2011). When fetal lymphocytes enter the maternal circulation, they can live for more than 20 years. Stem cell interchange also occurs with engraftment in several maternal tissues including the thyroid (Bianchi, 2003; Khosrotehrani, 2004). A high prevalence of Y-chromosome-positive cells has been identified using fluorescence in situ hybridization (FISH) in thyroid glands of women with Hashimoto thyroiditis—60 percent, or Graves disease—40 percent (Renné, 2004). In another study of women giving birth to a male fetus, Lepez and colleagues (2011) identified significantly more circulating male mononuclear cells in those with Hashimoto thyroiditis.

Hyperthyroidism
The incidence of thyrotoxicosis or hyperthyroidism in pregnancy is varied and complicates between 2 and 17 per 1000 births when gestational-age appropriate TSH threshold values are used (Table 58-1). Because normal pregnancy simulates some clinical findings similar to thyroxine (T4) excess, clinically mild thyrotoxicosis may be difficult to diagnose. Suggestive findings include tachycardia that exceeds that usually seen with normal pregnancy, thyromegaly, exophthalmos, and failure to gain weight despite adequate food intake. Laboratory confirmation is by a markedly depressed TSH level along with an elevated serum free T4 (fT4) level. Rarely, hyperthyroidism is
caused by abnormally high serum triiodothyronine (T3) levels—so-called T3-toxicosis.

**Thyrotoxicosis and Pregnancy**

The overwhelming cause of thyrotoxicosis in pregnancy is Graves disease, an organ-specific autoimmune process associated with thyroid-stimulating TSH-receptor antibodies as previously discussed. Because these antibodies are specific to Graves hyperthyroidism, such assays have been proposed for diagnosis, management, and prognosis in pregnancies complicated by hyperthyroidism (Barbesino, 2013). At Parkland Hospital, these receptor antibody assays are generally reserved for cases in which fetal thyrotoxicosis is suspected. With Graves disease, during the course of pregnancy, hyperthyroid symptoms may initially worsen because of chorionic gonadotropin stimulation, but then subsequently diminish with decreases in receptor antibody titers in the second half of pregnancy (Mestman, 2012; Stagnaro-Green, 2011a). Amino and coworkers (2003) have found that levels of blocking antibodies are also decreased during pregnancy.

**Treatment.** Thyrotoxicosis during pregnancy can nearly always be controlled by thionamide drugs. Propylthiouracil (PTU) has been historically preferred because it partially inhibits the conversion of T4 to T3 and crosses the placenta less readily than methimazole. The latter has also been associated with a rare methimazole embryopathy characterized by esophageal or choanal atresia as well as aplasia cutis, a congenital skin defect. Yoshihara and associates (2012) analyzed more than 5000 Japanese women with first-trimester hyperthyroidism and found a twofold increased risk of major fetal malformations in pregnancies exposed to methimazole compared with the risk from PTU. Specifically, seven of nine cases with aplasia cutis and the only case of esophageal atresia were in the group of methimazole-exposed infants.

Until recently, PTU has been the preferred thionamide in the United States (Brent, 2008). In 2009, however, the Food and Drug Administration issued a safety alert on PTU-associated hepatotoxicity. This warning prompted the American Thyroid Association and the American Association of Clinical Endocrinologists (2011) to recommend PTU therapy during the first trimester followed by methimazole beginning in the second trimester. The obvious disadvantage is that this might lead to poorly controlled thyroid function. Accordingly, at Parkland Hospital we continue to prescribe PTU treatment throughout pregnancy.

Transient leukopenia can be documented in up to 10 percent of women taking antithyroid drugs, but this does not require therapy cessation. In 0.3 to 0.4 percent, however, agranulocytosis
develops suddenly and mandates drug discontinuance. It is not dose related, and because of its acute onset, serial leukocyte counts during therapy are not helpful. Thus, if fever or sore throat develops, women are instructed to discontinue medication immediately and report for a complete blood count (Brent, 2008).

As mentioned above, hepatotoxicity is another potentially serious side effect that develops in 0.1 to 0.2 percent. Serial measurement of hepatic enzymes has not been shown to prevent fulminant PTU-related hepatotoxicity. Also, approximately 20 percent of patients treated with PTU develop antineutrophil cytoplasmic antibodies (ANCA). However, only a small percentage of these subsequently develop serious vasculitis (Helfgott, 2002; Kimura, 2013). Finally, although thionamides have the potential to cause fetal complications, these are uncommon. In some cases, thionamides may even be therapeutic, because TSH-receptor antibodies cross the placenta and can stimulate the fetal thyroid gland to cause thyrotoxicosis and goiter.

The initial thionamide dose is empirical. For nonpregnant patients, the American Thyroid Association recommends that methimazole be used at an initial higher daily dose of 10 to 20 mg orally followed by a lower maintenance dose of 5 to 10 mg. If PTU is selected, a dose of 50 to 150 mg orally three times daily may be initiated depending on clinical severity (Bahn, 2011). At Parkland Hospital, we usually initially give 300 or 450 mg of PTU daily in three divided doses for pregnant women. Occasionally, daily doses of 600 mg are necessary. As discussed, we generally do not transition women to methimazole during the second trimester. The goal is treatment with the lowest possible thionamide dose to maintain thyroid hormone levels slightly above or in the high normal range while TSH levels remains suppressed (Bahn, 2011). Serum free T₄ concentrations are measured every 4 to 6 weeks (National Academy of Clinical Biochemistry, 2002).

Subtotal thyroidectomy can be performed after thyrotoxicosis is medically controlled. This seldom is done during pregnancy but may be appropriate for the very few women who cannot adhere to medical treatment or in whom drug therapy proves toxic (Davison, 2001; Stagnaro-Green, 2012a). Surgery is best accomplished in the second trimester. Potential drawbacks of thyroidectomy during pregnancy include inadvertent resection of parathyroid glands and injury to the recurrent laryngeal nerve (Fitzpatrick, 2010).

Thyroid ablation with therapeutic radioactive iodine is contraindicated during pregnancy. These doses may also cause fetal thyroid gland destruction. Thus, when given unintentionally, many clinicians recommend abortion. Any exposed fetus must be carefully evaluated, and the incidence of fetal hypothyroidism depends on gestational age and radioiodine dose (Berlin, 2001). Tran and colleagues (2010) describe a case in which a relatively high dose (19.8 mCi) of radioiodine early in the first trimester resulted in a normal euthyroid male infant assessed at 6 months. The authors hypothesized that the exposure occurred well before thyroid embryogenesis. There is no evidence that radioiodine given before pregnancy causes fetal anomalies if enough time has passed to allow radiation effects to dissipate and if the woman is euthyroid (Ayala, 1998). The International Commission on Radiological Protection has recommended that women avoid pregnancy for 6 months after radioablative therapy (Brent, 2008). Moreover, during lactation, the breast also concentrates a substantial amount of iodide. This may pose neonatal risk due to ¹³¹I-containing milk ingestion and maternal risk from significant breast irradiation. To limit maternal exposure and her cancer risks, a delay of 3 months between lactation and ablation will more reliably ensure complete breast involution (Sisson, 2011).

**Pregnancy Outcome.** Women with thyrotoxicosis have pregnancy outcomes that largely depend on whether metabolic control is achieved. For example, as discussed in Chapter 18 (p. 353), excess thyroxine may cause miscarriage (Anselmo, 2004). In untreated women or in those who...
remain hyperthyroid despite therapy, there is a higher incidence of preeclampsia, heart failure, and adverse perinatal outcomes (Table 58-2). A prospective cohort study from China reported that women with clinical hyperthyroidism had a 12-fold increased risk of delivering an infant with hearing loss (Su, 2011). Perinatal mortality rates varied from 6 to 12 percent in several studies.

**Fetal and Neonatal Effects**

In most cases, the perinate is euthyroid. In some, however, hyper- or hypothyroidism can develop with or without a goiter (Fig. 58-3). Clinical hyperthyroidism develops in approximately 1 percent of neonates born to women with Graves disease (Barbesino, 2013; Fitzpatrick, 2010; Luton 2005). If fetal thyroid disease is suspected, nomograms are available for sonographically measured thyroid volume (Gietka-Czernel, 2012; Ranzini, 2001).
FIGURE 58-3 Term neonate delivered of a woman with a 3-year history of thyrotoxicosis that recurred at 26 weeks’ gestation. The mother was given methimazole 30 mg orally daily and was euthyroid at delivery. Laboratory studies showed that the infant was hypothyroid.

The fetus or neonate who was exposed to excessive maternal thyroxine may have any of several clinical presentations. First, goitrous thyrotoxicosis is caused by placental transfer of thyroid-stimulating immunoglobulins. Nonimmune hydrops and fetal demise have been reported with fetal thyrotoxicosis (Nachum, 2003; Stulberg, 2000). The best predictor of perinatal thyrotoxicosis is presence of thyroid-stimulating TSH-receptor antibodies in women with Graves disease. This is especially true if their levels are more than threefold higher than the upper normal limit (Barbesino, 2013). In a study of 72 pregnant women with Graves disease, Luton and associates (2005) reported that none of the fetuses in 31 low-risk mothers had a goiter, and all were euthyroid at delivery. Low risk was defined by no antithyroid medications during the third trimester or absence of antithyroid antibodies. Conversely, in a group of 41 women who either were taking antithyroid medication at delivery or had thyroid receptor antibodies, 11 fetuses—27 percent—had sonographic evidence of a goiter at 32 weeks’ gestation. Seven of these 11 were determined to be hypothyroid, and the remaining fetuses were hyperthyroid. In response to such results, the American Thyroid Association and American Association of Clinical Endocrinologists (2011) recommend routine evaluation of TSH-receptor antibodies between 22 and 26 weeks’ gestation in women with Graves disease. The American College of Obstetricians and Gynecologists (2013) however, does not recommend such testing because management is rarely changed by the results. If the fetus is thyrotoxic, treatment is by adjustment of maternal thionamide drugs even though maternal thyroid function may be within the targeted range (Duncombe, 2001; Mestman, 2012). Occasionally, neonatal thyrotoxicosis may also require short-course antithyroid drug treatment.
A second presentation is goitrous hypothyroidism caused by fetal exposure to maternally administered thionamides (see Fig. 58-3). Although there are theoretical neurological implications, reports of adverse fetal effects seem to have been exaggerated. Available data indicate that thionamides carry an extremely small risk for causing neonatal hypothyroidism (Momotani, 1997; O’Doherty, 1999). For example, of the 239 treated thyrotoxic women shown in Table 58-1, there was evidence of hypothyroidism in only four infants despite relatively high maternal PTU doses. Furthermore, at least four long-term studies report no abnormal intellectual and physical development of these children (Mestman, 1998). If hypothyroidism is identified, the fetus can be treated by a reduced maternal antithyroid medication dose and injection of intraamnionic thyroxine if necessary.

A third presentation, nongoitrous hypothyroidism, may develop from transplacental passage of maternal TSH-receptor blocking antibodies (Fitzpatrick, 2010; Gallagher, 2001). And finally, fetal thyrotoxicosis after maternal thyroid gland ablation, usually with $^{131}$I radioiodine, may result from transplacental thyroid-stimulating antibodies. In the previously described case of early fetal exposure to radioiodine, neonatal thyroid studies indicated transient hyperthyroidism from maternal transfer of stimulating antibodies (Tran, 2010).

**Fetal Diagnosis.** Evaluation of fetal thyroid function is somewhat controversial. Although fetal thyroid sonographic assessment has been reported in women taking thionamide drugs or those with thyroid-stimulating antibodies, most investigators do not currently recommend this routinely (Cohen, 2003; Luton, 2005). Kilpatrick (2003) recommends umbilical blood sampling and fetal antibody testing only if the mother has previously undergone radioiodine ablation. Because fetal hyper- or hypothyroidism may cause hydrops, growth restriction, goiter, or tachycardia, fetal blood sampling may be appropriate if these are identified (Brand, 2005). The Endocrine Society Clinica Practice Guidelines recommend umbilical blood sampling only when the diagnosis of fetal thyroid disease cannot be reasonably ascertained based on clinical and sonographic data (Garber, 2012). Diagnosis and treatment are considered further in Chapter 16 (p. 324).

**Thyroid Storm and Heart Failure**

Both are acute and life-threatening in pregnancy. Thyroid storm is a hypermetabolic state and is rare in pregnancy. In contrast, pulmonary hypertension and heart failure from cardiomyopathy caused by the profound myocardial effects of thyroxine is common in pregnant women (Sheffield, 2004). As shown in Table 58-2, heart failure developed in 8 percent of 90 women with uncontrolled thyrotoxicosis. In these women, cardiomyopathy is characterized by a high-output state, which may lead to a dilated cardiomyopathy (Fadel, 2000; Klein, 1998). The pregnant woman with thyrotoxicosis has minimal cardiac reserve, and decompensation is usually precipitated by preeclampsia, anemia, sepsis, or a combination of these. Fortunately, thyroxine-induced cardiomyopathy and pulmonary hypertension are frequently reversible (Sheffield, 2004; Siu, 2007; Vydt, 2006).

**Management.** Treatment for thyroid storm or heart failure is similar and should be carried out in an intensive care area that may include special-care units within labor and delivery (Fitzpatrick, 2010; Zeeman, 2003). Shown in Figure 58-4 is our stepwise approach to medical management of thyroid storm or thyrotoxic heart failure. An hour or two after initial thionamide administration, iodide is given to inhibit thyroidal release of $T_3$ and $T_4$. It can be given intravenously as sodium iodide or orally as either saturated solution of potassium iodide (SSKI) or Lugol solution. With a history of iodine-induced anaphylaxis, lithium carbonate, 300 mg every 6 hours, is given instead.
Most authorities recommend dexamethasone, 2 mg intravenously every 6 hours for four doses, to further block peripheral conversion of \( T_4 \) to \( T_3 \). If a \( \beta \)-blocker drug is given to control tachycardia, its effect on heart failure must be considered. Propranolol, labetalol, and esmolol have all been used successfully. Coexisting severe preeclampsia, infection, or anemia should be aggressively managed before delivery is considered.

**FIGURE 58-4** One management method for thyroid storm or thyrotoxic heart failure. gtt = drops;
Hyperemesis Gravidarum and Gestational Transient Thyrotoxicosis

Transient biochemical features of hyperthyroidism may be observed in 2 to 15 percent of women in early pregnancy (Fitzpatrick, 2010). Many women with hyperemesis gravidarum have abnormally high serum thyroxine levels and low TSH levels (Chap. 54, p. 1070). This results from TSH-receptor stimulation from massive—but normal for pregnancy—concentrations of hCG. This transient condition is also termed gestational transient thyrotoxicosis. Even if associated with hyperemesis, antithyroid drugs are not warranted (American College of Obstetricians and Gynecologists, 2013). Serum thyroxine and TSH values become more normal by midpregnancy (Fitzpatrick, 2010).

Thyrotoxicosis and Gestational Trophoblastic Disease

The prevalence of increased thyroxine levels in women with molar pregnancy has been reported to be between 25 and 65 percent (Hershman, 2004). As discussed, abnormally high hCG levels lead to overstimulation of the TSH receptor. Because these tumors are now usually diagnosed early, clinically apparent hyperthyroidism has become less common. With definitive treatment, serum free-T\textsubscript{4} levels usually normalize rapidly in parallel with the decline in hCG concentrations. This is discussed further in Chapter 20 (p. 399).

Subclinical Hyperthyroidism

Third-generation TSH assays with an analytical sensitivity of 0.002 mU/mL permit identification of subclinical thyroid disorders. These biochemically defined extremes usually represent normal biological variations but may herald the earliest stages of thyroid dysfunction. Subclinical hyperthyroidism is characterized by an abnormally low serum TSH concentration in concert with thyroxine hormone levels within the normal reference range (Surks, 2004). Long-term effects of persistent subclinical thyrotoxicosis include osteoporosis, cardiovascular morbidity, and progression to overt thyrotoxicosis or thyroid failure. Casey and Leveno (2006b) identified subclinical hyperthyroidism in 1.7 percent of pregnant women. Importantly, these investigators showed that subclinical hyperthyroidism was not associated with adverse pregnancy outcomes. In separate retrospective analyses of almost 25,000 women who underwent thyroid screening throughout pregnancy, Wilson and colleagues (2012) and Tudela and coworkers (2012) confirmed no relationship between subclinical hyperthyroidism and preeclampsia or gestational diabetes.

The American Thyroid Association and American Association of Clinical Endocrinologists guidelines recommend consideration for treatment of subclinical hyperthyroidism in individuals 65 years or older and in postmenopausal women to improve cardiovascular health and bone mineral density. There is, however, no convincing evidence that subclinical hyperthyroidism should be treated in younger nonpregnant individuals. Thus, treatment seems especially unwarranted in pregnancy because antithyroid drugs may affect the fetus. Women identified with subclinical hyperthyroidism may benefit from periodic surveillance, and approximately half eventually have normal TSH concentrations.

Hypothyroidism

Overt or symptomatic hypothyroidism, as shown in Table 58-3, has been reported to complicate...
between 2 and 10 pregnancies per 1000. It is characterized by insidious nonspecific clinical findings that include fatigue, constipation, cold intolerance, muscle cramps, and weight gain. A pathologically enlarged thyroid gland depends on the etiology of hypothyroidism and is more likely in women in areas of endemic iodine deficiency or those with Hashimoto thyroiditis. Other findings include edema, dry skin, hair loss, and prolonged relaxation phase of deep tendon reflexes. *Clinical or overt hypothyroidism* is confirmed when an abnormally high serum TSH level is accompanied by an abnormally low thyroxine level. *Subclinical hypothyroidism* is defined by an elevated serum TSH level and *normal* serum thyroxine concentration (Surks, 2004). Included in the spectrum of subclinical thyroid disease are asymptomatic individuals with measurable antithyroid peroxidase or antithyroglobulin antibodies. Euthyroid autoimmune thyroid disease represents a new investigative frontier in screening and treatment of thyroid dysfunction during pregnancy.

**Overt Hypothyroidism and Pregnancy**

The most common cause of hypothyroidism in pregnancy is Hashimoto thyroiditis, characterized by glandular destruction from autoantibodies, particularly antithyroid peroxidase antibodies. Clinical identification of hypothyroidism is especially difficult during pregnancy because many of the signs or symptoms are also common to pregnancy itself. Thyroid analyte testing should be performed on symptomatic women or those with a history of thyroid disease (American College of Obstetricians and Gynecologists, 2013). As discussed in *Chapter 18* (p. 353), *severe hypothyroidism* during pregnancy is uncommon, probably because it is often associated with infertility and increased spontaneous abortion rates (Abalovich, 2002; De Groot, 2012). Even women with treated hypothyroidism undergoing in vitro fertilization have a significantly decreased chance of achieving pregnancy (Scoccia, 2012).

**Treatment.** The American Thyroid Association and American Association of Clinical Endocrinologists (2011) recommend replacement therapy for hypothyroidism beginning with levothyroxine in doses of 1 to 2 μg/kg/day or approximately 100 μg daily. Women who are athyreotic after thyroidectomy or radiiodine therapy may require higher doses. Surveillance is with TSH levels measured at 4- to 6-week intervals, and the thyroxine dose is adjusted by 25- to 50-μg increments until TSH values become normal. Pregnancy is associated with an increase
thyroxine requirement in approximately a third of supplemented women (Abalovich, 2010; Alexander, 2004). Because a similar increased requirement is seen in women with postmenopausal hypothyroidism after estrogen replacement, the increased demand in pregnancy is believed to be related to increased estrogen production (Arafah, 2001).

Increased thyroxine requirements begin as early as 5 weeks. In a randomized trial that provided an increased levothyroxine dose at pregnancy confirmation in 60 mothers, Yassa and coworkers (2010) found that a 29- to 43-percent increase in the weekly dose maintained serum TSH values < 5.0 mU/L during the first trimester in all women. Importantly, however, this increase caused TSH suppression in more than a third of women. Significant hypothyroidism may develop early in women without thyroid reserve such as those with a previous thyroidectomy, those with prior radioiodine ablation, or those undergoing assisted reproductive techniques (Alexander, 2004; Loh, 2009; Rotondi, 2004). Anticipatory 25-percent increases in thyroxine replacement at pregnancy confirmation will reduce this likelihood. All other women with hypothyroidism should undergo TSH testing at initiation of prenatal care.

**Pregnancy Outcome with Overt Hypothyroidism.** Observational studies, although limited, indicate that there are excessive adverse perinatal outcomes associated with overt thyroxine deficiency (Table 58-4). With appropriate replacement therapy, however, adverse effects are not increased in most reports (Matalon, 2006; Tan, 2006; Wolfberg, 2005). In one dissenting study, however, there was an increased risk for some pregnancy complications even in women taking replacement therapy (Wikner, 2008). Most experts agree that adequate hormone replacement during pregnancy minimizes the risk of adverse outcomes and most complications (Abalovich, 2002; Fitzpatrick, 2010).

**Fetal and Neonatal Effects.** There is no doubt that maternal and fetal thyroid abnormalities are related. In both, thyroid function is dependent on adequate iodide intake, and its deficiency early in pregnancy can cause both maternal and fetal hypothyroidism. And as discussed, maternal TSH-receptor-blocking antibodies can cross the placenta and cause fetal thyroid dysfunction. Rovelli and colleagues (2010) evaluated 129 neonates born to women with autoimmune thyroiditis. They found that 28 percent had an elevated TSH level on the third or fourth day of life, and 47 percent of these had TPO antibodies on day 15. Still, autoantibodies were undetectable at 6 months of age. It seems paradoxical that despite these transient laboratory findings in the neonate, TPO and antithyroglobulin (TG) antibodies have little or no effect on fetal thyroid function (Fisher, 1997). Indeed, prevalence of fetal hypothyroidism in women with Hashimoto thyroiditis is estimated to be only 1 in 180,000 neonates (Brown, 1996).

**Subclinical Hypothyroidism**

This thyroid condition is common in women, but its incidence can be variable depending on age, race, dietary iodine intake, and serum TSH thresholds used to establish the diagnosis (Cooper, 2012). According to Fitzpatrick and Russell (2010), its prevalence in pregnancy has been estimated to be between 2 and 5 percent. In two large studies totaling more than 25,000 pregnant women screened in the first half of pregnancy, subclinical hypothyroidism was identified in 2.3 percent of women (Casey, 2005; Cleary-Goldman, 2008). The rate of progression to overt thyroid failure is affected by TSH level, age, other disorders such as diabetes, and presence and concentration of antithyroid antibodies. Diez and Iglesias (2004) prospectively followed 93 nonpregnant women with subclinical hypothyroidism for 5 years and reported that in a third, TSH values became normal. In the other two thirds, those women whose TSH levels were 10 to 15 mU/L developed overt disease at a rate of 19 per 100 patient-years. Those women whose TSH levels were < 10 mU/L developed overt hypothyroidism at a rate of 2 per 100 patient-years. The U.S. Preventative Services Task Force on screening for subclinical hypothyroidism also reported that nearly all patients who develop overt hypothyroidism within 5 years have an initial TSH level > 10 mU/L (Helfand, 2004; Karmisholt, 2008). In a 20-year follow-up study of 5805 women who were screened in early pregnancy, only 3 percent developed thyroid disease. Of the 224 women identified with subclinical hypothyroidism during pregnancy, 36 (17 percent) developed thyroid disease in the next 20 years, and most of these had either TPO or TG antibodies during pregnancy (Männistö, 2010). Consequently, the likelihood of progression to overt hypothyroidism during pregnancy in otherwise healthy women with subclinical hypothyroidism seems unlikely.

**Subclinical Hypothyroidism and Pregnancy**

Observational studies spanning almost 25 years and shown in Table 58-4 suggest that subclinical hypothyroidism is likely associated with some adverse pregnancy outcomes. In 1999, interest was heightened by two studies that suggested that undiagnosed maternal thyroid hypofunction may impair fetal neuropsychological development. In one study, Pop and associates (1999) described 22 women who had free T4 levels < 10th percentile in early pregnancy whose offspring were at increased risk for impaired psychomotor development. In the other study, Haddow and coworkers (1999) retrospectively evaluated children born to 48 untreated women whose serum TSH values were > 98th percentile. Some had diminished school performance, reading recognition, and intelligent quotient (IQ) scores. Although described as “subclinically hypothyroid,” these women had an abnormally low mean serum free thyroxine level, and thus, many had overt hypothyroidism.

To further evaluate any adverse effects, Casey and colleagues (2005) identified subclinical
hypothyroidism in 2.3 percent of 17,298 women screened before midpregnancy. As shown in Table 58-5, these women had higher incidences of preterm birth, placental abruption, and admission of infants to the intensive care nursery compared with euthyroid women. In the study of 10,990 participants in the First- and Second-Trimester Evaluation of Risk (FASTER) Trial Cleary-Goldman and associates (2008) did not find such a link with these adverse obstetrical outcomes.

RDS = respiratory distress syndrome.
Data from Casey, 2007.

In a study of 24,883 women screened throughout pregnancy, Wilson and coworkers (2012) found that women identified with subclinical hypothyroidism had an almost twofold increased risk of severe preeclampsia. The authors hypothesized that this was related to endothelial cell dysfunction that has been linked to subclinical hypothyroidism in older patients. In their analysis of the same cohort, Tudela and associates (2012) identified a consistent relationship between increasing TSH level and risk for gestational diabetes. More specifically, 6.3 percent of women with subclinical hypothyroidism were diagnosed with gestational diabetes compared with 4.2 percent in euthyroid women. Nelson and colleagues (2014) evaluated 230 women diagnosed with subclinical hypothyroidism during a prior pregnancy. These women were at increased risk for diabetes and stillbirth in subsequent pregnancies. Although these findings are intriguing, there is currently no evidence that identification and treatment of subclinical hypothyroidism during pregnancy improves these outcomes.

**TSH Level Screening in Pregnancy.** Because of the findings from the 1999 studies cited above, some professional organizations recommend routine prenatal screening and treatment for subclinical hypothyroidism (Gharib, 2005). The American College of Obstetricians and Gynecologists (2013) has reaffirmed that although observational data were consistent with the possibility that subclinical hypothyroidism was associated with adverse neuropsychological development, there have been no interventional trials to demonstrate improvement. The College
thus has consistently recommended against implementation of screening until further studies are
done to validate or refute these findings (American College of Obstetricians and Gynecologists
2012).

Lazarus and colleagues (2012) reported the findings of the international multicenter Controlled
Antenatal Thyroid Screening (CATS) study of thyroid screening and treatment of subclinica
hypothyroidism and isolated maternal hypothyroxinemia during pregnancy. The primary outcome
was offspring IQ scores at 3 years of age. Cognitive function in the children was not improveć with
screening and treatment. A second comparable study is being conducted by the Maternal-Fetal
Medicine Units Network, and the results are anticipated in 2016.

Consequent to the Lazarus study, clinical practice guidelines from the Endocrine Society, The
American Thyroid Association, and the American Association of Clinical Endocrinologists now
uniformly recommend screening only those at increased risk during pregnancy (De Groot, 2012;
Garber, 2012). Furthermore, previous cost-effectiveness analyses that favored a universal
screening strategy are no longer valid since they were based on assumptions of improved
neurodevelopmental outcomes in offspring (Dosiou, 2008; Thung, 2009).

Isolated Maternal Hypothyroxinemia

Women with low serum free $T_4$ values but a normal range TSH level are considered to have
isolated maternal hypothyroxinemia. This was identified by Casey and colleagues (2007) in 1.3
percent of more than 17,000 pregnant women screened at Parkland Hospital before 20 weeks.
Cleary-Goldman and associates (2008) found a 2.1-percent incidence in the FASTER Trial cohort
described earlier. As discussed previously, offspring of women with isolated hypothyroxinemia
have been reported to have neurodevelopmental difficulties at age 3 weeks, 10 months, and 2 years
(Kooistra, 2006; Pop, 1999, 2003). These findings have not stimulated recommendations for
prenatal serum thyroxine screening. Importantly, free $T_4$ estimates by currently available
immunoassays may not be accurate during pregnancy because of sensitivity to alterations in
binding proteins (Lee, 2009).

In a study of 233 women with isolated maternal hypothyroxinemia, Casey and colleagues
(2007) reported that there were no increased adverse perinatal outcomes compared with those of
euthyroid women (see Table 58-5). And, as shown in Figure 58-2, unlike subclinical
hypothyroidism, these women had a low prevalence of antithyroid antibodies. The only other
finding was from Cleary-Goldman and coworkers (2008), who reported a twofold incidence of
fetal macrosomia. Taken together, these findings indicate that isolated maternal hypothyroxinemia
has no apparent serious adverse effects on pregnancy outcome. Finally, the aforementioned CATS
study did not find improved neurodevelopmental outcomes in women with isolated
hypothyroxinemia who were then treated with thyroxine (Lazarus, 2012). Because of this, routine
screening for isolated hypothyroxinemia is not recommended.

Euthyroid Autoimmune Thyroid Disease

Autoantibodies to TPO and TG have been identified in 6 to 20 percent of reproductive-age
women (Thangaratinam, 2011). Most who test positive for such antibodies, however, are
euthyroid. That said, such women are at a two- to fivefold increased risk for early pregnancy loss
(Stagnaro-Green, 2004; Thangaratinam, 2011). The presence of thyroid antibodies has also been
associated with preterm birth (Stagnaro-Green, 2009). In a randomized treatment trial of 115
euthyroid women with TPO antibodies, Negro and coworkers (2006) reported that treatment with
levothyroxine astoundingly reduced the preterm birth rate from 22 to 7 percent. Contrarily, Abbassi-Ghanavati and associates (2010) evaluated pregnancy outcomes in more than 1000 untreated women with TPO antibodies and did not find an increased risk for preterm birth compared with the risk in 16,000 euthyroid women without antibodies. These investigators, however, found a threefold increased risk of placental abruption in these women. As with nonpregnant subjects with TPO antibodies, these women are also at increased risk for progression of thyroid disease and postpartum thyroiditis (Stagnaro-Green, 2012a).

This group of euthyroid women with abnormally high thyroid autoantibody levels represents a new focus of thyroid research. Dosiou and colleagues (2012) performed a cost-effectiveness analysis of universal screening for autoimmune thyroid disease during pregnancy. Their results favored universal screening. There is, however, a paucity of studies that show benefit to identifying and treating euthyroid women with thyroid autoantibodies. Thus, calls for routine antibody screening seem premature. Currently, universal screening for the thyroid autoantibodies is not recommended by any professional organizations (De Groot, 2012; Stagnaro-Green, 2011a, 2012a).

Iodine Deficiency

Decreasing iodide fortification of table salt and bread products in the United States during the past 25 years has led to occasional iodide deficiency (Caldwell, 2005; Hollowell, 1998). Importantly, the most recent National Health and Nutrition Examination survey indicated that, overall, the United States population remains iodine sufficient (Caldwell, 2011). Even so, experts agree that iodine nutrition in vulnerable populations such as pregnant women requires continued monitoring. In 2011 the Office of Dietary Supplements of the National Institutes of Health sponsored a workshop to prioritize iodine research. Participants emphasized the decline in median urinary iodine to 125 μg/L in pregnant women and the serious potential impact on the developing fetus (Swanson, 2012).

Dietary iodine requirements are increased during pregnancy due to increased thyroid hormone production, increased renal losses, and fetal iodine requirements. Adequate iodine is requisite for fetal neurological development beginning soon after conception, and abnormalities are dependent on the degree of deficiency. The World Health Organization (WHO) has estimated that at least 50 million people worldwide have varying degrees of preventable brain damage due to iodine deficiency (Brundtland, 2002). Although it is doubtful that mild deficiency causes intellectual impairment, supplementation does prevent fetal goiter (Stagnaro-Green, 2012b). Severe deficiency, on the other hand, is frequently associated with damage typically encountered with endemic cretinism (Delange, 2001). It is presumed that moderate deficiency has intermediate and variable effects. Berbel and associates (2009) began daily supplementation in more than 300 pregnant women with moderate deficiency at three time periods—4 to 6 weeks, 12 to 14 weeks, and after delivery. They found improved neurobehavioral development scores in offspring of women supplemented with 200 μg potassium iodide very early in pregnancy. Similarly, Velasco and coworkers (2009) found improved Bayley Psychomotor Development scores in offspring of women supplemented with 300 μg of iodide in the first trimester. In contrast, Murcia and colleagues (2011) identified lower psychomotor scores in 1-year-old infants whose mothers reported daily supplementation of more than 150 μg. There are two ongoing randomized controlled trials of iodine supplementation in mildly to moderately iodine-deficient pregnant women in India and Thailand. These studies should provide needed answers as to whether iodine supplementation in these women is beneficial (Pearce, 2013).
The Institute of Medicine (2001) recommends daily iodine intake during pregnancy of 220 μg/day, and 290 μg/day for lactating women (Chap. 9, p. 180). The Endocrine Society (De Groot 2012) recommends an average iodine intake of 150 μg per day in childbearing-aged women, and this should be increased to 250 μg during pregnancy and breast feeding. The American Thyroid Association has recommended that 150 μg of iodine be added to prenatal vitamins to achieve this average daily intake (Becker, 2006). According to Leung and coworkers (2011), however, only 51 percent of the prenatal multivitamins in the United States contain iodine. It has even been suggested that because most cases of maternal hypothyroxinemia worldwide are related to relative iodine deficiency, supplementation may obviate the need to consider thyroxine treatment in such women (Gyamfi, 2009).

On the other hand, experts caution against oversupplementation. Teng and associates (2006) contend that excessive iodine intake—defined as > 300 μg/day—may lead to subclinical hypothyroidism and autoimmune thyroiditis. And the Endocrine Society, in accordance with the WHO, advises against exceeding twice the daily recommended intake of iodine, or 500 μg/day (De Groot, 2012; Leung, 2011).

**Congenital Hypothyroidism**

Because the clinical diagnosis of hypothyroidism in neonates is usually missed, universal newborn screening was introduced in 1974 and is now required by law in all states. Congenital hypothyroidism develops in approximately 1 in 3000 newborns and is one of the most preventable causes of mental retardation (LaFranchi, 2011). Developmental disorders of the thyroid gland such as agenesis and hypoplasia account for 80 to 90 percent of these cases (LaFranchi, 2011; Topaloglu, 2006). The exact underlying etiology of thyroid dysgenesis remains unknown. The remaining primary congenital hypothyroidism cases are caused by hereditary defects in thyroid hormone production. The list of identified gene mutations that cause hypothyroidism continues to grow rapidly (Moreno, 2008).

Early and aggressive thyroxine replacement is critical for infants with congenital hypothyroidism. Still, some infants identified by screening programs with severe congenital hypothyroidism who were treated promptly will exhibit cognitive deficits into adolescence (Song, 2001). Therefore, in addition to timing of treatment, the severity of congenital hypothyroidism is an important factor in long-term cognitive outcomes (Kempers, 2006). Accordingly, in infants with screening results suggestive of severe hypothyroidism, therapy should be started immediately without waiting for confirmatory results (Abduljabbar, 2012). Olivieri and colleagues (2002) reported that 8 percent of 1420 infants with congenital hypothyroidism also had other major congenital malformations.

**Postpartum Thyroiditis**

Transient autoimmune thyroiditis is consistently found in approximately 5 to 10 percent of women during the first year after childbirth (Amino, 2000; Stagnaro-Green, 2011b, 2012a). Postpartum thyroid dysfunction with an onset within 12 months includes hyperthyroidism, hypothyroidism, or both. The propensity for thyroiditis antedates pregnancy and is directly related to increasing serum levels of thyroid autoantibodies. Up to 50 percent of women who are thyroid-antibody positive in the first trimester will develop postpartum thyroiditis (Stagnaro-Green, 2012a). In a Dutch study of 82 women with type 1 diabetes, postpartum thyroiditis developed in 16 percent and was threefold higher than in the general population (Gallas, 2002). Importantly, 46 percent of those identified
Clinical Manifestations
In clinical practice, postpartum thyroiditis is diagnosed infrequently because it typically develops months after delivery and causes vague and nonspecific symptoms that often are thought to be stresses of motherhood (Stagnaro-Green, 2004). The clinical presentation varies, and classically there are two recognized clinical phases that may develop in succession. The first and earliest is destruction-induced thyrotoxicosis with symptoms from excessive release of hormone from glandular disruption. The onset is abrupt, and a small, painless goiter is commonly found. Although there may be many symptoms, only fatigue and palpitations are more frequent in thyrotoxic women compared with normal controls. This thyrotoxic phase usually lasts only a few months. Thionamides are ineffective, and if symptoms are severe, a β-blocker agent may be given. The second and usually later phase is clinical hypothyroidism from thyroiditis between 4 and 8 months postpartum. Thyromegaly and other symptoms are common and more prominent than during the thyrotoxic phase. Thyroxine replacement with 25 to 75 μg/day is typically given for 6 to 12 months.

Stagnaro-Green and associates (2011b) reported postpartum follow-up from 4562 Italian pregnant women who had been screened for thyroid disease in pregnancy. Serum TSH and anti-TPO antibody levels were measured again at 6 and 12 months. Overall, two thirds of 169 women (3.9 percent) with postpartum thyroiditis were identified to have hypothyroidism only. The other third were diagnosed with hyperthyroidism, but only 14 percent of all women demonstrated the “classic” biphasic progression described above. These findings are consistent with data compiled from 20 other studies between 1982 and 2008 (Stagnaro-Green, 2012a).

Importantly, women who experience either type of postpartum thyroiditis have an approximately 30-percent risk of eventually developing permanent hypothyroidism, and the annual progression rate is 3.6 percent (Lucas, 2005; Muller, 2001; Premawardhana, 2000). Women at increased risk for developing hypothyroidism are those with higher titers of thyroid antibodies and higher TSH levels during the initial hypothyroid phase. Others may develop subclinical disease but half of those with thyroiditis who are positive for TPO antibodies develop permanent hypothyroidism by 6 to 7 years (Stagnaro-Green, 2012a).

An association between postpartum thyroiditis and postpartum depression has been proposed but remains unresolved. Lucas and coworkers (2001) found a 1.7-percent incidence of postpartum depression at 6 months in women with thyroiditis as well as in controls. Pederson and colleagues (2007) found a significant correlation between abnormal scores on the Edinburgh Postnatal Depression Scale and total thyroxine values in the low normal range during pregnancy in 31 women. Similarly unsettled is the link between depression and thyroid antibodies. Kuijpens and associates (2001) reported that TPO antibodies were a marker for postpartum depression in euthyroid women. In a randomized trial, Harris and coworkers (2002) reported no difference in postpartum depression in 342 women with TPO antibodies who were given either levothyroxine or placebo.

Nodular Thyroid Disease
Thyroid nodules can be found in 1 to 2 percent of reproductive-aged women (Fitzpatrick, 2010). Management of a palpable thyroid nodule during pregnancy depends on gestational age and mass size. Small nodules detected by sensitive sonographic methods are more common during pregnancy in some populations. For example, Kung and associates (2002) used high-resolution sonography
and found that 15 percent of Chinese women had nodules larger than 2 mm in diameter. Almost half were multiple, and the nodules usually enlarged modestly across pregnancy and did not regress postpartum. Biopsy of those > 5 mm$^3$ that persisted at 3 months usually showed nodular hyperplasia, and none was malignant. In some studies, however, up to 40 percent of solitary nodules were malignant (Doherty, 1995; Rosen, 1986). Even so, most were low-grade neoplasms.

Evaluation of thyroid nodules during pregnancy should be similar to that for nonpregnant patients. As discussed in Chapter 46 (p. 934), most recommend against radioiodine scanning in pregnancy despite the fact that tracer doses used are associated with minimal fetal irradiation (Popoveniuc, 2012). Sonographic examination reliably detects nodules larger than 0.5 cm, and their solid or cystic structure also is determined. According to the American Association of Clinical Endocrinologists, sonographic characteristics associated with malignancy include hypoechogenic pattern, irregular margins, and microcalcifications (Gharib, 2005). Fine-needle aspiration (FNA) is an excellent assessment method, and histological tumor markers and immunostaining are reliable to evaluate for malignancy (Bartolazzi, 2001; Hegedüs, 2004). If the FNA biopsy shows a follicular lesion, surgery may be deferred until after delivery.

Evaluation of thyroid cancer involves a multidisciplinary approach (American College of Obstetricians and Gynecologists, 2013). Most thyroid carcinomas are well differentiated and pursue an indolent course. When thyroid malignancy is diagnosed during the first or second trimester, thyroidectomy may be performed before the third trimester (Chap. 63, p. 1231). In women without evidence of an aggressive thyroid cancer, or in those diagnosed in the third trimester, surgical treatment can be deferred to the immediate postpartum period (Gharib, 2010).

### PARATHYROID DISEASES

The function of parathyroid hormone (PTH) is to maintain extracellular fluid calcium concentration. This 115-amino acid hormone acts directly on bone and kidney and indirectly on small intestine through its effects on synthesis of vitamin D (1,25$\text{[OH}_2\text{-D}$) to increase serum calcium. Secretion is regulated by serum ionized calcium concentration through a negative feedback system. Calcitonin is a potent parathyroid hormone that acts as a physiological parathyroid hormone antagonist. The interrelationships between these hormones, calcium metabolism, and PTH-related protein produced by fetal tissue are discussed in Chapter 4 (p. 70).

Fetal calcium needs—300 mg/day in late pregnancy and a total of 30 g—as well as increased renal calcium loss from augmented glomerular filtration, substantively increase maternal calcium demands. Pregnancy is associated with a twofold rise in serum concentrations of 1,25-dihydroxyvitamin D, which increases gastrointestinal calcium absorption. The effectuating hormone is probably of placental and decidual origin because maternal PTH levels are low normal or decreased during pregnancy (Cooper, 2011; Molitch, 2000). Total serum calcium levels decline with serum albumin concentrations, but ionized calcium levels remain unchanged. Vargas Zapata (2004), and others, have suggested a role for insulin-like growth factor-1 (IGF-1) in maternal calcium homeostasis and bone turnover, especially in mothers with low calcium intake.

### Hyperparathyroidism

Hypercalcemia is caused by hyperparathyroidism or cancer in 90 percent of cases. Primary hyperparathyroidism is reported most often in women older than 50 (Miller, 2008). Because many
automated laboratory systems include serum calcium measurement, hyperparathyroidism has changed from being a condition defined by symptoms to one that is discovered on routine screening (Pallan, 2012). It has a reported prevalence of 2 to 3 per 1000 women, but some have estimated the rate to be as high as 14 per 1000 when asymptomatic cases are included (Farford, 2007; Schnatz, 2005). Almost 80 percent are caused by a solitary adenoma, and another 15 percent by hyperfunction of all four glands. In the remainder, a malignancy and the cause of increased serum calcium levels are obvious. Of note, PTH produced by tumors is not identical to the natural hormone and may not be detected by routine assays.

In most patients, the serum calcium level is only elevated to within 1 to 1.5 mg/dL above the upper normal limit. This may help to explain why only 20 percent of those who have abnormally elevated levels are symptomatic (Bilezikian, 2004). In a fourth, however, symptoms become apparent when the serum calcium level continues to rise. Hypercalcemic crisis manifests as stupor, nausea, vomiting, weakness, fatigue, and dehydration.

All women with symptomatic hyperparathyroidism should be surgically treated. Guidelines for management in nonpregnant patients were revised after the Third International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism (Bilezikian, 2009). Indications for parathyroidectomy include a serum calcium level 1.0 mg/dL above the upper normal range, a calculated creatinine clearance less than 60 mL/min, reduced bone density, or age < 50 years. Those not meeting these criteria should undergo annual calcium and creatinine level measurement and bone density assessment every 1 to 2 years (Pallan, 2012).

Hyperparathyroidism in Pregnancy

In their review, Schnatz and Thaxton (2005) found fewer than 200 reported cases complicating pregnancy. As in nonpregnant patients, hyperparathyroidism is usually caused by a parathyroid adenoma. Gravidas with ectopic parathyroid hormone production and rare cases of parathyroid carcinoma have been reported (Montoro, 2000). Symptoms include hyperemesis, generalized weakness, renal calculi, and psychiatric disorders. Occasionally, pancreatitis is the presenting finding (Cooper, 2011; Dahan, 2001).

Pregnancy theoretically improves hyperparathyroidism because of significant calcium shunting to the fetus and augmented renal excretion (Power, 1999). When the “protective effects” of pregnancy are withdrawn, however, there is significant danger of postpartum hypercalcemic crisis. This life-threatening complication can be seen with serum calcium levels greater than 14 mg/dL and is characterized by nausea, vomiting, tremors, dehydration, and mental status changes (Malekar-Raikar, 2011). Early reports described excessive stillbirths and preterm deliveries in pregnancies complicated by hyperparathyroidism (Shangold, 1982). More recent reports, however, described lower rates of stillbirth, neonatal death, and neonatal tetany (Kovacs, 2011). Other fetal complications include miscarriage, fetal-growth restriction, and low birthweight (Chamarthi, 2011). Schnatz (2005) reported a 25-percent incidence of preeclampsia.

Management in Pregnancy. Surgical removal of a symptomatic parathyroid adenoma is preferable. This should prevent fetal and neonatal morbidities, as well as postpartum parathyroid crises (Kovacs, 2011). Elective neck exploration during pregnancy is usually well tolerated, even in the third trimester (Graham, 1998; Kort, 1999; Schnatz, 2005). In one woman, a mediastinal adenoma was removed at 23 weeks (Rooney, 1998).

None of the three International Workshop Conferences on Asymptomatic Hyperparathyroidism have addressed its management during pregnancy (Bilezikian, 2009). Medical management may be appropriate in asymptomatic pregnant women with mild hypercalcemia. If so, patients are
carefully monitored in the postpartum period for hypercalcemic crisis (Kovacs, 2011). Initial medical management might include calcitonin to decrease skeletal calcium release, or oral phosphate, 1 to 1.5 g daily in divided doses to bind excess calcium. For women with dangerously elevated serum calcium levels or those who are mentally obtunded with hypercalcemic crisis, emergency treatment is instituted. Diuresis with intravenous normal saline is begun so that urine flow exceeds 150 mL/hr. Furosemide is given in conventional doses to block tubular calcium reabsorption. Importantly, hypokalemia and hypomagnesemia should be prevented. Adjunctive therapy includes mithramycin, which inhibits bone resorption.

**Neonatal Effects.** Normally, cord blood calcium levels are higher than maternal levels (Chap. 7, p. 135). With maternal hyperparathyroidism, abnormally elevated maternal and thence fetal levels further suppress fetal parathyroid function. Because of this, after birth, there is a rapidly decreasing newborn calcium level, and 15 to 25 percent of these infants develop severe hypocalcemia with or without tetany (Molitch, 2000). Neonatal hypoparathyroidism caused by maternal hyperparathyroidism is usually transient and should be treated with calcium and calcitriol. Calcitriol will not be effective in preterm infants, however, because the intestinal vitamin D receptor is not sufficiently expressed (Kovacs, 2011). Neonatal tetany or seizures should stimulate an evaluation for maternal hyperparathyroidism (Beattie, 2000; Ip, 2003; Jaafar, 2004).

Hypoparathyroidism

The most common cause of hypocalcemia is hypoparathyroidism that usually follows parathyroid or thyroid surgery. Hypoparathyroidism is estimated to follow up to 7 percent of total thyroidectomies (Shoback, 2008). It is rare and characterized by facial muscle spasms, muscle cramps, and paresthesias of the lips, tongue, fingers, and feet. This can progress to tetany and seizures. Chronically, hypocalcemic pregnant women may also have a fetus with skeletal demineralization resulting in multiple bone fractures in the neonatal period (Alikasifoglu, 2005).

Maternal treatment includes 1,25-dihydroxyvitamin D₃ (calcitriol), dihydrotachysterol, or large vitamin D doses of 50,000 to 150,000 U/day; calcium gluconate or calcium lactate in doses of 3 to 5 g/day; and a low-phosphate diet. The therapeutic challenge in women with known hypoparathyroidism is management of blood calcium levels. The goal during pregnancy is maintenance of the corrected calcium level in the low normal range. It is possible that the increased calcium absorption typical of pregnancy will result in lower calcium requirements or that the fetal demand for calcium will result in increased need. Since both scenarios are possible, it is best to carefully monitor the corrected serum calcium on a frequent, perhaps monthly, basis throughout pregnancy (Cooper, 2011; Kovacs, 2011). The fetal risks from large doses of vitamin D have not been established.

Pregnancy-Associated Osteoporosis

Even with remarkably increased calcium requirements, it is uncertain whether pregnancy causes osteopenia in most women (Kaur, 2003; To, 2003). In one study of 200 pregnant women in which bone mass was measured using quantitative ultrasonometry of the calcaneus, Kraemer and colleagues (2011) demonstrated a decline in bone density during pregnancy. Women who breast fed, carried twin pregnancies, or had a low body mass index (BMI) were at higher risk of bone loss. From their review, Thomas and Weisman (2006) cite a 3- to 4-percent average reduction in
bone-mineral density during pregnancy. Lactation also represents a period of negative calcium balance that is corrected through maternal skeletal resorption. Feigenberg and coworkers (2008) found cortical bone mass reductions using ultrasound in young primiparas in the puerperium compared with nulligravid controls. Rarely, some women develop idiopathic osteoporosis while pregnant or lactating. Its incidence is estimated to be 4 per million women (Hellmeyer, 2007).

The most common symptom of osteoporosis is back pain in late pregnancy or postpartum. Other symptoms are hip pain, either unilateral or bilateral, and difficulty in weight bearing until nearly immobilized (Maliha, 2012). In more than half of women, no apparent reason for osteopenia is found. Some known causes include heparin, prolonged bed rest, and corticosteroid therapy (Cunningham, 2005; von Mandach, 2003). In a few cases, overt hyperparathyroidism or thyrotoxicosis eventually develops.

Treatment is problematical and includes calcium and vitamin D supplementation as well as standard pain management. Shown in Figure 58-5 is a hip radiograph from a woman treated at Parkland Hospital during the third trimester for transient osteoporosis of pregnancy.

![Figure 58-5](image-url) Anteroposterior plain radiograph with abdominal shielding of a 25-year-old patient’s hips at 26-weeks’ gestation. She complained of left hip and knee pain and progressive weakness. Her transient osteoporosis of the left femur responded over 3 months to physical therapy combined with vitamin D and calcium supplementation.

For women with pregnancy-associated osteopenia, long-term surveillance indicates that although bone density improves, these women and their offspring may have chronic osteopenia (Carbone, 1995). There is an ongoing randomized, placebo-controlled trial of vitamin D supplementation in pregnant women to determine its effect on neonatal bone mineral content as assessed by dual-energy x-ray absorptiometry (DEXA) (Harvey, 2012).

ADRENAL GLAND DISORDERS
Pregnancy has profound effects on adrenal cortical secretion and its control or stimulation. These interrelationships were reviewed by Lekarev and New (2011) and are discussed in detail in Chapter 4 (p. 70).

**Pheochromocytoma**

These tumors are clinically uncommon and complicate approximately 1 per 10,000 pregnancies. Notably, they are found in 0.1 percent of hypertensive patients (Abdelmannan, 2011). However, they are more commonly found at autopsy with infrequent clinical recognition. Pheochromocytomas are chromaffin tumors that secrete catecholamines and usually are located in the adrenal medulla, although 10 percent are located in sympathetic ganglia. They are called the 10-percent tumor because approximately 10 percent are bilateral, 10 percent are extraadrenal, and 10 percent are malignant. These tumors can be associated with medullary thyroid carcinoma and hyperparathyroidism in some of the autosomally dominant or recessive multiple endocrine neoplasia syndromes, as well as in neurofibromatosis and von Hippel-Lindau disease.

Symptoms are usually paroxysmal and manifest as hypertensive crisis, seizure disorders, or anxiety attacks. Hypertension is sustained in 60 percent of patients, but half of these also have paroxysmal crises. Other symptoms during paroxysmal attacks are headaches, profuse sweating, palpitations, chest pain, nausea and vomiting, and pallor or flushing.

The standard screening test is quantification of catecholamine metabolites in a 24-hour urine specimen (Abdelmannan, 2011). Diagnosis is established by measurement of a 24-hour urine collection with at least two of three assays for free catecholamines, metanephrines, or vanillylmandelic acid (VMA). Determination of plasma catecholamine levels may be accurate but is associated with technical difficulties (Conlin, 2001; Lenders, 2002). Boyle and colleagues (2007) determined that measurement of urinary free metanephrine was superior to assessment of a VMA or urinary or plasma catecholamine level. In nonpregnant patients, adrenal localization is usually successful with either computed tomography (CT) or magnetic resonance (MR) imaging. For most cases, preferred treatment is laparoscopic adrenalectomy (Lal, 2003).

**Pheochromocytoma Complicating Pregnancy**

These tumors are rare but result in dangerous pregnancy complications. Geelhoed (1983) provided an earlier review of 89 cases in which 43 mothers died. Maternal death was much more common if the tumor was not diagnosed antepartum—58 versus 18 percent. As seen in Table 58-6, maternal mortality rates are now lower but still formidable. In their review of 60 cases, Sarathi and associates (2010) confirmed that antepartum diagnosis is the most important determinant of maternal mortality risk. Maternal death was rare if the diagnosis is made antepartum.

Diagnosis of pheochromocytoma in pregnancy is similar to that for nonpregnant patients. MR imaging is the preferred imaging technique because it almost always locates adrenal and extraadrenal pheochromocytomas (Fig. 58-6) (Manger, 2005). In many cases, the principal challenge is to differentiate preeclampsia from the hypertensive crisis caused by pheochromocytoma. Desai and coworkers (2009) describe a woman who was initially treated for severe preeclampsia, suffered an intrapartum fetal death, and was then treated for presumed peripartum cardiomyopathy. When she returned 1 week later with paroxysmal hypertension, pheochromocytoma was diagnosed and her blood pressure and ventricular function returned to normal after tumor resection. Grimbert and colleagues (1999) diagnosed two pheochromocytomas during 56 pregnancies in 30 women with von Hippel-Lindau disease.

Management
Immediate control of hypertension and symptoms with an α-adrenergic blocker such as phenoxybenzamine is imperative. The dose is 10 to 30 mg, two to four times daily. After α-blockade is achieved, β-blockers may be given for tachycardia. In many cases, surgical exploration and tumor removal are performed during pregnancy, preferably during the second trimester (Dong, 2014; Miller, 2005). Successful laparoscopic removal of adrenal tumors has become the norm (Junglee, 2007; Kim, 2006; Miller, 2012; Zuluaga-Gómez, 2012). If diagnosed later in pregnancy, either planned cesarean delivery with tumor excision or postpartum resection is appropriate.

Recurrent tumors are troublesome, and even with good blood pressure control, dangerous peripartum hypertension may develop. We have cared for three women in whom recurrent pheochromocytoma was identified during pregnancy. Hypertension was managed with phenoxybenzamine in all three. Two infants were healthy, but a third was stillborn in a mother with a massive tumor burden who was receiving phenoxybenzamine, 100 mg daily. In all three women, tumor was resected postpartum.
Cushing Syndrome

This syndrome is rare and has an annual incidence of 2 to 3 per million. The female:male ratio is 3:1 (Steffenson, 2010). Most cases are iatrogenic from long-term corticosteroid treatment. However, endogenous Cushing syndrome is typically due to Cushing disease, which is bilateral adrenal hyperplasia stimulated by corticotropin-producing pituitary adenomas. Most are small microadenomas < 1 cm, and half measure ≤ 5 mm. Rarely, abnormal secretion of hypothalamic corticotropin-releasing factor may cause corticotropic hyperplasia. Such hyperplasia may also be caused by nonendocrine tumors that produce polypeptides similar to either corticotropin-releasing factor or corticotropin. Less than a fourth of cases of Cushing syndrome are corticotropin independent, and most of these are caused by an adrenal adenoma. Tumors are usually bilateral, and half are malignant. Occasionally, associated androgen excess may lead to severe virilization (Danilowicz, 2002).

The typical cushingoid body habitus is caused by adipose tissue deposition that characteristically results in moon facies, a buffalo hump, and truncal obesity. Fatigability and weakness, hypertension, hirsutism, and amenorrhea are each encountered in 75 to 85 percent of nonpregnant patients (Hatipoglu, 2012; Williams, 2001). Personality changes, easy bruisability, and cutaneous striae are common. Up to 60 percent may have impaired glucose tolerance. Diagnosis is verified by elevated plasma cortisol levels that cannot be suppressed by dexamethasone or by elevated 24-hour urine free cortisol excretion (Boscaro, 2001). Neither test is totally accurate, and both are more difficult to interpret in obese patients. CT and MR imaging are used to localize pituitary and adrenal tumors or hyperplasia.

Cushing Syndrome and Pregnancy

Because most women have corticotropin-dependent Cushing syndrome, associated androgen excess may cause anovulation, and pregnancy is rare. In their review, Lekarev and New (2011) identified fewer than 140 reported cases of Cushing syndrome in pregnancy. These differ compared with nonpregnant women in that half are caused by corticotropin-independent adrenal adenomas (Abdelmannan, 2011; Klibanski, 2006). Approximately 30 percent of cases are from a pituitary adenoma, and 10 percent from adrenal carcinomas (Lekarev, 2011; Lindsay, 2005). All reports stress difficulties in diagnosis because of pregnancy-induced increases in plasma cortisol, corticotropin, and corticotropin-releasing factor levels. Measurement of 24-hour urinary free cortisol excretion is recommended, with consideration for normal elevation in pregnancy.

Pregnancy outcomes in women with Cushing syndrome are listed in Table 58-7. Heart failure is common during pregnancy and is a major cause of maternal mortality (Buescher, 1992). Hypercortisolism in pregnancy may also cause poor wound healing, osteoporotic fracture, and psychiatric complications (Kamoun, 2014).

| TABLE 58-7. Maternal and Perinatal Complications in Pregnancies Complicated by Cushing Syndrome |
Long-term medical therapy for Cushing syndrome usually is ineffective, and definitive therapy is resection of the pituitary or adrenal adenoma or bilateral adrenalectomy for hyperplasia (Lekarev, 2011; Motivala, 2011). During pregnancy, management of hypertension in mild cases may suffice until delivery. In their review, Lindsay and associates (2005) described primary medical therapy in 20 women with Cushing syndrome. Most were successfully treated with metyrapone as an interim treatment until definitive surgery after delivery. A few cases were treated with oral ketoconazole. However, because this drug also blocks testicular steroidogenesis, treatment during pregnancy with a male fetus is worrisome. Mifepristone, the norethindrone derivative used for abortion and labor induction, has shown promise for treating Cushing disease but should not be used in pregnancy for obvious reasons. If necessary, pituitary adenomas can be treated by transsphenoidal resection (Boscaro, 2001; Lindsay, 2005). Unilateral adrenalectomy has been safely performed in the early third trimester and can also be curative (Abdelmannan, 2011).

## Adrenal Insufficiency—Addison Disease

Primary adrenocortical insufficiency is rare because more than 90 percent of total gland volume must be destroyed for symptoms to develop. Autoimmune adrenalitis is the most common cause in the developed world, but tuberculosis is a more frequent etiology in resource-poor countries (Kamoun, 2014). There is an increased incidence of concurrent Hashimoto thyroiditis, premature ovarian failure, type 1 diabetes, and Graves disease. These polyglandular autoimmune syndromes also include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis.

Untreated adrenal hypofunction frequently causes infertility, but with replacement therapy, ovulation is restored. The incidence of primary adrenal insufficiency has been cited as being as
high as 1 in 3000 births in Norway (Lekarev, 2011). If untreated, symptoms often include weakness, fatigue, nausea and vomiting, and weight loss (Mestman, 2002). Because serum cortisol levels are increased during pregnancy, the finding of a low value should prompt an adrenocorticotropic hormone (ACTH) stimulation test to document the lack of response to infused corticotropin (Salvatori, 2005).

In a large Swedish cohort study, 1188 women with Addison disease were compared with more than 11,000 age-matched controls who delivered between 1973 and 2006. Women diagnosed with adrenal insufficiency within 3 years of delivery were twice as likely to deliver preterm, were three times more likely to deliver a low-birthweight infant, and were more likely to undergo cesarean delivery (Björnsdottir, 2010). Most pregnant women with Addison disease are already taking cortisone-like drugs. These should be continued and women observed for evidence of either inadequate or excessive corticosteroid replacement. During labor, delivery, and postpartum, or after a surgical procedure, corticosteroid replacement must be increased appreciably to approximate the normal adrenal response—so-called stress doses. Hydrocortisone, 100 mg, is usually given intravenously every 8 hours. It is important that shock from causes other than adrenocortical insufficiency—for example, hemorrhage or sepsis—be recognized and treated promptly.

**Primary Aldosteronism**

Hyperaldosteronism is caused by an adrenal aldosteronoma in approximately 75 percent of cases. Idiopathic bilateral adrenal hyperplasia comprise the remainder, except for rare cases of adrenal carcinoma (Abdelmannan, 2011; Ganguly, 1998). Findings include hypertension, hypokalemia, and muscle weakness. High serum or urine levels of aldosterone confirm the diagnosis.

In normal pregnancy, as discussed in Chapter 4 (p. 61), progesterone blocks aldosterone action, and thus there are very high levels of aldosterone (Appendix, p. 1290). Accordingly, the diagnosis of hyperaldosteronism during pregnancy can be difficult. Since renin levels are suppressed in pregnant women with hyperaldosteronism, a plasma aldosterone-to-renin activity ratio may be helpful for diagnosis (Kamoun, 2014). Medical management includes potassium supplementation and antihypertensive therapy. In many cases, hypertension responds to spironolactone, but β-blockers or calcium-channel blockers may be preferred because of the potential fetal antiandrogenic effects of spironolactone. Mascetti and coworkers (2011) reported successful use of amiloride in a pregnant woman. Use of eplerenone, a mineralocorticoid receptor antagonist, has also been reported (Cabassi, 2012). Tumor resection is curative, and laparoscopic adrenalectomy has been shown to be safe (Kamoun, 2014; Kosaka, 2006; Miller, 2012).

**PITUITARY DISORDERS**

There is impressive pituitary enlargement during pregnancy, predominately from lactotrophic cellular hyperplasia induced by estrogen stimulation (Chap. 4, p. 67).

**Prolactinomas**

These adenomas are found often in nonpregnant women since the advent of widely available serum prolactin assays. Serum levels less than 25 pg/mL are considered normal in nonpregnant women
Adenoma symptoms and findings include amenorrhea, galactorrhea, and hyperprolactinemia. Tumors are classified arbitrarily by their size measured by CT or MR imaging. A microadenoma is ≤ 10 mm, and a macroadenoma is > 10 mm. Treatment for microadenomas is usually with bromocriptine, a dopamine agonist and powerful prolactin inhibitor, which frequently restores ovulation. For suprasellar macroadenomas, most recommend surgical resection before pregnancy is attempted (Schlechte, 2007).

In a pooled analysis of more than 500 pregnant women with prolactinomas, only 1.4 percent with microadenomas developed symptomatic enlargement during pregnancy (Molitch, 2003). Symptomatic enlargement of macroadenomas, however, is more frequent and was found in 26 percent of 84 pregnant women included in this analysis. Schlechte (2007) also reported that 15 to 35 percent of suprasellar macroadenomas have tumor enlargement that causes visual disturbances, headaches, and diabetes insipidus.

Gillam and colleagues (2006) recommend that pregnant women with microadenomas be queried regularly for headaches and visual symptoms. Those with macroadenomas should be followed more closely and have visual field testing during each trimester. CT or MR imaging is recommended only if symptoms develop. Serial serum prolactin levels are of little use because of normal increases during pregnancy (Appendix, p. 1291). Symptomatic tumor enlargement should be treated immediately with a dopamine antagonist such as bromocriptine or cabergoline. The safety of bromocriptine in pregnancy is well established. It is less well known for cabergoline, which is increasingly used in nonpregnant women because it is better tolerated and more effective. It is generally considered safe for use in pregnancy (Briggs, 2011). Lebbe and colleagues (2010) described 100 pregnancies exposed to cabergoline and found no adverse effects. Similar findings were reported in 85 exposed Japanese pregnant women (Ono, 2010). Surgery is recommended for women with no response, and Gondim and associates (2003) have described transnasal transseptal endoscopic resection.

### Acromegaly

This is caused by excessive growth hormone, usually from an acidophilic or a chromophobic pituitary adenoma. In normal pregnancy, pituitary growth hormone levels decrease as placental epitopes are secreted. Diagnosis is confirmed by the failure of an oral glucose tolerance test to suppress pituitary growth hormone (Melmed, 2006). There have been fewer than 100 cases of acromegaly reported during pregnancy (Motivala, 2011). Pregnancy is probably rare in women with acromegaly, because half are hyperprolactinemic and anovulatory. In a recent report describing 46 pregnant women with acromegaly, Caron and coworkers (2010) concluded that such women were at marginally increased risk for gestational diabetes and hypertension.

Management is similar to that for prolactinomas, with close monitoring for symptoms of tumor enlargement. Dopamine agonist therapy is not as effective as it is for prolactinomas. And transsphenoidal resection, generally considered first-line treatment outside of pregnancy, may be necessary for symptomatic tumor enlargement during pregnancy (Motivala, 2011). Guven and associates (2006) reported a case of pituitary apoplexy necessitating emergent transsphenoidal adenoma resection and cesarean delivery at 34 weeks. Successful treatment of pregnant women with the somatostatin-receptor ligand octreotide and with the GH analogue pegvisomant has also been reported (Brian, 2007; Herman-Bonert, 1998; Neal, 2000).

### Diabetes Insipidus
The vasopressin deficiency evident in diabetes insipidus is usually due to a hypothalamic or pituitary stalk disorder rather than to a pituitary lesion (Lamberts, 1998). True diabetes insipidus is a rare complication of pregnancy.

Therapy for diabetes insipidus is intranasal administration of a synthetic analogue of vasopressin, desmopressin, which is 1-deamino-8-d-arginine vasopressin (DDAVP). Ray (1998) reviewed 53 cases in which DDAVP was used during pregnancy with no adverse sequelae. Most women require increased doses during pregnancy because of an increased metabolic clearance rate stimulated by placental vasopressinase (Lindheimer, 1994). By this same mechanism, subclinical diabetes insipidus may become symptomatic or cases of transient diabetes insipidus may be encountered during pregnancy (Brewster, 2005; Wallia, 2013). The prevalence of vasopressinase-induced diabetes insipidus is estimated at 2 to 4 per 100,000 pregnancies (Wallia, 2013).

In our experiences, as described in Chapter 55 (p. 1086), transient secondary diabetes insipidus is more likely encountered with acute fatty liver of pregnancy (Nelson, 2013). This probably is due to altered vasopressinase clearance because of hepatic dysfunction.

### Sheehan Syndrome

Sheehan (1937) reported that pituitary ischemia and necrosis associated with obstetrical blood loss could result in hypopituitarism. With modern methods of hemorrhagic shock treatment, Sheehan syndrome is now seldom encountered (Feinberg, 2005; Tessnow, 2010). An example is shown in Figure 58-7. Affected women may have persistent hypotension, tachycardia, hypoglycemia, and lactation failure. Because deficiencies of some or all pituitary responsive hormones may develop after the initial insult, Sheehan syndrome can be heterogenous and may not be identified for years (Tessnow, 2010). In one cohort study of 60 women from Costa Rica with Sheehan syndrome, the average time to diagnosis was 13 years (Gei-Guardia, 2011). Because adrenal insufficiency is the most life-threatening complication, adrenal function should be immediately assessed in any woman suspected of having Sheehan syndrome. After glucocorticoid replacement, subsequent analyses and replacement of thyroid, gonadal, and growth hormones should be considered (Gei-Guardia, 2011; Tessnow, 2010).
Sheehan syndrome in a 23-year-old primipara who had major postpartum hemorrhage and hypotension intraoperatively during cesarean delivery. Magnetic resonance imaging was obtained because she failed to lactate, and her serum prolactin level was 18 ng/mL. This sagittal magnetic resonance image shows a large pituitary gland mass (arrows) consistent with hemorrhage. Subsequent imaging showed complete hematoma involution, and replacement therapy was not required.

**Lymphocytic Hypophysitis**

This autoimmune pituitary disorder is characterized by massive infiltration by lymphocytes and plasma cells with parenchymal destruction of the gland. Most cases are temporally linked to pregnancy (Caturegli, 2005; Foyouzi, 2011; Madsen, 2000). There are varying degrees of hypopituitarism or symptoms of mass effect, including headaches and visual field defects. A sellar mass is seen with CT or MR imaging. A mass accompanied by a modestly elevated serum prolactin level—usually < 100 pg/mL—suggests lymphocytic hypophysitis. In contrast, levels > 200 pg/mL are encountered with a prolactinoma. The etiology is unknown, but nearly 30 percent
have a history of coexisting autoimmune diseases including Hashimoto thyroiditis, Addison disease, type 1 diabetes, and pernicious anemia. Treatment is with hormone replacement and because the disease may be self-limited, a careful withdrawal of hormone replacement should be attempted after inflammation resolution (Foyouzi, 2011; Gagneja, 1999). Surgery during pregnancy is warranted only in cases of severe chiasmal compression unresponsive to corticosteroid therapy (Lee, 2003).

Connective-tissue disorders, which are also termed collagen-vascular disorders, have two basic underlying causes. First are the **autoantibody-mediated immune-complex diseases** in which connective-tissue damage is caused by deposition of immune complexes in specific organ(s) or tissue sites. Because these are manifest by sterile inflammation—predominately of the skin, joints, blood vessels, and kidneys—they are referred to as rheumatic diseases. Many of these immune-complex diseases are more prevalent in women, for example, systemic lupus erythematosus (SLE), rheumatoid arthritis, and a host of vasculitis syndromes. Second are the **inherited disorders** of bone, skin, cartilage, blood vessels, and basement membranes. Some examples include Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome.

**SYSTEMIC SCLEROSIS—SCLERODERMA**

**VASCULITIS SYNDROMES**

**INFLAMMATORY MYOPATHIES**

**HEREDITARY CONNECTIVE-TISSUE DISORDERS**

These disorders can be separated into those associated with and those without autoantibody formation. So-called *rheumatoid factor (RF)* is an autoantibody found in many autoimmune inflammatory conditions such as SLE, rheumatoid arthritis, systemic sclerosis (scleroderma), mixed connective-tissue disease, dermatomyositis, polymyositis, and various vasculitis syndromes. The *RF-seronegative spondyloarthropathies* are strongly associated with expression of the HLA-B27 antigen and include ankylosing spondylitis, psoriatic arthritis, Reiter disease, an
other arthritis syndromes.

Pregnancy may mitigate activity in some of these syndromes as a result of the immunosuppression that also allows successful engraftment of fetal and placental tissues. These changes are discussed in detail in Chapters 4 and 5 (p. 56). One example is pregnancy-induced predominance of T2 helper cells compared with cytokine-producing T1 helper cells (Keeling, 2009). Pregnancy hormones alter immune cells, for example, estrogens upregulate and androgens downregulate T-cell response, and progesterone is immunosuppressive (Cutolo, 2006; Häupl, 2008a; Robinson, 2012).

Some immune-mediated diseases may either be caused or activated as a result of previous pregnancies. To explain, fetal cells and free fetal DNA are detectable in maternal blood beginning early in pregnancy (Simpson, 2013; Sitar, 2005; Waldorf, 2008). Fetal cell microchimerism is the persistence of fetal cells in the maternal circulation and organs following pregnancy. These persistent fetal cells may stimulate autoantibodies, or they may become engrafted in maternal tissues. This raises the possibility that fetal cell microchimerism is related to the predilection of autoimmune disorders for women (Adams, 2004; Lissauer, 2009). Evidence for this includes findings of fetal stem cells engrafted in maternal tissues in women with autoimmune thyroiditis and systemic sclerosis (Jimenez, 2005; Srivatsa, 2001). Such microchimerism has also been described in women with SLE and those with rheumatoid arthritis-associated HLA alleles (Johnson, 2001; Lee, 2010; Rak, 2009a). Similarly, engrafted maternal cells may provoke autoimmune conditions in a woman’s offspring (Ye, 2012). Perhaps related, women with SLE have a 0.6 male:female offspring ratio suggesting excessive male fetal loss in these women (Aggarwal, 2013).

### Systemic Lupus Erythematosus

Lupus is a heterogeneous autoimmune disease with a complex pathogenesis that results in interactions between susceptibility genes and environmental factors (Hahn, 2012; Tsokos, 2011). Immune system abnormalities include overactive B lymphocytes that are responsible for autoantibody production. These result in tissue and cellular damage when autoantibodies or immune complexes are directed at one or more cellular nuclear components (Tsokos, 2011). In addition, immunosuppression is impaired, including regulatory T-cell function (Tower, 2013). Some autoantibodies produced in patients with lupus are shown in Table 59-1.

<tbody>
<tr>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Almost 90 percent of lupus cases are in women, and its prevalence in those of childbearing age is approximately 1 in 500 (Lockshin, 2000). Accordingly, the disease is encountered relatively frequently during pregnancy. The 10-year survival rate is 70 to 90 percent (Hahn, 2012; Tsokos, 2011). Infection, lupus flares, end-organ failure, hypertension, stroke, and cardiovascular disease account for most deaths.

Genetic influences are implicated by a higher concordance with monozygotic compared with dizygotic twins—25 versus 2 percent, respectively. Moreover, there is a 10-percent frequency in patients with one affected family member. The relative risk of disease is increased if there is inheritance of the “autoimmunity gene” on chromosome 16 that predisposes to SLE, rheumatoid arthritis, Crohn disease, and psoriasis (Hahn, 2012). Susceptibility genes such as HLA-A1, B8 DR3, DRB1, and TET3 explain only a portion of the genetic heritability (Hom, 2008; Tsokos, 2011; Yang, 2013).

### Clinical Manifestations and Diagnosis

Lupus is notoriously variable in its presentation, course, and outcome (Table 59-2). Findings may be confined initially to one organ system, and others become involved later. Or, the disease may first manifest with multisystem involvement. Common findings are malaise, fever, arthritis, rash, pleuropneumocardiitis, photosensitivity, anemia, and cognitive dysfunction. At least half of patients have renal involvement. There is evidence that lupus is associated with decline in attention, memory, and reasoning (Kozora, 2008). Although Libman-Sacks endocarditis was described with lupus, it is likely due to presence of subsequently discussed antiphospholipid antibodies (Hojnik, 1996).

**TABLE 59-2. Clinical Manifestations of Systemic Lupus Erythematosus**
Identification of antinuclear antibodies (ANA) is the best screening test. However, a positive result is not specific for lupus. For example, low titers are found in normal individuals, other autoimmune diseases, acute viral infections, and chronic inflammatory processes. Several drugs can also cause a positive reaction. Antibodies to double-stranded DNA (dsDNA) and to Sm (Sm) antigens are relatively specific for lupus, whereas other antibodies are not (see Table 59-1). Although hundreds of autoantibodies have been described in SLE, only a few have been shown to participate in tissue injury (Sherer, 2004; Tsokos, 2011). Microarray profiles are being developed for customized and more accurate SLE diagnoses (Lin, 2013; Yeste, 2013).

Anemia develops frequently, and there may be leukopenia and thrombocytopenia. Proteinuria and casts are found in the half of patients with glomerular lesions. Lupus nephritis can also cause renal insufficiency, which is more common if there are antiphospholipid antibodies (Moroni, 2004). Other laboratory findings include false-positive syphilis serology, prolonged partial thromboplastin time, and higher rheumatoid factor levels. Elevated serum D-dimer levels often follow a flare or infection, but unexplained persistent elevations are associated with a high risk for thrombosis (Wu, 2008).

The diagnostic criteria for SLE are listed in Table 59-3. If any four or more of these 11 criteria are present, serially or simultaneously, the diagnosis of lupus is made.

Modified from Hahn, 2012.
Importantly, numerous drugs can induce a lupus-like syndrome. These include procainamide, quinidine, hydralazine, α-methyldopa, phenytoin, and phenobarbital. Drug-induced lupus is rarely associated with glomerulonephritis and usually regresses when the medication is discontinued (Rubin, 1997).

### Lupus and Pregnancy

Of nearly 16.7 million pregnancies in the United States from 2000 to 2003, 13,555 were complicated by lupus—an incidence of approximately 1 in 1250 pregnancies (Clowse, 2008). During the past several decades, pregnancy outcomes in women with SLE have improved.
remarkably. Important factors for pregnancy outcome include whether disease is active at the beginning of pregnancy, age and parity, coexistence of other medical or obstetrical disorders, and whether antiphospholipid antibodies are detected (p. 1173). There is evidence that newly diagnosed lupus during pregnancy tends to be severe (Zhao, 2013).

During pregnancy, lupus improves in a third of women, remains unchanged in a third, and worsens in the remaining third. Thus, in any given pregnancy, the clinical condition can worsen or **flare** without warning (Khamashta, 1997). Petri (1998) reported a 7-percent risk of major morbidity during pregnancy. Women who have confined cutaneous lupus do not usually have adverse outcomes (Hamed, 2013). Frequent complications in a cohort of 13,555 women with SLE during pregnancy are shown in Table 59-4. The maternal mortality and severe morbidity rate was 325 per 100,000. In a review of 13 studies with 17 maternal deaths attributable to SLE and lupus nephritis, all occurred in those with active disease (Ritchie, 2012).

Data from Clowse, 2008.

From the foregoing, it is certain that lupus can be life threatening for both mother and fetus. Generally speaking, pregnancy outcome is best in those women in whom: (1) lupus activity has been quiescent for at least 6 months before conception; (2) there is no lupus nephritis manifest by
proteinuria or renal dysfunction; (3) there is no evidence of the antiphospholipid antibody syndrome or lupus anticoagulant; and (4) superimposed preeclampsia does not develop (Peart, 2014; Stojan, 2012).

**Lupus Nephritis.** Active nephritis has been associated with particularly bad pregnancy outcomes, although these have improved remarkably during the past 30 years (Moroni, 2005; Stojan, 2012). Women with renal disease have a high incidence of gestational hypertension and preeclampsia. However, if their disease remains in remission, they usually have good pregnancy outcomes (Huong, 2001; Moroni, 2002). Of the 125 pregnancies reported by Lockshin (1989), 63 percent of women with preexisting renal disease developed preeclampsia compared with only 14 percent of those without underlying renal disease. Moroni and Ponticelli (2005) reviewed results from a total of 309 pregnancies complicated by established lupus nephritis. Of these, 30 percent suffered a flare, and 40 percent of these had associated renal insufficiency. The maternal mortality rate was 1.3 percent.

In two studies describing pregnancy outcomes in women with lupus nephritis, Wagner and coworkers (2009) compared outcomes of 58 women cared for during 90 pregnancies at the Mayo Clinic. Active nephritis was associated with a significantly higher incidence of maternal complications compared with women without nephritis—57 versus 11 percent. Quiescent nephritis had a nonsignificant effect on preeclampsia rates compared with lupus patients without renal impairment. The fetal death rate with active maternal nephritis was 35 percent compared with 9 percent in those with quiescent nephritis. In another study, Imbasciati and associates (2009) described outcomes in 113 pregnancies in 81 women with known lupus nephritis. During a third of pregnancies, there was a renal flare. After excluding nine miscarriages, of the 104 remaining pregnancies, a third were delivered preterm, a third of infants weighed < 2500 g, and the perinatal mortality rate was 6 percent.

Most recommend continuation of immunosuppressive therapy for nephritis during pregnancy. It is not clear whether the dose should be increased peripartum. Although it is often stated that this is the time that activation or exacerbations are most likely to develop, the evidence is not conclusive.

**Lupus versus Preeclampsia-Eclampsia.** Chronic hypertension complicates up to 30 percent of pregnancies in women with SLE (Egerman, 2005). And as discussed, preeclampsia is common, and superimposed preeclampsia is encountered even more often in those with nephritis or antiphospholipid antibodies (Bertsias, 2008). It may be difficult, if not impossible to differentiate lupus nephropathy from severe preeclampsia if the kidney is the only involved organ (Petri, 2007). Central nervous system involvement with lupus may culminate in convulsions similar to those of eclampsia. Thrombocytopenia, with or without hemolysis, may further confuse the diagnosis because of its similarity to the hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome. Management is identical to that for preeclampsia-eclampsia, described in Chapter 40 (p. 749).

**Management During Pregnancy**

Lupus management consists primarily of monitoring maternal clinical and laboratory conditions as well as fetal well-being (Lateef, 2012). Pregnancy-induced thrombocytopenia and proteinuria resemble lupus disease activity, and the identification of a lupus flare is confounded by the increase in facial and palmar erythema of normal pregnancy (Lockshin, 2003). Some authorities have advocated a number of numerical scales to emphasize ongoing disease activity. Components are weighted for severity, both with the SLE-Pregnancy Disease Activity Index (SLEPDAI) an
with the Lupus Activity Index (Buyon, 1999; Ruiz-Irastorza, 2004). We have not found these to be useful.

Lupus activity monitoring and identification of lupus flares by various laboratory techniques has been recommended. The sedimentation rate may be misleading because of pregnancy-induced hyperfibrinogenemia. Serum complement levels are also normally increased in pregnancy (Chap. 4, p. 56 and Appendix, p. 1291). And, although falling or low levels of complement components C3, C4, and CH50 are more likely to be associated with active disease, higher levels provide no assurance against disease activation. Our experiences, as well as those of Varner and colleagues (1983) and Lockshin and Druzin (1995), are that there is no correlation between clinical manifestations of disease and complement levels.

Serial hematological studies may detect changes in disease activity. Hemolysis is characterized by a positive Coombs test, anemia, reticulocytosis, and unconjugated hyperbilirubinemia. Thrombocytopenia, leukopenia, or both may develop. According to Lockshin and Druzin (1995), chronic thrombocytopenia in early pregnancy may be due to antiphospholipid antibodies. Later, thrombocytopenia may indicate preeclampsia.

Serum aminotransferase activity reflects hepatic involvement, as does a rise in serum bilirubin levels. Azathioprine therapy also may induce enzyme elevations. Urine is tested frequently to detect new-onset or worsening proteinuria. Overt proteinuria that persists is an ominous sign, even more so if accompanied by other evidence of the nephrotic syndrome or abnormal serum creatinine levels.

The fetus should be closely observed for adverse effects such as growth restriction and oligohydramnios. Many recommend screening for anti-SS-A (anti-Ro) and anti-SS-B (anti-La) antibodies, because of associated fetal complications described subsequently. As discussed in Chapter 17 (p. 335), antepartum fetal surveillance is done as outlined by the American College of Obstetricians and Gynecologists (2012a). Unless hypertension develops or there is evidence of fetal compromise or growth restriction, pregnancy is allowed to progress to term. Peripartum corticosteroids in “stress doses” are given to women who are taking these drugs or who recently have done so.

**Pharmacological Treatment.** There is no cure, and complete remissions are rare. Approximately a fourth of women have mild disease, which is not life threatening, but may be disabling because of pain and fatigue. Arthralgia and serositis can be managed by occasional doses of nonsteroidal antiinflammatory drugs (NSAIDs). However, chronic or large intermittent dosing is avoided due to pregnancy side effects with these drugs described in Chapter 12 (p. 247) (Briggs, 2011). Low-dose aspirin can be used throughout gestation. Severe disease is managed with corticosteroids such as prednisone, 1 to 2 mg/kg orally per day. After the disease is controlled, this dose is tapered to a daily morning dose of 10 to 15 mg. Corticosteroid therapy can result in the development of gestational diabetes.

Immunosuppressive agents such as azathioprine are beneficial in controlling active disease (Contreras, 2004; Hahn, 2012). In nonpregnant patients, these are usually reserved for lupus nephritis or disease that is corticosteroid resistant. Azathioprine has a good safety record during pregnancy (Fischer-Betz, 2013; Petri, 2007). Its recommended daily oral dose is 2 to 3 mg/kg. According to Buhimschi and Weiner (2009), cyclophosphamide is teratogenic, and although not usually recommended during pregnancy, severe disease may be treated after 12 weeks’ gestation. As discussed in Chapter 12 (p. 250), medications to be avoided include mycophenolate mofetil and methotrexate (Anderka, 2009; Briggs, 2011; Food and Drug Administration, 2008). In some situations, mycophenolate is the only treatment that achieves disease stability. In these cases,
counseling regarding fetal risks is essential (Bramham, 2012).

Antimalarials help control skin disease. Although these agents cross the placenta, hydroxychloroquine has not been associated with congenital malformations. Because of the long half-life of antimalarials and because discontinuing therapy can precipitate a lupus flare, most recommend their continuation during pregnancy (Borden, 2001; Harris, 2002). Levy and associates (2001) randomly assigned 20 pregnant women to receive hydroxychloroquine or placebo and reported improved SLEPDAI scores with hydroxychloroquine.

When severe disease supervenes—usually a lupus flare—high-dose glucocorticoid therapy is given. Petri (2007) recommends pulse therapy consisting of methylprednisolone, 1000 mg given intravenously over 90 minutes daily for 3 days, then a return to maintenance doses if possible.

**Perinatal Mortality and Morbidity**

Adverse perinatal outcomes are increased significantly in pregnancies complicated by lupus. These include preterm delivery, fetal-growth restriction, stillbirths, and neonatal lupus syndrome (Madazli, 2014). Outcomes are worse with a lupus flare, significant proteinuria, or renal impairment, and with chronic hypertension, preeclampsia, or both (Aggarwal, 1999; Bramham, 2012; Scott, 2002; Wagner, 2009). The observations of Lee and coworkers (2009) are worrisome. In a mouse SLE model, they showed that autoantibodies directed against the N-methyl-D-aspartate neuroreceptor caused fetal neurotoxicity. This suggests an underlying etiology for the CNS manifestations and learning disorders in children of affected mothers. Ongoing work on anti-dsDNA antibodies has identified peptides that can protect target organs from antibody-mediated damage (Diamond, 2011).

The reasons at least partially responsible for adverse fetal consequences include decidual vasculopathy with placental infarction and decreased perfusion (Hanly, 1988; Lubbe, 1984). Placental pathology is discussed in more detail in **Chapter 6** (p. 119).

**Neonatal Lupus Syndrome.** This unusual constellation is characterized by newborn skin lesions—lupus dermatitis; a variable number of hematological and systemic derangements; and occasionally congenital heart block (Boh, 2004; Lee, 2009). Although usually associated with anti-SS-A and -SS-B antibodies, McGeachy and Lam (2009) described an affected infant in whom only anti-ribonucleoprotein (RNP) antibodies were found. Thrombocytopenia and hepatic involvement are seen in 5 to 10 percent of affected infants. One report suggests that neonatal lupus may appear up to 4 weeks after birth (Stirnemann, 2002). Lockshin and colleagues (1988) prospectively followed 91 infants born to women with lupus. Eight were possibly affected—four had definite neonatal lupus and four had possible disease. Clinical manifestations, which include cutaneous lupus, thrombocytopenia, and autoimmune hemolysis, are transient and clear within a few months (Lee, 1984). This may not be so for congenital heart block. In subsequent offspring, the recurrence risk for neonatal lupus is up to 25 percent (Julkunen, 1993).

**Congenital Heart Block.** Fetal and neonatal heart block results from diffuse myocarditis and fibrosis in the region between the atrioventricular (AV) node and bundle of His. Buyon and associates (1993) reported that congenital heart block developed almost exclusively in fetuses of women with antibodies to the SS-A or SS-B antigens. These antibodies may also cause otherwise unexplained stillbirths (Ottaviani, 2004). Even in the presence of such antibodies, however, the incidence of myocarditis is only 2 to 3 percent but increases to 20 percent with a prior affected child (Bramham, 2012; Lockshin, 1988). Fetal cardiac monitoring should be performed between 18 and 26 weeks’ gestation in pregnancies with either of these antibodies. The cardiac lesion is
Maternal administration of corticosteroids, plasma exchange, or intravenous immunoglobulin have not been found to reduce the risk of congenital heart block. Corticosteroid therapy to treat fetal heart block has not been subjected to randomized trials. There is some evidence that early treatment may mitigate fetal myocarditis. Shinohara and coworkers (1999) reported no heart block in 26 neonates whose mothers received corticosteroids before 16 weeks’ gestation as part of SLE maintenance therapy. By contrast, 15 of 61 neonates with heart block were born to women in whom corticosteroid therapy was begun after 16 weeks for SLE exacerbation. Rein and colleagues (2009) followed 70 fetuses prospectively of mothers positive for anti-SS-A or -SS-B antibodies, with serial fetal kinetocardiography (FKCG) to measure AV conduction time. In six fetuses, first-degree heart block developed at 21 to 34 weeks, and maternal dexamethasone treatment was associated with normalization of AV conduction in all within 3 to 14 days. There were no recurrences, and the infants all were well at a median follow-up of 4 years. However, as noted in Chapter 16 (p. 322), corticosteroids may be less effective for higher degrees of heart block. Moreover, potential benefit should be weighed against the risks of chronic corticosteroid treatment, including impaired fetal growth (Friedman, 2009).

Long-Term Prognosis and Contraception

In general, women with lupus and chronic vascular or renal disease may limit family size because of morbidity associated with the disease as well as increased adverse perinatal outcomes. Two large multicenter clinical trials have shown that combination oral contraceptives (COCs) did not increase the incidence of lupus flares (Petri, 2005; Sánchez-Guerrero, 2005). Still, the American College of Obstetricians and Gynecologists (2013) recommends that COC use be avoided in women who have nephritis, antiphospholipid antibodies, or vascular disease. Progestin-only implants and injections provide effective contraception with no known effects on lupus flares (Chabbert-Buffet, 2010). Concerns that intrauterine device (IUD) use and immunosuppressive therapy lead to increased infection rates in these patients are not evidenced-based. Tubal sterilization may be advantageous and is performed with greatest safety postpartum or whenever the disease is quiescent. These options are discussed in further detail in Chapters 38 and 39.

Antiphospholipid Antibody Syndrome

Phospholipids are the main lipid constituents of cell and organelle membranes. There are proteins in plasma that associate noncovalently with these phospholipids. Antiphospholipid antibodies are directed against these phospholipids or phospholipid-binding proteins (Erkan, 2011; Giannakopoulos, 2013; Tsokos, 2011). This antibody group may be of IgG, IgM, and IgA classes alone or in combination. Antiphospholipid antibodies are most common with lupus and other connective-tissue disorders, although a small proportion of otherwise normal women and men are found to have these antibodies in various forms.

The stimulus for autoantibody production is unclear, but it possibly is due to a preceding infection. The pathophysiology encountered in the antiphospholipid antibody syndrome—variably referred to as APAS or APS—is mediated by one or more of the following: (1) activation of various procoagulants, (2) inactivation of natural anticoagulants, (3) complement activation, and (4) inhibition of syncytiotrophoblast differentiation (Moutsopoulos, 2012; Tsokos, 2011). Clinically, these result in arterial or venous thromboses or pregnancy morbidity, and virtually
Central nervous system involvement is one of the most prominent clinical manifestations. In addition to cerebrovascular arterial and venous thrombotic events, there may be psychiatric features and even multiple sclerosis (Binder, 2010; Sanna, 2003). Renovascular involvement may lead to renal failure that may be difficult to differentiate from lupus nephritis (D’Cruz, 2009). Peripheral and visceral thromboses are also a feature. For example, Ahmed and associates (2009) reported a postpartum woman who developed spontaneous cecal perforation associated with a mesenteric vessel infarction. As discussed in Chapter 18 (p. 359), antiphospholipid antibodies have been associated with excessive pregnancy loss (Branch, 2010). These and other detrimental effects on pregnancy outcomes are discussed subsequently.

A small proportion of these patients develop the catastrophic antiphospholipid antibody syndrome—CAPS. This is defined as a rapidly progressive thromboembolic disorder simultaneously involving three or more organ systems or tissues (Moutsopoulos, 2012).

**Specific Antiphospholipid Antibodies**

Several autoantibodies have been described that are directed against a specific phospholipid or phospholipid-binding protein. First, $\beta_2$-glycoprotein I—also known as apolipoprotein H—is a phospholipid-binding plasma protein that inhibits prothrombinase activity within platelets and inhibits ADP-induced platelet aggregation (Giannakopoulos, 2013; Shi, 1993). Thus, its normal action is to inhibit procoagulant binding and thereby prevent coagulation cascade activation. Logically, antibodies directed against $\beta_2$-glycoprotein I would inhibit its anticoagulant activity and promote thrombosis. This is important from an obstetrical viewpoint because $\beta_2$-glycoprotein I is expressed in high concentrations on the syncytiotrophoblastic surface. Complement activation may contribute to it pathogenesis (Avalos, 2009; Tsokos, 2011). Teleologically, this seems appropriate because the decidua intuitively should be a critical area to prevent coagulation that might result in intervillous space thrombosis. Another possibility is that $\beta_2$-glycoprotein I may be involved in implantation, and it may result in pregnancy loss via an inflammatory mechanism (Iwasawa, 2012; Meroni, 2011).

Second, lupus anticoagulant (LAC) is a heterogeneous group of antibodies directed also against phospholipid-binding proteins. LAC induces prolongation in vitro of the prothrombin, partial thromboplastin, and Russell viper venom times (Feinstein, 1972). Thus, paradoxically, this so-called anticoagulant is actually powerfully thrombotic in vivo.
Antibodies against Natural Anticoagulants

Antiphospholipid antibodies have also been described that are directed against the natural anticoagulant proteins C and S (Robertson, 2006). Another is directed against the anticoagulant protein annexin V, which is expressed in high concentrations by the syncytiotrophoblast (Chamley, 1999; Giannakopoulos, 2013). That said, criteria to diagnosis antiphospholipid-antibody syndrome require testing for elevated levels of the following antiphospholipid antibodies: LAC, ACA, and anti-β<sub>2</sub> glycoprotein I. Testing for other antibodies is not recommended (American College of Obstetricians and Gynecologists, 2012b).

Antiphospholipid Antibody Syndrome Diagnosis

Clinical classification criteria shown in Table 59-5 provide indications for testing. By international consensus, the syndrome is diagnosed based on laboratory and clinical criteria (Miyakis, 2006). First, one of two clinical criteria—which are vascular thrombosis or certain pregnancy morbidity—must be present. In addition, at least one laboratory criterion that includes LAC activity or medium- to high-positive levels of specific IgG- or IgM-ACAs must be confirmed on two occasions 12 weeks apart.

Tests for LAC are nonspecific coagulation tests. The partial thromboplastin time is generally prolonged because the anticoagulant interferes with conversion of prothrombin to thrombin in vitro. Tests considered more specific are the dilute Russell viper venom test and the platelet neutralization procedure. There is currently disagreement as to which of these two is best for screening. If either is positive, then identification of LAC is confirmed.

Branch and Khamashta (2003) recommend conservative interpretation of results based on repeated tests from a reliable laboratory that are consistent with each clinical case. Only approximately 20 percent of patients with APS have a positive LAC reaction alone. Thus anticardiolipin enzyme-linked immunosorbent assay (ELISA) testing should also be performed. Many laboratories have a premade panel to use for APS testing.

Efforts have been made to standardize ACA assays by using ELISA. Values are reported in units and expressed as negative, low-positive, medium-positive, or high-positive (Harris, 1987a,b). Despite this, these assays remain without international standardization (Adams, 2013; Branch, 2003; Capuano, 2007). Interlaboratory variation can be large, and agreement between commercial kits is poor.

Pregnancy and Antiphospholipid Antibodies

Nonspecific low levels of antiphospholipid antibodies are identified in approximately 5 percent of normal adults (Branch, 2010). When Lockwood and coworkers (1989) first studied 737 normal pregnant women, they reported that 0.3 percent had lupus anticoagulant and 2.2 percent had elevated concentrations of either IgM or IgG anticardiolipin antibodies. Later studies confirmed this, and taken together, they totaled almost 4000 normal pregnancies with an average prevalence for APAs of 4.7 percent. This is the same as for normal nonpregnant individuals (Harris, 1991; Pattison, 1993; Yasuda, 1995).

In women with high levels of ACAs, and especially when lupus anticoagulant is identified, there are increased risks for decidual vasculopathy, placental infarction, fetal-growth restriction, early-onset preeclampsia, and recurrent fetal death. Some of these women, like those with lupus,
also have a high incidence of venous and arterial thromboses, cerebral thrombosis, hemolytic anemia, thrombocytopenia, and pulmonary hypertension (American College of Obstetricians and Gynecologists, 2012b; Clowse, 2008). In 191 LAC-negative women with antiphospholipid antibody syndrome, women with antibodies to cardiolipin and β₂-glycoprotein I had significantly higher miscarriage rates than if either one alone was positive (Liu, 2013).

**Pregnancy Pathophysiology.** It is not precisely known how these antibodies cause damage, but it is likely that their actions are multifactorial (Tsokos, 2011). Platelets may be damaged directly by antiphospholipid antibody or indirectly by binding β₂-glycoprotein I, which causes platelets to be susceptible to aggregation (Chamley, 1999; Giannakopoulos, 2013). Rand and colleagues (1997a,b, 1998) propose that phospholipid-containing endothelial cell or syncytiotrophoblast membranes may be damaged directly by the antiphospholipid antibody or indirectly by antibody binding to either β₂-glycoprotein I or annexin V. This prevents the cell membranes from protecting the syncytiotrophoblast and endothelium. It results in exposure of basement membrane to which damaged platelets can adhere and form a thrombus (Lubbe, 1984).

Pierro and associates (1999) reported that antiphospholipid antibodies decreased decidual production of the vasodilating prostaglandin E₂. Decreased protein C or S activity and increased prothrombin activation may also be contributory (Ogunyemi, 2002; Zangari, 1997). Amengual and coworkers (2003) presented evidence that thrombosis with APS is due to activation of the tissue factor pathway. Finally, uncontrolled placental complement activation by antiphospholipid antibodies may play a role in fetal loss and growth restriction (Holers, 2002).

Complications from APS cannot be completely explained by thrombosis alone. Animal models suggest that these are due to inflammation rather than thrombosis (Cohen, 2011). Some investigators theorize that APS-associated clotting is triggered by a “second hit” from innate inflammatory immune responses and recommend antiinflammatory agents (Meroni, 2011).

**Adverse Pregnancy Outcomes.** Antiphospholipid antibodies are associated with increased rates of fetal wastage (Chap. 18, p. 359). In most early reports, however, women were included because they had had repeated adverse outcomes. Both are common—recall that the incidence of antiphospholipid antibodies in the general obstetrical population is about 5 percent and early pregnancy loss approximates 20 percent. Accordingly, data currently are too limited to allow precise conclusions to be drawn concerning the impact of these antibodies on adverse pregnancy outcomes. Fetal deaths, however, are more characteristic with APS than are first-trimester miscarriages (Oshiro, 1996; Roque, 2001). It has also been shown that women with higher antibody titers have worse outcomes compared with those with low titers (Nodler, 2009; Simchen, 2009).

Looking at the issue another way, the frequency of antiphospholipid antibodies may be increased with associated adverse obstetrical outcomes. Polzin and colleagues (1991) identified antiphospholipid antibodies in a fourth of 37 women with growth-restricted fetuses, however, none had evidence for lupus anticoagulant. Approximately a third of women with APS will develop preeclampsia during pregnancy (Clark, 2007b). Moodley and associates (1995) found antiphospholipid antibodies in 11 percent of 34 women with severe preeclampsia before 30 weeks.

When otherwise unexplained fetal deaths are examined, the data are mixed. Haddow and coworkers (1991) measured ACAs in 309 pregnancies with fetal death and found no differences compared with those in 618 normal pregnancies. In women with a history of recurrent pregnancy loss, those with antiphospholipid antibodies had a higher rate of preterm delivery (Clark, 2007a).
In a case-control study of 582 stillbirths and 1547 live births, Silver and colleagues (2013) found a three- to fivefold increased risk for stillbirth in women with elevated anticardiolipin and anti-β_2_-glycoprotein I levels. Due to the risk of fetal-growth abnormalities and stillbirth, serial sonographic assessment of fetal growth and antepartum testing in the third trimester are recommended by the American College of Obstetricians and Gynecologists (2012b).

**Treatment in Pregnancy.** Because of the heterogeneity of studies, current treatment recommendations for women with antiphospholipid antibodies can be confusing (Branch, 2003; Robertson, 2006). As discussed, antiphospholipid antibodies that bind to immunoglobulins G, M, and A are semiquantified, and GPL, MPL, and APL binding units are expressed as negative, low-positive, medium-positive, or high-positive (American College of Obstetricians and Gynecologists, 2012b). Of the three, higher titers for GPL and MPL anticardiolipin antibodies are clinically important, whereas low-positive titers are of questionable clinical significance. And any titer of APL antibodies has no known relevance at this time.

As discussed in Chapter 52 (p. 1033), women with prior thromboembolic events who have antiphospholipid antibodies are at risk for recurrence in subsequent pregnancies. For these women, prophylactic anticoagulation with heparin throughout pregnancy and for 6 weeks postpartum with either heparin or warfarin is recommended (American College of Obstetricians and Gynecologists, 2012b). For those without history of thromboembolic events, recommendations for management from the American College of Obstetricians and Gynecologists (2012b) and the American College of Chest Physicians (Bates, 2012) are varied and listed in Table 52-8 (p. 1046). Some acceptable schemes include close antepartum observation with or without prophylactic or intermediate-dose heparin, and some form of postpartum anticoagulation for 4 to 6 weeks.

Recent trials have caused the need for heparin to be questioned in women with antibodies but no history of thrombosis (Branch, 2010). Although this is less clear, some recommend that women be treated if they have medium- or high-positive ACA titers or LAC activity and a previous second- or third-trimester fetal death not attributable to other causes (Dizon-Townson, 1998; Lockshin, 1995). Some report that women with recurrent early pregnancy loss and medium- or high-positive titers of antibodies may benefit from therapy (Robertson, 2006). Some individual agents are now considered for pregnant women with antiphospholipid antibody syndrome who have no prior thromboembolic event. These agents are described in the following paragraphs.

**Aspirin,** given in doses of 60 to 80 mg orally daily, blocks the conversion of arachidonic acid to thromboxane A_2_ while sparing prostacyclin production. This reduces synthesis of thromboxane A_2_, which usually causes platelet aggregation and vasoconstriction, and simultaneously spares prostacyclin, which normally has the opposite effect. There appear to be no major side effects from low-dose aspirin other than a slight risk of small-vessel bleeding during surgical procedures. Low-dose aspirin does not appear to reduce adverse pregnancy outcomes in antiphospholipid antibody-positive women without the complete syndrome (Del Ross, 2013).

**Unfractionated heparin** is given subcutaneously in dosages of 5000 to 10,000 units every 12 hours. Some prefer low-molecular-weight heparin, such as 40 mg enoxaparin once daily, because of its ease of administration and smaller risk of osteoporosis and heparin-induced thrombocytopenia (Kwak-Kim, 2013). With therapeutic dosing, some recommend measurement of heparin levels because clotting tests may be altered by lupus anticoagulant (Cowchock, 1998). The rationale for heparin therapy is to prevent venous and arterial thrombotic episodes. Heparin therapy also prevents thrombosis in the microcirculation, including the decidual-trophoblastic interface (Toglia, 1996). As discussed, heparin binds to β_2_-glycoprotein I, which coats the...
syncytiotrophoblast. This prevents binding of anticardiolipin and anti-β₂-glycoprotein I antibodies to their surfaces, which likely prevents cellular damage (Chamley, 1999; Tsokos, 2011). Heparin also binds to antiphospholipid antibodies in vitro and likely in vivo. It is problematic that heparin therapy is associated with a number of complications that include bleeding, thrombocytopenia, osteopenia, and osteoporosis. A detailed description of the use of various heparins and their doses and adverse effects is found in Chapter 52 (p. 1037).

Glucocorticosteroids generally should not be used with primary APS—that is, without an associated connective-tissue disorder. For women with lupus or those being treated for APS who develop lupus, corticosteroid therapy is indicated (Carbone, 1999). In such cases of secondary APS seen with lupus, the dose of prednisone should be maintained at the lowest effective level to prevent flares.

Immunoglobulin therapy is controversial and has usually been reserved for women with either overt disease or heparin-induced thrombocytopenia, or both (Alijotas-Reig, 2013). It is used when other first-line therapies have failed, especially in the setting of preeclampsia and fetal-growth restriction (Cowchock, 1996, 1998; Heilmann, 2003; Silver, 1997). Intravenous immunoglobulin (IVIG) is administered in doses of 0.4 g/kg daily for 5 days—total dose of 2 g/kg. This is repeated monthly, or it is given as a single dose of 1 g/kg each month. Treatment is expensive, and at $75 per gram, one course for a 70-kg woman costs more than $10,000. A Cochrane review of seven trials found no improvement in the livebirth rate for immunotherapy given to women with recurrent pregnancy loss (Porter, 2006). Xiao and associates (2013) studied prednisone and aspirin in 87 patients compared with prednisone, aspirin, low-molecular-weight heparin, and IVIG in 42 women with antiphospholipid antibody syndrome. They reported livebirth rates of 84 and 98 percent and obstetrical morbidity rates of 23 and 7 percent, respectively. We are of the view that randomized trials are needed before there is widespread application of this expensive and cumbersome therapy.

Immunosuppression has not been well evaluated, but azathioprine and cyclosporine do not appear to improve standard therapies (Silver, 1997). As mentioned with lupus on page 1172, methotrexate, cyclophosphamide, and mycophenolate mofetil are contraindicated because of teratogenic potential (Briggs, 2011; Buhimschi, 2009). Hydroxychloroquine therapy may be beneficial with APS (Albert, 2014).

Aspirin plus heparin is the most efficacious regimen (de Jesus, 2014). Low-dose unfractionated heparin—7500 to 10,000 units is used subcutaneously twice daily. Concurrently, low-dose aspirin—60 to 80 mg orally once daily—is given. Although typically given in addition to heparin in women with a prior thromboembolic event, the benefit of aspirin is unclear (American College of Obstetricians and Gynecologists, 2012b; Bouvier, 2014).

Treatment Efficacy. Fetal loss is common in women with antiphospholipid antibodies if untreated (Branch, 1992; Rai, 1995). Even with treatment, recurrent fetal loss rates remain at 20 to 30 percent (Branch, 2003; Empson, 2005; Ernest, 2011). Importantly, some women with lupus and antiphospholipid antibodies have normal pregnancy outcomes without treatment. Again, it is emphasized that women with lupus anticoagulant and prior bad pregnancy outcomes have had liveborns without treatment (Trudinger, 1988).

In a manner similar to neonatal lupus syndrome (p. 1172), up to 30 percent of neonates demonstrate passively acquired antiphospholipid antibodies, and thus there is concern for their adverse effects. For example, Tincani and coworkers (2009) found increased learning disabilities in these children. Simchen and colleagues (2009) reported a fourfold increased risk for perinatal strokes. Of 141 infants followed in a European registry, the rate of preterm birth was 16 percent.
low birthweight, 17 percent; and behavioral abnormalities in 4 percent of the children. There were no cases of neonatal thrombosis (Motta, 2010).

**Rheumatoid Arthritis**

This is a chronic multisystem disease of unknown cause with an immunologically mediated pathogenesis. Infiltrating T cells secrete cytokines that mediate inflammation and systemic symptoms. Its worldwide prevalence is 0.5 to 1 percent, women are affected three times more often than men, and peak onset is from 25 to 55 years (Shah, 2012). The cardinal feature is inflammatory synovitis that usually involves the peripheral joints. The disease has a propensity for cartilage destruction, bony erosions, and joint deformities. Criteria for classification are shown in Table 59-6, and a score of 6 or greater fulfills the requirements for definitive diagnosis.

ACPA = anti-citrullinated protein antibody; CCP = cyclic citrullinated peptides; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; IP = interphalangeal joint; MCP = metacarpophalangeal joint; MTP = metatarsophalangeal joint; PIP = proximal interphalangeal joint; RF = rheumatoid factor.

Criteria established in collaboration with the American College of Rheumatology and the European League Against Rheumatism. A score ≥ 6 fulfills criteria for diagnosis. Modified from Aletaha, 2010.

There is a genetic predisposition, and heritability is estimated at 15 to 30 percent (McInnes, 2011). Genome-wide associated studies have identified more than 30 loci involved in rheumatoid arthritis pathogenesis (Kurkó, 2013). There is an association with the class II major histocompatibility complex molecule HLA-DR4 and HLA-DRB1 alleles (McInnes, 2011; Sha...
In addition, there is a genetic component to joint destruction in rheumatoid arthritis, as alterations in the *IL2RA* gene are associated with less destructive disease (Knevel, 2013). Cigarette smoking appears to increase the risk of rheumatoid arthritis (Papadopoulos, 2005). As discussed subsequently, a protective effect of pregnancy has been reported for development of rheumatoid arthritis, and this may be related to HLA-disparate fetal microchimerism (Guthrie 2010; Hazes, 1990).

**Clinical Manifestations**

Rheumatoid arthritis is a chronic polyarthritis with symptoms of synovitis, fatigue, anorexia, weakness, weight loss, depression, and vague musculoskeletal symptoms. The hands, wrists, knees, and feet are commonly involved. Pain, aggravated by movement, is accompanied by swelling and tenderness. Extraarticular manifestations include rheumatoid nodules, vasculitis, and pleuropulmonary symptoms. The American College of Rheumatology criteria for rheumatoid arthritis diagnosis have been revised and are shown in Table 59-6 (Aletaha, 2010). The revision focuses on features at earlier stages to permit earlier therapy initiation with a goal of preventing or decreasing long-term sequelae.

**Management**

Treatment is directed at pain relief, inflammation reduction, protection of articular structures, and preservation of function. Physical and occupational therapy and self-management instructions are essential. Although aspirin and other NSAIDs are the cornerstone of symptomatic therapy, they do not retard disease progression. Conventional NSAIDs nonspecifically inhibit both cyclooxygenase-1 (COX-1)—an enzyme critical to normal platelet function, and COX-2—an enzyme that mediates inflammatory response mechanisms. Gastritis with acute bleeding is an unwanted side effect common to conventional NSAIDs. Specific COX-2 inhibitors have been used to avert this complication. However, there are now concerns that their long-term use is associated with increased risk for myocardial infarction, stroke, and heart failure (Solomon, 2005). A systematic review by Adams and colleagues (2012) identified two studies of women treated for inflammatory arthritis. They reported a higher rate of cardiac malformations in infants exposed to NSAIDs in the first trimester. In addition, NSAIDs are associated with early spontaneous abortions, ductus constrictions, and neonatal pulmonary hypertension (Briggs, 2011). Thus, risks versus benefits of these medications must be considered.

Glucocorticoid therapy may be added to NSAIDs. Of these, prednisone, 7.5 mg orally daily for the first 2 years of active disease, substantively reduces progressive joint erosions (Kirwan, 1995). Although corticosteroids are usually avoided if possible, low-dose therapy is used by some along with salicylates.

Because NSAIDs and glucocorticoids are primarily for symptomatic relief, the American College of Rheumatology (2012) recommends disease-modifying antirheumatic drugs (DMARDs). These have the potential to reduce or prevent joint damage and are given within 3 months of diagnosis. There are several DMARDs, and many have considerable toxicity. For example, methotrexate and leflunomide are teratogenic (Briggs, 2011). Sulfasalazine and hydroxychloroquine are safe for use in pregnancy (Partlett, 2011; Raza, 2010). These, combined with COX-2 inhibitors and with relatively low-dose prednisone—7.5 to 20 mg daily—for flares are often all the pharmacotherapy needed. Azathioprine treatment may be used if immunosuppressive drugs are warranted. From their review, Kuriya and associates (2011) found that a fourth of women with rheumatoid arthritis took a DMARD within 6 months of conception. During pregnancy, 4 percent of 393 pregnant women were given a category D or X medication.
Methotrexate was the most common—2.9 percent. These authors advocate continued efforts to counsel women and their physicians regarding potential risks of many rheumatoid arthritis therapies during pregnancy.

Cytokine inhibitors, which include etanercept (Enbrel), adalimumab (Humira), and infliximab (Remicade), are also being used (McInnes, 2011). The newer immune-targeted drugs for rheumatoid arthritis have shown great promise. But, their use in pregnancy is limited, and fetal safety issues are a concern (Makol, 2011; Ojeda-Uribe, 2013). In the review by Kuriya and coworkers (2011) discussed earlier, 13 percent of 393 women were given a biological cytokine-inhibiting DMARD—primarily etanercept. Experience with these agents in pregnancy has been accruing (Verstappen, 2011). Berthelot and colleagues (2009) found more than 300 reported cases in their review and noted no fetal effects from exposure. Patients considered for etanercept treatment can be entered into a registry at 877-311-8972. There is also little known regarding pregnancy effects of the interleukin-1 receptor antagonist, anakinra (Kineret), and the antagonist to the B-cell CD20 antigen, rituximab (Rituxan).

Other drugs used less frequently include penicillamine, gold salts, minocycline, and cyclosporine. Orthopedic surgery for joint deformities, including replacement, is frequently performed outside of pregnancy.

**Pregnancy and Rheumatoid Arthritis**

Up to 90 percent of women with rheumatoid arthritis will experience improvement during pregnancy (de Man, 2008). Animal studies suggest this may be due to regulatory T-cell alterations. Transfer of regulatory T cells from pregnant mice conferred protection to those not pregnant (Munoz-Suano, 2012). That said, some women develop disease during pregnancy, and others become worse (Nelson, 1997).

A downside to this respite during pregnancy is that postpartum exacerbation is common (Østensen, 2007). This may be due to alterations in innate immunity postpartum (Häupl, 2008b). Barrett and coworkers (2000a) reported that a postpartum flare was more common if women were breast feeding. These same investigators performed a prospective United Kingdom study involving 140 women with rheumatoid arthritis (Barrett, 2000b). During 1 to 6 months postpartum, there was only a modest fall in objective disease activity, and only 16 percent had complete remission. At least 25 percent had substantive levels of disability. They observed that although overall disease actually did not exacerbate postpartum, the mean number of inflamed joints increased significantly.

There are some studies that report a protective effect of pregnancy for women developing subsequent new-onset rheumatoid arthritis. Silman and associates (1992) performed a case-control study of 88 affected women. They found that although there was a protective effect of pregnancy in the long term, the likelihood of new-onset rheumatoid arthritis was increased sixfold during the first 3 postpartum months. Pikwer and colleagues (2009) reported a significant reduction in the risk of subsequent arthritis in women who breast fed longer than 12 months.

As an explanation for these findings, and as discussed previously, sex hormones supposedly interfere with a number of putative processes involved in arthritis pathogenesis, including immunoregulation and interactions with the cytokine system (Häupl, 2008a,b). First, Unger and associates (1983) reported that amelioration of rheumatoid arthritis correlated with serum levels of pregnancy-associated α2-glycoprotein. This compound has immunosuppressive properties. Second, Nelson and coworkers (1993) reported that amelioration of disease was associated with a disparity in HLA class II antigens between mother and fetus. They suggested that the maternal immune response to paternal HLA antigens may play a role in pregnancy-induced remission of
arthritis. In addition to monocyte activations, there also may be T-lymphocyte activation (Förger, 2008).

### Juvenile Rheumatoid Arthritis

This is a group of diseases that are the most frequent cause of chronic arthritis in children. They persist into adulthood. Østensen (1991) reviewed outcomes of 76 pregnancies in 51 affected Norwegian women. Pregnancy had no effects on presentation of disease, but disease activity usually became quiescent or remained so during pregnancy. Postpartum flares were common as was discussed for rheumatoid arthritis. Joint deformities often developed in these women, and 15 of 20 cesarean deliveries were done for contracted pelves or joint prostheses. These observations are supported by the summary of similar results in 39 Polish women with juvenile rheumatoid arthritis (Musiej-Nowakowska, 1999).

### Perinatal Outcome.

There are no obvious adverse effects of rheumatoid arthritis on pregnancy outcome, but an increased risk for preterm birth is debated (Klipple, 1989; Langen, 2014; Wallenius, 2011). In a population-based cohort study, Skomsvoll and associates (2002) reported that women with rheumatic disease with two previous poor pregnancy outcomes were at high risk for recurrent adverse outcomes. Kaplan (1986) reported that women who later develop the disease had a prior higher-than-expected incidence of spontaneous abortion. However, Nelson and colleagues (1992) did not corroborate this.

### Management During Pregnancy.

Treatment of symptomatic women during pregnancy is with aspirin and NSAIDs. These are used with appropriate concerns for first-trimester effects, impaired hemostasis, prolonged gestation, premature ductus arteriosus closure, and persistent pulmonary circulation (Chap. 12, p. 247) (Briggs, 2011). Low-dose corticosteroids are also prescribed as indicated. Gold compounds have been administered in pregnancy. Of 14 women experiencing 20 pregnancies on gold therapy, 75 percent delivered healthy liveborn neonates (Almarzouqi, 2007).

Immunosuppressive therapy with azathioprine, cyclophosphamide, or methotrexate is not routinely used during pregnancy. Of these, only azathioprine should be considered during early pregnancy because the other agents are teratogenic (Briggs, 2011; Buhimschi, 2009). As noted earlier, DMARDs including sulfasalazine and hydroxychloroquine are acceptable for use in pregnancy.

If the cervical spine is involved, particular attention is warranted during pregnancy. Subluxation is common, and pregnancy, at least theoretically, predisposes to this because of joint laxity (Chap. 4, p. 71). Importantly, there are anesthesia concerns regarding endotracheal intubation.

Following pregnancy, contraceptive counseling may include combination oral contraceptives. These are a logical choice because of their effectiveness and their potential to improve disease (Bijlsma, 1992; Farr, 2010). That said, all methods of contraception are appropriate.

### Systemic Sclerosis—Scleroderma

This is a chronic multisystem disorder of unknown etiology. It is characterized by microvascular damage, immune system activation leading to inflammation, and excessive deposition of collagen in the skin and often in the lungs, heart, gastrointestinal tract, and kidneys. It is uncommon, displays a 3-to-1 female dominance, and typically affects those aged 30 to 50 years.

This strong prevalence of scleroderma in women and its increased incidence in the years...
following childbirth contribute to the hypothesis that microchimerism is involved as discussed on page 1168 (Lambert, 2010). Artlett and coworkers (1998) demonstrated Y-chromosomal DNA in almost half of women with systemic sclerosis compared with only 4 percent of controls. Rak and colleagues (2009b) identified male microchimerism in peripheral blood mononuclear cells more frequently in women with limited versus diffuse scleroderma—20 versus 5 percent.

**Clinical Course**

The hallmark is overproduction of normal collagen. In the more benign form—*limited cutaneous systemic sclerosis*—progression is slow. With *diffuse cutaneous systemic sclerosis*, skin thickening progresses rapidly, and skin fibrosis is followed by gastrointestinal tract fibrosis, especially the distal esophagus (Varga, 2012). Pulmonary interstitial fibrosis along with vascular changes may cause pulmonary hypertension. Antinuclear antibodies are found in 95 percent of patients, and immunoincompetence often develops.

Frequent symptoms are Raynaud phenomenon, which includes cold-induced episodic digital ischemia in 95 percent, as well as swelling of the distal extremities and face. Half of patients have symptoms from esophageal involvement, especially fullness and epigastric burning pain. Pulmonary involvement is common and causes dyspnea. The 10-year cumulative survival rate is 70 percent in those with pulmonary fibrosis, and pulmonary arterial hypertension is the main causes of death (Joven, 2010; Ranque, 2010). Women with limited cutaneous disease such as the *CREST syndrome*—calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia—have milder disease.

*Overlap syndrome* refers to the presence of systemic sclerosis with features of other connective-tissue disorders. *Mixed-connective-tissue disease* is a term used for the syndrome involving features of lupus, systemic sclerosis, polymyositis, rheumatoid arthritis, and high titers of anti-RNP antibodies (see Table 59-1). The disorder is also termed *undifferentiated connective-tissue disease* (Spinillo, 2008).

Although systemic sclerosis cannot be cured, treatment directed at end-organ involvement can relieve symptoms and improve function (Varga, 2012). Hydroxychloroquine and low-dose corticosteroids are helpful, and intravenous immunoglobulin may be indicated for pericarditis and hemolytic anemia. Renal involvement and hypertension are common. At times, angiotensin-converting enzyme (ACE) inhibitors may be required for blood pressure control despite their known teratogenicity (Buhimschi, 2009). *Scleroderma renal crisis* develops in up to a fourth of these patients and is characterized by obliterative vasculopathy of the renal cortical arteries. This results in renal failure and malignant hypertension. Interstitial restrictive lung disease is common and frequently becomes life threatening. Associated pulmonary hypertension is usually fatal. Cyclophosphamide provides some improvement (Tashkin, 2006).

**Pregnancy and Systemic Sclerosis**

The prevalence of scleroderma in pregnancy is estimated from a study of nearly 11.2 million pregnant women registered in the Nationwide Inpatient Sample. In this study, Chakravarty and associates (2008) reported that 504 women suffered from systemic sclerosis—a prevalence of approximately 1 in 22,000 pregnancies. These women usually have stable disease during gestation if their baseline function is good. As perhaps expected, dysphagia and reflux esophagitis are aggravated by pregnancy (Steen, 1999). Dysphagia results from loss of esophageal motility due to neuromuscular dysfunction. A decrease in amplitude or disappearance of peristaltic waves in the lower two thirds of the esophagus is seen using manometry. Symptomatic treatment for reflux is described in Chapter 54 (p. 1072). Women with renal insufficiency and malignant hypertension
have an increased incidence of superimposed preeclampsia. In the presence of rapidly worsening renal or cardiac disease, pregnancy termination should be considered. As discussed, renal crisis is life threatening and is treated with ACE inhibitors, but it does not improve with delivery (Gayed, 2007). Pulmonary hypertension usually contraindicates pregnancy (Chap. 49, p. 987).

Vaginal delivery may be anticipated, unless the soft tissue thickening wrought by scleroderma produces dystocia requiring cesarean delivery. Tracheal intubation for general anesthesia has special concerns because of limited ability of these women to open their mouths widely (Black, 1989). Because of esophageal dysfunction, aspiration is also more likely, and epidural analgesia is preferable.

**Pregnancy Outcomes**

Maternal and fetal outcomes are related to the severity of underlying disease. Steen and colleagues (1989, 1999) described pregnancies in 214 women with systemic sclerosis—45 percent had diffuse disease. Major complications included renal crisis in three women and increased rates of preterm birth. Chung and coworkers (2006) also reported increased rates of preterm delivery, fetal-growth restriction, and perinatal mortality. A multicenter study of 109 pregnancies from 25 centers reported higher rates of preterm delivery, fetal-growth restriction, and very-low-birthweight infants (Taraboreli, 2012). These are likely related to placental abnormalities that include decidual vasculopathy, acute atherosis, and infarcts. These reduce placental blood flow and are found in many cases (Doss, 1998; Papakonstantinou, 2007).

**Contraception**

Scleroderma may be associated with subfertility (Bernatsky, 2008; Lambe, 2004). For women who do not choose pregnancy, several reversible contraceptive methods are acceptable. However, hormonal agents, especially combination oral contraceptives, probably should not be used, especially in women with pulmonary, cardiac, or renal involvement. Due to the often unrelenting progression of systemic sclerosis, permanent sterilization should also be considered.

**Vasculitis Syndromes**

Inflammation and damage to blood vessels may be primary or due to another disease. Most cases are presumed to be caused by immune-complex deposition (Langford, 2012). Primary causes include polyarteritis nodosa, Wegener granulomatosis, Churg-Strauss syndrome, temporal or giant cell arteritis, Takayasu arteritis, Henoch-Schönlein purpura, Behçet syndrome, and cutaneous or hypersensitivity arteritis (Goodman, 2014). Some of these syndromes have antibodies directed against proteins in the cytoplasmic granules of leukocytes—antineutrophil cytoplasmic antibodies—ANCA. Their role in vasculitis is unclear, and disease activity is not related to increasing titers.

**Polyarteritis Nodosa**

This necrotizing vasculitis of small and medium-sized arteries is characterized clinically by myalgia, neuropathy, gastrointestinal disorders, hypertension, and renal disease (Goodman, 2014). Approximately a third of cases are associated with hepatitis B antigenemia (Langford, 2012).

Symptoms are nonspecific and vague. Fever, weight loss, and malaise are present in more than half of cases. Renal failure, hypertension, and arthralgias are common. Diagnosis is made by biopsy, and treatment consists of high-dose prednisone plus cyclophosphamide. Vasculitis due to
hepatitis B antigenemia responds to antivirals, glucocorticoids, and plasma exchange (Chap. 55, p. 1090).

There have been only a few reports of documented cases of polyarteritis nodosa associated with pregnancy. Even without definitive data, active arteritis in pregnancy is associated with high mortality rates. Owen and Hauth (1989) reviewed the courses of 12 such pregnant women. In seven, polyarteritis first manifested during pregnancy, and it was rapidly fatal by 6 weeks postpartum. The diagnosis was not made until autopsy in six of the seven women. Four women continued pregnancy, which resulted in one stillborn and three successful outcomes.

Wegener Granulomatosis
This is a necrotizing granulomatous vasculitis of the upper and lower respiratory tract and kidney. Disease frequently includes sinusitis and nasal disease—90 percent; pulmonary infiltrates, cavities, or nodules—85 percent; glomerulonephritis—75 percent; and musculoskeletal lesions—65 percent (Sneller, 1995). At least 90 percent have polyangiitis (Langford, 2012). It is uncommon and usually encountered after 50 years of age. Koukoura and associates (2008) reviewed 36 cases reported in association with pregnancy. In another report, a woman with Wegener disease developed thrombotic microangiopathy associated renal impairment at 32 weeks. A second woman had pneumonitis, but pregnancy did not appear to affect disease activity (Pagnoux, 2011). Because subglottic stenosis is found in up to a fourth, the anesthesia team should be consulted during pregnancy (Engel, 2011; Kayatas, 2012).

Corticosteroids are standard treatment, but azathioprine, cyclosporine, and intravenous immunoglobulin may also be used. For severe disease in the late second or third trimester, cyclophosphamide in combination with prednisolone seems acceptable.

Takayasu Arteritis
Also called pulseless disease, this syndrome is most prevalent in young women. It is a chronic inflammatory arteritis affecting large vessels (Goodman, 2014). Unlike temporal arteritis, which develops almost exclusively after age 55, the onset of Takayasu arteritis is almost always before age 40. It is associated with abnormal angiography of the upper aorta and its main branches and with upper extremity vascular impairment. Death usually results from congestive heart failure or cerebrovascular events. Computed tomography or magnetic resonance angiography can detect this disorder before the development of severe vascular compromise (Numano, 1999). Takayasu arteritis may respond symptomatically to corticosteroid therapy, however, it is not curative. Selection of surgical bypass or angioplasty has improved survival rates.

Severe renovascular hypertension, cardiac involvement, or pulmonary hypertension worsen pregnancy prognosis. Hypertension is relatively common and should be carefully controlled. Blood pressure is measured in the lower extremity. Overall, the prognosis for pregnancy is good (de Jesús, 2012; Hernández-Pacheco, 2011; Hidaka, 2012; Johnston, 2002; Kraemer, 2008; Mandal, 2012). When the abdominal aorta is involved, however, pregnancy outcome may be disastrous (Sharma, 2000). Vaginal delivery is preferred, and epidural analgesia has been advocated for labor and delivery (Langford, 2002).

Other Vasculitides
Vasculitis caused by Henoch-Schönlein purpura is uncommon after childhood. Tayabali and associates (2012) reviewed 20 pregnancies complicated by this vasculitis and described cutaneous lesions in three fourths. Approximately half had arthralgias. Jadaon and colleagues
(2005) described 135 pregnancies in 31 women with Behçet disease compared with matched nonaffected controls. Although there were no deleterious effects of pregnancy on the underlying disease, the miscarriage rate was significantly increased threefold. Hwang and coworkers (2009) described necrotizing villitis and decidual vasculitis in a placenta from a first-trimester pregnancy termination and another from a term delivery. Churg-Strauss vasculitis is rare in pregnancy. Hot and associates (2007) described a pregnant woman who responded to intravenous immune globulin therapy. Corradi and associates (2009) described an affected 35-year-old woman at term whose necrotizing vasculitis involved the heart, and she subsequently underwent cardiac transplantation.

INFLAMMATORY MYOPATHIES

This is the largest group of acquired and potentially treatable causes of skeletal muscle weakness. That said, these disorders have a prevalence of 1 in 100,000 persons (Dalakas, 2012). There are three major groups: polymyositis, dermatomyositis, and inclusion-body myositis, which all present with progressive asymmetrical muscle weakness. They have a variable association with connective-tissue diseases, malignancy, drugs, systemic autoimmune disease such as Crohn disease, and viral, bacterial, and parasitic infections.

Polymyositis is a subacute inflammatory myopathy that is frequently associated with one of the autoimmune connective-tissue disorders. Dermatomyositis manifests as a characteristic rash accompanying or preceding weakness. Laboratory findings include elevated muscle enzyme levels in serum and an abnormal electromyogram. Confirmation is by biopsy, which shows perivascular and perimysial inflammatory infiltrates, vasculitis, and muscle fiber degeneration. It usually develops alone but can overlap with scleroderma or mixed connective-tissue disease.

Prevailing theories suggest that the syndromes are caused by viral infections, autoimmune disorders, or both. Importantly, approximately 15 percent of adults who develop dermatomyositis have an associated malignant tumor. The timing of myositis and tumor appearance may be separated by several years. The most common sites of associated cancer are breast, lung, stomach, and ovary. The disease usually responds to high-dose corticosteroid therapy, immunosuppressive drugs such as azathioprine or methotrexate, or IVIG (Dalakas, 2012; Williams, 2007). Linardaki and colleagues (2011) report successful treatment with IVIG and corticosteroids in pregnancy.

Experiences in pregnancy are garnered mostly from case series and reviews. Gutierrez and coworkers (1984) reviewed outcomes in 10 pregnancies among seven women with active disease. They reported three abortions, three perinatal deaths, and five preterm deliveries. Rosenzweig and colleagues (1989) reviewed 24 pregnancy outcomes in 18 women with primary polymyositis-dermatomyositis. In 12, the diagnosis preceded pregnancy. Of these, a fourth had an exacerbation in the second or third trimester. Excluding abortions, there were two perinatal deaths and two growth-restricted neonates. In the other 12 in whom disease became manifest first during pregnancy, outcomes were even less favorable. Excluding abortions, half of the eight pregnancies resulted in perinatal death, and one woman died postpartum. Ohno (1992) and Papapetropoulos (1998) and their coworkers described similar cases. From their review, Doria and associates (2004) concluded that pregnancy outcome was related to disease activity and that new-onset disease was particularly aggressive.
Numerous inherited mutations involve genes that encode for structural proteins of bone, skin, cartilage, blood vessels, and basement membranes. Although connective tissues contain many complex macromolecules such as elastin and more than 30 proteoglycans, the most common constituents are fibrillar collagen types I, II, and III. Various mutations, some recessively and some dominantly inherited, result in clinical syndromes that include Marfan and Ehlers-Danlos syndromes, osteogenesis imperfecta, chondrodysplasias, and epidermolysis bullosa. Of concern during pregnancy is the predilection for these disorders to result in aortic aneurysms (Schoenhoff, 2013).

### Marfan Syndrome

This is a common autosomal dominant connective-tissue disorder that has a prevalence of 1 in 3000 to 5000 (Prockop, 2012). Marfan syndrome affects both sexes equally. It is caused by a mutation of the fibrillin-1 (FBN1) gene on the long arm of chromosome 15 (Loeys, 2002). The FBN1 gene has a high mutation rate, and there are many mild, subclinical cases. In severe disease, there is degeneration of the elastic lamina in the media of the aorta. This weakness predisposes to aortic dilatation or dissecting aneurysm, which appears more commonly during pregnancy (Bloom, 2010; Curry, 2014; Savi, 2007). Marfan syndrome complicating pregnancy is discussed in detail in Chapter 49 (p. 993).

### Ehlers–Danlos Syndrome

This disease is characterized by various connective tissue changes, including skin hyperelasticity. In the more severe types, there is a strong tendency for rupture of any of several arteries to cause either stroke or bleeding. Rupture of the colon or uterus has been described. There are several types of disease based on skin, joint, or other tissue involvement. Some are autosomal dominant, some recessive, and some X-linked (Solomons, 2013). Their aggregate prevalence is approximately 1 in 5000 births (Prockop, 2012). Types I, II, and III are autosomally dominant, and each accounts for about 30 percent of cases. Type IV is uncommon but is known to predispose to preterm delivery, maternal great-vessel rupture, postpartum bleeding, and uterine rupture (Pepin, 2000). In most, the underlying molecular defect is one of collagen or procollagen.

In general, women with Ehlers-Danlos syndrome have an increased frequency of preterm rupture of membranes, preterm delivery, and antepartum and postpartum hemorrhage (Volkov, 2006). Several cases of spontaneous uterine rupture have been described (Bloom, 2010; Rudd, 1983; Walsh, 2007). Tissue fragility makes episiotomy repair and cesarean delivery difficult. Sorokin and colleagues (1994) surveyed female members of the Ehlers-Danlos National Foundation. They reported a stillbirth rate of 3 percent, a preterm delivery rate of 23 percent, and a cesarean delivery rate of 8 percent. Fifteen percent had problematic postpartum bleeding. A maternal and fetal death from spontaneous rupture of the right iliac artery was described by Esaka and coworkers (2009). Finally, Bar-Yosef and associates (2008) described a newborn with multiple congenital skull fractures and intracranial hemorrhage caused by Ehlers-Danlos type VIIC.

### Osteogenesis Imperfecta
This disorder is characterized by very low bone mass resulting in brittle bones. Affected patients often have blue sclerae, hearing loss, a history of multiple fractures, and dental abnormalities. There are seven subtypes that range from severe to mild clinical disease. Subtypes show differing genetic inheritance and include autosomal dominant, autosomal recessive, and sporadic patterns. Type I is the mildest form, whereas type II is typically lethal in utero (Prockop, 2012). There are well-characterized gene mutations coding for type I procollagen. These are associated with the specific subtypes. For example, the typical mutation with type I is a premature stop codon in the COL1A1 gene (Sykes, 1990). Osteogenesis imperfecta has a prevalence of 1 in 30,000 births for type I and 1 in 60,000 for type II.

Women with osteogenesis imperfecta, most commonly type I, may have successful pregnancies (Lyra, 2010). That said, there are several risks in pregnancy, including fractures, complications related to scoliosis with restrictive lung disease, micrognathia, brittle teeth, an unstable cervical spine, uterine rupture, and cephalopelvic disproportion. These women may also have hyperthyroidism and valvular heart disease. It is not unusual for affected women to enter pregnancy having had 20 to 30 prior fractures. Most women with this skeletal disorder require minimal treatment other than management of the fractures and consideration of bisphosphonates to decrease bone loss. The anesthesia team should be consulted during pregnancy regarding plans for delivery (Murray, 2010).

Depending on the type of osteogenesis imperfecta, the fetus may be affected and may also suffer fractures in utero or during delivery (Chap. 10, p. 217). Prenatal diagnosis is available in many situations, if desired.

A number of neurological diseases are relatively common in women of childbearing age. In the past, some of these may have precluded pregnancy, however, few do so now. Most of those encountered during pregnancy are the same as for nonpregnant women. That said, there are a few neurological disorders that may be seen more frequently in pregnant women. Some examples are Bell palsy, specific types of strokes, and benign intracranial hypertension or pseudotumor cerebri. Neurovascular disorders are an important cause of maternal mortality and accounted for 10 percent of maternal deaths in the United States from 1998 through 2005 (Berg, 2010b).

Because many neurological disorders are chronic, they frequently precede pregnancy. Although most women with chronic neurological disease who become pregnant will have successful outcomes, some of these disorders have specific risks with which clinicians should be familiar. Conversely, some women will have new-onset neurological symptoms during pregnancy, and these frequently must be distinguished from other pregnancy complications. Psychiatric disorders may also manifest with cognitive and neuromuscular abnormalities, and they should be considered in the evaluation.
Computed tomography (CT) and magnetic resonance (MR) imaging have opened new vistas for the diagnosis, classification, and management of many neurological and psychiatric disorders. As discussed in Chapter 46 (p. 933), these cranial imaging methods can be used safely during pregnancy. CT scanning is commonly used whenever rapid diagnosis is necessary and is excellent for detecting recent hemorrhage (Smith, 2012). Because it does not use radiation, MR imaging is often preferred. It is particularly helpful to diagnose demyelinating diseases, screen for arteriovenous malformations, evaluate congenital and developmental nervous system abnormalities, identify posterior fossa lesions, and diagnose spinal cord diseases (Gjelsteen, 2008). Whenever either test is done, the woman should be positioned in a left lateral tilt with a wedge under one hip to prevent hypotension as well as to diminish aortic pulsations, which may degrade the image.

Cerebral angiography with contrast injection, usually via the femoral artery, is a valuable adjunct to the diagnosis and treatment of some cerebrovascular diseases. Fluoroscopy delivers more radiation but can be performed with abdominal shielding. Positron emission tomography (PET) and functional MRI (fMRI) have not been evaluated for use in pregnant patients (Chiapparini, 2010).

HEADACHE

The National Health Interview Survey is provided by the Centers for Disease Control and Prevention (Pleis, 2010). In the 2009 survey, a fifth of all women aged 18 to 44 years reported a severe headache or migraine within the past 3 months, and headache was the most common neurological complaint during pregnancy. Smitherman and coworkers (2013) found that 26 percent of nonpregnant women in this age group were similarly affected. Interestingly, Aegidius and colleagues (2009) reported an overall decrease in prevalence of all headache types during pregnancy in nulliparas, especially during the third trimester. The classification of headaches by the International Headache Society (2004) is shown in Table 60-1. Primary headaches are more common in pregnant women than those with secondary causes (Digre, 2013). Migraine headaches are those most likely to be affected by the hormonal changes of pregnancy (Torelli, 2010).

**TABLE 60-1. Classification of Headache**

- **Primary**
  - Tension-type (69%)
  - Migraine (16%)
  - Cluster and other trigeminal autonomic cephalgias (< 1%)
  - Other

- **Secondary**
  - Systemic infection (63%)
  - Head or neck trauma (4%)
Tension-Type Headache

These are most common, and characteristic features include muscle tightness and mild to moderate pain that can persist for hours in the back of the neck and head. There are no associated neurological disturbances or nausea. The pain usually responds to rest, massage, application of heat or ice, antiinflammatory medications, or mild tranquilizers.

Migraine Headache

These headaches have a 1-year prevalence in all women of approximately 15 percent, and thus they are frequently encountered during pregnancy. The term *migraine* describes a periodic, sometimes incapacitating neurological disorder characterized by episodic attacks of severe headache and autonomic nervous system dysfunction (Goadsby, 2012). The International Headache Society (2004) classifies three migraine types based on the presence or absence of an aura as well as chronicity:

1. **Migraine without aura**—was formerly termed common migraine—and is characterized by a unilateral throbbing headache, nausea and vomiting, or photophobia.
2. **Migraine with aura**—formerly termed classic migraine—has similar symptoms preceded by premonitory neurological phenomena such as visual scotoma or hallucinations. A third of patients have this type of migraine, which sometimes can be averted if medication is taken at the first premonitory sign.
3. **Chronic migraine** is defined by a migraine headache occurring at least 15 days each month for more than 3 months.

Migraines may begin in childhood, peak in adolescence, and tend to diminish in both frequency and severity with advancing years. According to Lipton and associates (2007), their annual prevalence is 17 percent in women and 6 percent in men. Another 5 percent of women have *probable migraine*, that is, they have all criteria but one (Silberstein, 2007). Migraines are especially common in young women and have been linked to hormone levels (Torelli, 2010).

The exact pathophysiology of migraines is uncertain, but they occur when neuronal dysfunction leads to decreased cortical blood flow, activation of vascular and meningeal nociceptors, and stimulation of trigeminal sensory neurons (Brandes, 2007; D’Andrea, 2010). A predilection for the posterior circulation has been described by Kruit and coworkers (2004). Migraines—especially those with aura in young women—are associated with increased risk for ischemic strokes as discussed on page 1191. The risk is greater in those who smoke or use combination oral
Migraine in Pregnancy

The prevalence of migraine headaches in the first trimester is 2 percent (Chen, 1994). Prospective as well as observational studies have shown that most migraineurs have improvement during pregnancy (Adeney, 2006; Menon, 2008; Torelli, 2010). Still, migraines—usually those with an aura—occasionally appear for the first time during pregnancy. Pregnant women with preexisting migraine symptoms may have other symptoms suggestive of a more serious disorder, and new neurological symptoms should prompt a complete evaluation (Detsky, 2006; Heaney, 2010).

Although conventional thinking has been that migraine headaches do not pose increased maternal or fetal risks, several recent studies have refuted this (Allais, 2010). For example, women with severe migraines in the first 8 weeks may be at slightly increased risk for a fetus with limb-reduction defects (Banhidy, 2006). Preeclampsia and other cardiovascular morbidities are also increased (Facchinetti, 2009; Sanchez, 2008; Schürks, 2009). In a case-control study of nearly 18.5 million pregnancy-related discharges from 2000 through 2003, Bushnell and coworkers (2009) identified an incidence of migraine discharge codes of 185 per 100,000. Associated diagnoses and increased significant risks were found for migraines and stroke—15.8-fold; myocardial infarction—4.9; heart disease—2.1; venous thromboembolism—2.4; and preeclampsia/gestational hypertension—2.3-fold.

Management

Data are limited regarding nonpharmacological management in pregnancy such as biofeedback techniques, acupuncture, and transcranial magnetic stimulation (Airola, 2010; Dodick, 2010). Effective pharmacological interventions include nonsteroidal antiinflammatory drugs, and most migraine headaches respond to simple analgesics such as ibuprofen or acetaminophen, especially if given early. Because of patient idiosyncrasies, multitarget drug therapy is necessary in most cases for migraine relief (Gonzalez-Hernandez, 2014). Severe headaches should be treated aggressively with intravenous hydration and parenteral antiemetics and opioids. Although intravenous magnesium sulfate has gained favor in the past few years, a recent metaanalysis reported no beneficial effects (Choi, 2014). Ergotamine derivatives are potent vasoconstrictors that should be avoided in pregnancy (Briggs, 2011).

Triptans are serotonin 5-HT$_{1B/2D}$-receptor agonists that effectively relieve headaches by causing intracranial vasoconstriction (Contag, 2010). They also relieve nausea and vomiting and greatly reduce the need for analgesics. They can be given orally, by injection, as a rectal suppository, or as a nasal spray. The greatest experience is with sumatriptan (Imitrex), and although not studied extensively in pregnancy, it appears to be safe (Briggs, 2011; Nezvalová-Henriksen, 2010).

For women with frequent migraine headaches, oral prophylactic therapy is warranted. Amitriptyline (Elavil), 10 to 150 mg daily; propranolol (Inderal), 20 to 80 mg three times daily; or metoprolol (Lopressor, Toprol), 50 to 100 mg twice daily, is safe in pregnancy and has been used with success (Contag, 2010; Lucas, 2009; Marcus, 2007).

Cluster Headaches

This rare primary headache disorder is characterized by severe unilateral lancinating pain radiating to the face and orbit, lasting 15 to 180 minutes, and occurring with autonomic symptoms
and agitation. Pregnancy does not affect symptom severity. Affected women should avoid tobacco and alcohol. Acute management includes 100-percent oxygen therapy and sumatriptan given as a 6-mg dose subcutaneously (Calhoun, 2010; Francis, 2010). If recurrent, prophylaxis is administered using a calcium-channel blocking agent.

**SEIZURE DISORDERS**

The Centers for Disease Control and Prevention reported that the prevalence of epilepsy in adults in 2005 was 1.65 percent (Kobau, 2008). There are 1.1 million American women of childbearing age who are affected. After headaches, seizures are the next most prevalent neurological condition encountered in pregnant women, and they complicate 1 in 200 pregnancies (Brodie, 1996; Yerby, 1994). Importantly, epilepsy accounted for 13 percent of maternal deaths in the United Kingdom for the 2005 to 2007 triennium (Lewis, 2007). Seizure disorders are also associated with altered fetal development, and they can adversely affect other pregnancy outcomes. The teratogenic effects of several anticonvulsant medications are unquestioned. The American Academy of Neurology and the American Epilepsy Society have developed guidelines regarding treatment in pregnant women, which are discussed subsequently (Harden, 2009a–c).

**Pathophysiology**

A seizure is defined as a paroxysmal disorder of the central nervous system characterized by an abnormal neuronal discharge with or without loss of consciousness. Epilepsy encompasses different syndromes whose cardinal feature is a predisposition to recurrent unprovoked seizures. The International League Against Epilepsy Commission on Classification and Terminology recently updated its terminologies for seizures (Berg, 2010a, 2011; Shorvon, 2011). This new classification schema is under development, and for now, most adults can be said to have either focal or generalized seizures.

**Focal Seizures**

These originate in one localized brain area and affect a correspondingly localized area of neurological function. They are believed to result from trauma, abscess, tumor, or perinatal factors, although a specific lesion is rarely demonstrated. Focal seizures without dyscognitive features start in one region of the body and progress toward other ipsilateral areas of the body, producing tonic and then clonic movements. Simple seizures can affect sensory function or produce autonomic dysfunction or psychological changes. Cognitive function is not impaired, and recovery is rapid. Focal seizures with dyscognitive features are often preceded by an aura and followed by impaired awareness manifested by sudden behavioral arrest or motionless stare. Involuntary movements such as picking motions or lip smacking are common.

**Generalized Seizures**

These involve both brain hemispheres and may be preceded by an aura before an abrupt loss of consciousness. There is a strong hereditary component. In generalized tonic-clonic seizures, loss of consciousness is followed by tonic contraction of the muscles and rigid posturing, and then by clonic contractions of all extremities while the muscles gradually relax. Return to consciousness is gradual, and the patient may remain confused and disoriented for several hours. Absence seizures...
—also called petit mal seizures—are a form of generalized epilepsy that involve a brief loss of consciousness without muscle activity and are characterized by immediate recovery of consciousness and orientation.

### Causes of Seizure

Some identifiable causes of convulsive disorders in young adults include head trauma, alcohol- and other drug-induced withdrawals, cerebral infections, brain tumors, biochemical abnormalities, and arteriovenous malformations. A search for these is prudent with a new-onset seizure disorder in a pregnant woman. The diagnosis of idiopathic epilepsy is one of exclusion.

### Preconceptional Counseling

Women with epilepsy should undergo education and counseling before pregnancy (Chap. 8, p. 158). Folic acid supplementation with 0.4 mg per day is begun at least 1 month before conception. The dose is increased to 4 mg when the woman taking antiepileptic medication becomes pregnant. These medications are assessed and adjusted with a goal of monotherapy using the least teratogenic medication. If this is not feasible, then attempts are made to reduce the number of medications used and to use them at the lowest effective dose (Dunlop, 2008). Medication withdrawal should be considered if a woman is seizure free for 2 years or more.

### Epilepsy During Pregnancy

The major pregnancy-related risks to women with epilepsy are increased seizure rates with attendant mortality risks and fetal malformations. Seizure control is the main priority. Earlier studies described worsening seizure activity during pregnancy, however, this is not as common nowadays because of more effective drugs. Contemporary studies cite increased seizure activity in only 20 to 30 percent of pregnant women (Mawer, 2010; Vajda, 2008; Viinikainen, 2006). Women who are seizure free for at least 9 months before conception will likely remain so during pregnancy (Harden, 2009b).

Increased seizure frequency is often associated with decreased and thus subtherapeutic anticonvulsant serum levels, a lower seizure threshold, or both. An impressive number of pregnancy-associated alterations can result in subtherapeutic serum levels. These include nausea and vomiting, decreased gastrointestinal motility, antacid use that diminishes drug absorption, pregnancy hypervolemia offset by protein binding, induction of hepatic enzymes such as cytochrome oxidases, placental enzymes that metabolize drugs, and increased glomerular filtration that hastens drug clearance. Importantly, some women discontinue medication because of teratogenicity concerns. Finally, the seizure threshold can be affected by pregnancy-related sleep deprivation as well as hyperventilation and pain during labor.

### Pregnancy Complications

Women with epilepsy have a small increased risk of some pregnancy complications (Borthen, 2011; Harden, 2009b). A population-based study from Iceland found that epileptic women had a twofold increased cesarean delivery rate (Olafsson, 1998). In a cohort study from Montreal, Richmond and coworkers (2004) reported an increased incidence of nonproteinuric hypertension and labor induction. From a Swedish study of 1207 epileptic women, Pilo and colleagues (2006) reported a 1.5-fold increased incidence of cesarean delivery, preeclampsia, and postpartum
hemorrhage. Postpartum depression rates have also been reported to be increased in epileptic women (Turner, 2009). Finally, children of epileptic mothers have a 10-percent risk of developing a seizure disorder.

Embryo-Fetal Malformations

For years, it was difficult to separate effects of epilepsy versus its therapy as the primary cause of fetal malformations. As discussed in Chapter 8 (p. 158), it is now believed that untreated epilepsy is not associated with an increased fetal malformation rate (Thomas, 2008; Viinikainen, 2006). That said, the fetus of an epileptic mother who takes certain anticonvulsant medications has an indisputably increased risk for congenital malformations. Moreover, monotherapy is associated with a lower birth defect rate compared with multiagent therapy. Thus, if necessary, increasing monotherapy dosage is at least initially preferable to adding another agent (Buhimschi, 2009).

Specific drugs, when given alone, increase the malformation rate (Chap. 12, p. 246). Some of these are listed in Table 60-2. Phenytoin and phenobarbital increase the major malformation rate two- to threefold above baseline (Perucca, 2005; Thomas, 2008). A particularly potent teratogen is valproate, which has a dose-dependent effect and increases the malformation risk four- to eightfold (Eadie, 2008; Klein, 2014; Wyszynski, 2005). In general, with polytherapy, the risk increases with each drug added. At least at this time, the newer antiepileptic medications are reported to have no associations with a markedly increased risk of major birth defects (Molgaard-Nielson, 2011).

TABLE 60-2. Teratogenic Effects of Common Anticonvulsant Medications
Management in Pregnancy

The major goal is seizure prevention. To accomplish this, treatment for nausea and vomiting is provided, seizure-provoking stimuli are avoided, and medication compliance is emphasized. The fewest necessary anticonvulsants are given at the lowest dosage effective for seizure control. Although some providers routinely monitor serum drug levels during pregnancy, these concentrations may be unreliable because of altered protein binding. Free or unbound drug levels, although perhaps more accurate, are not widely available. Importantly, there is no evidence that such monitoring improves seizure control (Adab, 2006). For these reasons, drug levels may be informative if measured following seizures or if noncompliance is suspected. Some of the newer agents such as lamotrigine and oxcarbazepine may be more amenable to serum drug level monitoring (Harden, 2009a; Pennell, 2008).

For women taking anticonvulsant drugs, a targeted sonographic examination at midpregnancy is recommended by some to search for anomalies (Chap. 10, p. 197). Testing to assess fetal well-being is generally not indicated for women with uncomplicated epilepsy.

Breast Feeding and Contraception
There are limited available data regarding the safety of breast feeding with the various anticonvulsant medications. That said, no obvious deleterious effects, such as long-term cognitive issues, have been reported (Briggs, 2011; Harden, 2009c). Some of the anticonvulsant agents are associated with increased oral contraceptive failures. Thus, other more reliable methods should be considered (Chap 38, p. 696).

**CEREBROVASCULAR DISEASES**

Abnormalities of the cerebrovascular circulation include strokes—both ischemic and hemorrhagic, as well as anatomical anomalies, such as arteriovenous malformations and aneurysms. The current endemic of obesity in this country, along with concomitant increases in heart disease, hypertension, and diabetes, has also resulted in increased stroke prevalence (Centers for Disease Control and Prevention, 2012). Women have a higher lifetime risk of stroke than men as well as higher associated mortality rates (Martínez-Sánchez, 2011; Roger, 2012). Moreover, pregnancy increases the immediate and lifetime risk of both ischemic and hemorrhagic stroke (Jamieson, 2010; Jung, 2010).

Stroke is relatively uncommon in pregnant women, but it contributes disparately to maternal mortality rates. Reported incidences of strokes in pregnancy range from 1.5 to 71 per 100,000 pregnancies (James, 2005; Kuklina, 2011; Scott, 2012). The incidence is increasing as measured by pregnancy-related hospitalizations for stroke (Callaghan, 2008; Kuklina, 2011). Importantly, most are associated with hypertensive disorders or heart disease. Almost 9 percent of the pregnancy-related mortality rate in the United States is due to cerebrovascular accidents, with a third being associated with preeclampsia (Berg, 2010b).

**Risk Factors**

Most strokes in pregnancy manifest either during labor and delivery or in the puerperium. In a study of 2850 pregnancy-related strokes, approximately 10 percent developed antepartum, 40 percent intrapartum, and almost 50 percent postpartum (James, 2005). Several risk factors—unrelated and related to pregnancy—have been reported from studies that included more than 10 million pregnancies. These include older age; migraines, hypertension, obesity, and diabetes; cardiac disorders such as endocarditis, valvular prostheses, and patent foramen ovale; and smoking. Those related to pregnancy include hypertensive disorders, gestational diabetes, obstetrical hemorrhage, and cesarean delivery. By far, the most common risk factors are pregnancy-associated hypertensive disorders. As noted, one third of strokes are associated with gestational hypertension, and there is a three- to eightfold increased risk of stroke in hypertensive compared with normotensive women (Scott, 2012; Wang, 2011). Women with preeclampsia undergoing general anesthesia may be at higher risk of stroke compared with those given neuraxial anesthesia (Huang, 2010). Another risk factor for peripartum stroke is cesarean delivery, which increases the risk 1.5-fold compared with vaginal delivery (Lin, 2008).

Pregnancy-induced effects on cerebrovascular hemodynamics are unclear as related to risk for stroke. Although cerebral blood flow decreased by 20 percent from midpregnancy until term, importantly, it increased significantly with gestational hypertension (Zeeman, 2003, 2004b). Such hyperperfusion would at least intuitively be dangerous in women with certain vascular anomalies.
Ischemic Stroke

Acute occlusion or embolization of an intracranial blood vessel causes cerebral ischemia, which may result in death of brain tissue (Fig. 60-1). The more common associated conditions and etiologies of ischemic stroke are shown in Table 60-3. A transient ischemic attack (TIA) is caused by reversible ischemia, and symptoms usually last less than 24 hours. Patients with a stroke usually have a sudden onset of severe headache, hemiplegia or other neurological deficits, or occasionally, seizures. Focal neurological symptoms accompanied by an aura usually signify a first-episode migraine (Liberman, 2008).

Evaluation of an ischemic stroke includes echocardiography and cranial imaging with CT, MR, or angiography. Serum lipids are measured with the caveat that their values are distorted by normal pregnancy (Appendix, p. 1291). Antiphospholipid antibodies and lupus anticoagulant are sought—these cause up to a third of ischemic strokes in otherwise healthy young women (Chap. 59, p. 1173). Also, tests for sickle-cell syndromes are completed when indicated. With a thorough evaluation, most causes can be identified, although treatment is not always available. Some of these include cardiac-associated embolism, vasculitis, or vasculopathy such as Moyamoya disease (Ishimori, 2006; Miyakoshi, 2009; Simolke, 1991).

**Preeclampsia Syndrome**

In reproductive-age women, a significant proportion of pregnancy-related ischemic strokes are caused by gestational hypertension and preeclampsia syndrome (Jeng, 2004). As shown in Figure 60-1, areas of subcortical perivascular edema and petechial hemorrhage may progress to cerebral infarction (Aukes, 2007, 2009; Zeeman, 2004a). Although these are usually clinically manifest by an eclamptic convulsion, a few women will suffer a symptomatic stroke from a larger cortical infarction (Chap. 40, p. 742).

Other conditions with findings similar to preeclampsia include thrombotic microangiopathies (Chap. 56, p. 1116) and the reversible cerebral vasoconstriction syndrome (Chap. 40, p. 743).
The latter, which is also termed *postpartum angiopathy*, can cause extensive cerebral edema with necrosis as well as widespread infarction with areas of hemorrhage (Katz, 2014; Ramnarayan, 2009; Singhal, 2009).

**Cerebral Embolism**

These strokes usually involve the middle cerebral artery (see Fig. 60-1). They are more common during the latter half of pregnancy or early puerperium (Lynch, 2001). The diagnosis can be made with confidence only after thrombosis and hemorrhage have been excluded. The diagnosis is more certain if an embolic source is identified. Hemorrhage may be more difficult to exclude because embolization and thrombosis are both followed by hemorrhagic infarction. Paradoxical embolism is an uncommon cause, even considering that more than a fourth of adults have a patent foramen ovale through which right-sided venous thromboemboli are deported (Kizer, 2005; Scott, 2012). Foraminal closure may not improve outcomes in these patients, however, this procedure has been performed during pregnancy (Dark, 2011; Furlan, 2012). Assorted cardioembolic causes of stroke include arrhythmias—especially atrial fibrillation, valvular lesions, mitral valve prolapse, mural thrombus, infective endocarditis, and peripartum cardiomyopathy.

Management of embolic stroke in pregnancy consists of supportive measures and antiplatelet therapy. Thrombolytic therapy and anticoagulation are controversial issues at this time (Kizer, 2005; Li, 2012).

**Cerebral Artery Thrombosis**

Most thrombotic strokes affect older individuals and are caused by atherosclerosis, especially of the internal carotid artery. Many are preceded by one or more transient ischemic attacks. Thrombolytic therapy with recombinant tissue plasminogen activator—rt-PA or alteplase is recommended within the first 3-hour window if there is measurable neurological deficit and if neuroimaging has excluded hemorrhage. This can be used in pregnancy. A principal risk is hemorrhagic transformation of an ischemic stroke in approximately 5 percent of treated patients (van der Worp, 2007).

**Cerebral Venous Thrombosis**

In a 10-center study in the United States, 7 percent of cerebral venous thromboses were associated with pregnancy (Wasay, 2008). Even so, pregnancy-associated cerebral venous thrombosis is rare in developed countries, and reported incidences range from 1 in 11,000 to 1 in 45,000 pregnancies (Lanska, 1997; Simolke, 1991). In the Nationwide Inpatient Sample of more than 8 million deliveries, James and associates (2005) observed that venous thrombosis caused only 2 percent of pregnancy-related strokes (Saposnik, 2011). There are numerous predisposing causes, and the greatest risk is in late pregnancy and the puerperium.

Thrombosis of the lateral or superior sagittal venous sinus usually occurs in the puerperium and often in association with preeclampsia, sepsis, or thrombophilia (see Fig. 60-1). It is more common in patients with inherited thrombophilias, lupus anticoagulant, or antiphospholipid antibodies (Chaps. 52, p. 1029 and 59, p. 1173). Headache is the most common presenting symptom, neurological deficits are common, and up to a third of patients have convulsions (Wasay, 2008). Diagnosis is with MR venography (Saposnik, 2011).

Management includes anticonvulsants for seizures, and although heparinization is recommended by most, its efficacy is controversial (de Freitas, 2008; Saposnik, 2011; Smith, 2012). Antimicrobials are given if there is septic thrombophlebitis, and fibrinolytic therapy is reserved...
for those women failing systemic anticoagulation. The prognosis for venous thrombosis in pregnancy is better than in nonpregnant subjects, and mortality rates are less than 10 percent (McCaulley, 2011). The recurrence rate is 1 to 2 percent during a subsequent pregnancy (Mehraein, 2003).

**Recurrence Risk of Ischemic Stroke**

Women with previous ischemic stroke have a low risk for recurrence during a subsequent pregnancy unless a specific, persistent cause is identified. Lamy and colleagues (2000) followed 37 women who had an ischemic stroke during pregnancy or the puerperium, and none of their 24 subsequent pregnancies was complicated by another stroke. In another study of 23 women who had prepregnancy strokes from a variety of causes, there were 35 subsequent pregnancies without a stroke recurrence (Coppage, 2004). Finally, in a follow-up study of 1770 nonpregnant women with antiphospholipid-related ischemic stroke, investigators reported no difference in the recurrence risk as long as preventative treatment was given with warfarin or aspirin (Levine, 2004). In another study of nonpregnant subjects, low-dose aspirin following venous thromboembolism decreased the risk of a subsequent stroke (Brighton, 2012).

Currently, there are no firm guidelines regarding prophylaxis in pregnant women with a stroke history (Helms, 2009). The American Heart Association stresses the importance of controlling risk factors such as hypertension and diabetes (Furie, 2011). Women with antiphospholipid antibody syndrome or certain cardiac conditions should be considered for prophylactic anticoagulation as discussed in Chapters 49 (p. 979) and 59 (p. 1175).

**Hemorrhagic Stroke**

The two distinct categories of spontaneous intracranial bleeding are intracerebral and subarachnoid hemorrhage. The symptoms of a hemorrhagic stroke are similar to those of an ischemic stroke. Their differentiation is only possible with CT or MR imaging (Morgenstern, 2010).

**Intracerebral Hemorrhage**

Bleeding into the brain parenchyma most commonly is caused by spontaneous rupture of small vessels previously damaged by chronic hypertension as depicted in Figure 60-1 (Qureshi, 2001; Takebayashi, 1983). Thus, pregnancy-associated hemorrhagic strokes such as the one shown in Figure 60-2 are often associated with chronic hypertension and superimposed preeclampsia (Cunningham, 2005; Martin, 2005). Because of its location, this type of hemorrhage has much higher morbidity and mortality rates than does subarachnoid hemorrhage (Morgenstern, 2010). Chronic hypertension is uniquely associated with Charcot-Bouchard microaneurysms of the penetrating branches of the middle cerebral artery. Pressure-induced rupture causes bleeding in the putamen, thalamus, adjacent white matter, pons, and cerebellum. In the 28 women described by Martin and associates (2005), half died and most survivors had permanent disabilities. This cautions for the importance of proper management for gestational hypertension—especially systolic hypertension—to prevent cerebrovascular pathology (Chap. 40, p. 761).
Subarachnoid Hemorrhage

In a study of 639 cases of pregnancy-related subarachnoid hemorrhage from the Nationwide Inpatient Sample, the incidence was 5.8 per 100,000 pregnancies, with half being postpartum (Bateman, 2012). These bleeds are more likely caused by an underlying cerebrovascular malformation in an otherwise normal patient (see Fig. 60-1). Ruptured saccular or “berry” aneurysms cause 80 percent of all subarachnoid hemorrhages. The remaining cases are caused by a ruptured arteriovenous malformation, coagulopathy, angiopathy, venous thrombosis, infection, drug abuse, tumors, or trauma. Such cases are uncommon, and a ruptured aneurysm or angioma or bleeding from a vascular malformation has an incidence of 1 in 75,000 pregnancies. Although this frequency is not different from that in the general population, the mortality rate during pregnancy is reported to be as high as 35 percent.

Intracranial Aneurysm. Approximately 2 to 5 percent of adults have this lesion (see Fig. 60-1). Fortunately, only a small percentage rupture—approximately 0.1 percent for aneurysms < 10 mm and 1 percent for those > 10 mm (Smith, 2008). Most aneurysms identified during pregnancy arise from the circle of Willis, and 20 percent are multiple (Stoodley, 1998). Pregnancy does not increase the risk for aneurysmal rupture. However, because of their high prevalence, they are more likely to cause subarachnoid bleeding than other causes (Hirsch, 2009; Tiel Groenestege, 2009). Aneurysms are more likely to bleed during the second half of pregnancy—only approximately 20 percent bleed during the first half (Dias, 1990).

The cardinal symptom of a subarachnoid hemorrhage from an aneurysm rupture is sudden severe headache, accompanied by visual changes, cranial nerve abnormalities, focal neurological deficits, and altered consciousness. Patients typically have signs of meningeal irritation, nausea and vomiting, tachycardia, transient hypertension, low-grade fever, leukocytosis, and proteinuria. Prompt diagnosis and treatment may prevent potentially lethal complications. The American Heart Association recommends noncontrast cranial CT imaging as the first diagnostic test, although MR imaging may be superior (Chalela, 2007; Connolly, 2012).
Treatment includes bed rest, analgesia, and sedation, with neurological monitoring and strict blood pressure control. Repair of a potentially accessible aneurysm during pregnancy depends in part on the recurrent hemorrhage risk versus surgical risks. At least in nonpregnant patients, the risk of subsequent bleeding with conservative treatment is 20 to 30 percent for the first month and then 3 percent per year. The risk of rebleeding is highest within the first 24 hours, and recurrent hemorrhage leads to death in 70 percent.

Early repair is done by surgical clipping of the aneurysm or by endovascular coil placement completed using fluoroscopic angiography yet attempting to limit radiation exposure. For women remote from term, repair without hypotensive anesthesia seems optimal. For women near term, cesarean delivery followed by aneurysm repair is a consideration, and we have successfully done this in several cases. For aneurysms repaired either before or during pregnancy, most allow vaginal delivery if remote from aneurysmal repair. A problem is what defines “remote,” and although some recommend 2 months, the time for complete healing is unknown. For women who survive subarachnoid hemorrhage, but in whom surgical repair is not done, we agree with Cartlidge (2000) and recommend against bearing down—put another way, we favor cesarean delivery.

**Arteriovenous Malformations.** These are congenital focal abnormal conglomerations of dilated arteries and veins with subarteriolar disorganization (see Fig. 60-1). They lack capillaries and have resultant arteriovenous shunting. Although unclear, the risk of bleeding may increase with gestational age. When arteriovenous malformations (AVMs) bleed, half do so into the subarachnoid space, whereas half are intraparenchymal with subarachnoid extension (Smith, 2008). They are uncommon and are estimated to occur in 0.01 percent of the general population. Bleeding does not appear to be more likely during pregnancy (Finnerty, 1999; Horton, 1990). AVMs are correspondingly rare during pregnancy, and in the study from Parkland Hospital, there was only one AVM in nearly 90,000 deliveries (Simolke, 1991).

Treatment of AVMs in nonpregnant patients is largely individualized. There is no consensus whether all those that are accessible should be resected. It also depends on whether the lesion is symptomatic or an incidental finding; its anatomy and size; presence of associated aneurysm, which is found in up to 60 percent; and especially, whether or not the lesion has bled. After hemorrhage, the risk of recurrent bleeding in unrepaired lesions is 6 to 20 percent within the first year, and 2 to 4 percent per year thereafter (Friedlander, 2007; Smith, 2008). The mortality rate with a bleeding AVM is 10 to 20 percent. In pregnancy, the decision to operate is usually based on neurosurgical considerations, and Friedlander (2007) recommends strong consideration for treatment if bleeding occurs. Because of the high risk of recurrent hemorrhage from an unresected or inoperable lesion, we favor cesarean delivery. An unusual case of spontaneous regression of a cerebral AVM has been described (Couldwell, 2011).

### DEMYELINATING OR DEGENERATIVE DISEASES

The **demyelinating diseases** are neurological disorders characterized by immune-mediated focal or patchy destruction of myelin sheaths accompanied by an inflammatory response. The **degenerative diseases** are multifactorial and are characterized by progressive neuronal death.

**Multiple Sclerosis**
In the United States, multiple sclerosis (MS) is second only to trauma as a cause of neurological disability in middle adulthood (Hauser, 2012b). Because the disease affects women twice as often as men and usually begins in the 20s and 30s, women of reproductive age are most susceptible. The familial recurrence rate of MS is 15 percent, and the incidence in offspring is increased 15-fold.

The demyelinating characteristic of this disorder results from predominately T cell-mediated autoimmune destruction of oligodendrocytes that synthesize myelin. There is a genetic susceptibility and likely an environmental trigger such as exposure to certain bacteria and viruses, for example, *Chlamydophila pneumoniae*, human herpesvirus 6, or Epstein-Barr virus (Frohman, 2006; Goodin, 2009).

There are four clinical types of multiple sclerosis (Hauser, 2012b):

1. **Relapsing-remitting MS** accounts for initial presentation in 85 percent of affected individuals. It is characterized by unpredictable recurrent episodes of focal or multifocal neurological dysfunction usually followed by full recovery. Over time, however, relapses lead to persistent deficits.

2. **Secondary progressive MS** disease is relapsing-remitting disease that begins to pursue a progressive downhill course after each relapse. It is likely that all patients eventually develop this type.

3. **Primary progressive MS** accounts for 15 percent of cases. It is characterized by gradual progression of disability from the time of initial diagnosis.

4. **Progressive-relapsing MS** refers to primary progressive MS with apparent relapses.

Classic findings of MS include sensory loss, visual symptoms from optic neuritis, weakness, paresthesias, and a host of other neurological symptoms. Almost 75 percent of women with isolated optic neuritis develop multiple sclerosis within 15 years. Clinical diagnosis is confirmed by MR imaging and cerebrospinal fluid analysis. In greater than 95 percent of cases, MR imaging shows characteristic multifocal white matter plaques that represent discrete areas of demyelination such as shown in Figure 60-3. Their appearance and extent are less helpful for treatment response. Similarly, Kuhle and colleagues (2007) reported that identification of serum antibodies against myelin oligodendrocyte glycoprotein and myelin basic protein are not predictive of recurrent disease activity.
Effects of Pregnancy on MS

The PRegnancy In Multiple Sclerosis—PRIMS—study is a European prospective multicenter study in which 254 pregnancies were described (Vukusic, 2006). A principal finding was a confirmed 70-percent reduction in relapse risk during pregnancy, but with a significantly increased relapse rate postpartum. This may be related to increased pregnancy-induced numbers of T-helper lymphocytes with an increased T2/T1 ratio (Airas, 2008). In a metaanalysis of women with more than 1200 pregnancies complicated by multiple sclerosis, their relapse rate was 0.4 per year before pregnancy; 0.26 per year during pregnancy; and this increased to 0.7 per year after delivery (Finkelsztejn, 2011). Factors associated with postpartum relapse include a high relapse rate before pregnancy, relapses during pregnancy, and a high MS disability score (Portaccio, 2014; Vukusic, 2006). Breast feeding has no apparent effect on postpartum relapses (Airas, 2010; Portaccio, 2011).

Effects of MS on Pregnancy

There are usually no adverse effects on pregnancy outcome with uncomplicated disease. Some women may become fatigued more easily, those with bladder dysfunction are predisposed to urinary infection, and women with spinal lesions at or above T6 are at risk for autonomic dysreflexia. Dahl and coworkers (2006) described 449 such pregnancies, and they reported a higher labor induction rate and longer second-stage labor. The increased induction rate as well as elective operations contributed to the overall increased cesarean delivery rate. They also reported outcomes in 649 affected women and described a lower mean birthweight but similar perinatal
mortality rate compared with that of controls (Dahl, 2005). Other studies have corroborated that MS does not significantly affect obstetrical and neonatal outcomes (Finkelsztein, 2011).

**Management During Pregnancy and the Puerperium**

Goals are to arrest acute or initial attacks, employ disease-modifying agents, and provide symptomatic relief. Some treatments may need to be modified during pregnancy. Acute or initial attacks are treated with high-dose intravenous methylprednisolone—500 to 1000 mg daily for 3 to 5 days, followed by oral prednisone for 2 weeks. Plasma exchange may be considered. Symptomatic relief can be provided by analgesics; carbamazepine, phenytoin, or amitriptyline for neurogenic pain; baclofen (Lioresal, Kemstro) for spasticity; α2-adrenergic blockade for bladder neck relaxation; and cholinergic and anticholinergic drugs to stimulate or inhibit bladder contractions.

Several disease-modifying therapies can be used for relapsing multiple sclerosis or exacerbations. Examples include interferons β1a (Rebif) and β1b (Betaseron) and glatiramer acetate (Copaxone), which have been shown to decrease relapse rates by a third (Rudick, 2011). Data concerning safety in pregnancy are limited but overall reassuring (Amato, 2010; Salminen, 2010). Clinical trials with natalizumab (Tysabri), an alpha 4 integrin antagonist—especially when combined with interferon β1a—significantly reduced MS clinical relapse rates (Polman, 2006; Rudick, 2006). In a review of 35 pregnancies, early pregnancy drug exposure did not worsen outcomes (Hellwig, 2011). Because of limited data, however, women are currently advised to stop the drug 3 months before conception. Fingolimad (Gilenya) is a new oral medication, and pregnancy safety data are unavailable (Briggs, 2011).

Prevention of relapses postpartum is afforded by treatment with intravenous immune globulin (IVIG) given in a dose of 0.4 g/kg daily for 5 days during weeks 1, 6, and 12 (Argyriou, 2008). The Prevention of Postpartum Relapses with Progestin and Estradiol in Multiple Sclerosis (POPART’MUS) trial is a multicenter randomized controlled trial currently enrolling patients (Vukusic, 2009).

**Huntington Disease**

This adult-onset neurodegenerative disease results from an autosomal dominant expanded CAG trinucleotide repeat within the Huntington gene on chromosome 4. It is characterized by a combination of choreoathetotic movements, progressive dementia, and psychiatric manifestations. Because the mean age of onset is 40 years, Huntington disease rarely complicates pregnancy. Prenatal diagnosis is discussed in Chapter 14 (p. 297). However, prenatal screening is controversial because this usually is a late-onset adult disease. Thus, extensive pretest counseling is imperative (Novak, 2010).

**Myasthenia Gravis**

This autoimmune-mediated neuromuscular disorder affects approximately 1 in 7500 persons. It is more common in women, and its incidence peaks in their 20s and 30s. The etiology is unknown, but genetic factors likely play a role. Most patients demonstrate antibodies to the acetylcholine receptor, although 10 to 20 percent are seronegative. The latter often have antibodies to muscle-specific tyrosine kinase (MuSK) that regulates assembly of the acetylcholine receptor subunits at the neuromuscular junction (Cavalcante, 2011; Pal, 2011).
Cardinal features of MG are weakness and easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. Deep tendon reflexes are preserved. Cranial muscles are involved early and disparately, and diplopia and ptosis are common. Facial muscle weakness causes difficulty in smiling, chewing, and speaking. In 85 percent of patients, the weakness becomes generalized. Other autoimmune diseases may coexist, and hypothyroidism should be excluded. The clinical course is marked by exacerbations and remissions, especially when it first becomes clinically apparent. Remissions are not always complete and are seldom permanent. Systemic diseases, concurrent infections, and even emotional upset may precipitate exacerbations, of which there are three types:

1. **Myasthenic crises**—characterized by severe muscle weakness, inability to swallow, and respiratory muscle paralysis.
2. **Refractory crises**—characterized by the same symptoms but unresponsive to the usual therapy.
3. **Cholinergic crises**—excessive cholinergic medication leads to nausea, vomiting, muscle weakness, abdominal pain, and diarrhea.

All three of these can be life threatening, but a refractory crisis is a medical emergency. Those with bulbar myasthenia are at particular risk because they may be unable to swallow or even ask for help.

**Management**

Myasthenia is manageable but not curable. Thymectomy is generally recommended for long-term benefits in the 75 percent of patients who have thymic hyperplasia or a thymoma seen with CT or MR imaging (Drachman, 2012; Nam, 2011). Anticholinesterase medications such as pyridostigmine (Mestinon), an analogue of neostigmine, improve symptoms by impeding acetylcholine degradation. They seldom produce normal muscle function. Ironically, overdose is manifest by increased weakness—the cholinergic crisis—that may be difficult to differentiate from myasthenic symptoms. Most of those refractory to anticholinesterase therapy respond to immunosuppressive therapy with glucocorticoids, azathioprine, methotrexate, cyclosporine, and mycophenolate mofetil. Tacrolimus, an immunosuppressant used in organ transplantation, and rituximab, a chimeric monoclonal antibody, are currently being evaluated (Ibrahim, 2010; Maddison, 2011; Yoshikawa, 2011). Cyclophosphamide is reserved for severe, generalized refractory cases. When short-term, rapid clinical improvement is needed—such as for a surgical procedure or a myasthenic crisis—high-dose immunoglobulin G or plasma exchange is usually effective (Barth, 2011; Cortese, 2011; Mandawat, 2010).

**Myasthenia and Pregnancy**

Because the greatest period of risk is within the first year following diagnosis, it seems reasonable to postpone pregnancy until there is sustained improvement. Antepartum management of myasthenia includes close observation with liberal rest and prompt treatment of infections (Heaney, 2010; Kalidindi, 2007). Women in remission who become pregnant while taking corticosteroids or azathioprine should continue these. Thymectomy has been successfully performed during pregnancy in refractory cases (Ip, 1986). Acute onset of myasthenia or its exacerbation demands prompt hospitalization and supportive care. Plasmapheresis and high-dose immunoglobulin therapy should be used for emergency situations (Drachman, 2012).

Although pregnancy does not appear to affect the overall course of MG, fatigue common to most pregnancies may be exacerbated, and the expanding uterus may compromise respiration. During
pregnancy, maternal hypotension or hypovolemia are avoided. The clinical course of MG during pregnancy is unpredictable, and frequent hospitalizations are the norm. Up to a third of women have worsening MG during pregnancy, with exacerbations occurring equally in all three trimesters (Djelmis, 2002; Podciechowski, 2005).

Myasthenia gravis has no significant adverse effects on pregnancy outcomes (Wen, 2009). Preeclampsia is a concern because magnesium sulfate may precipitate a severe myasthenic crisis (Hamaoui, 2009; Heaney, 2010). Although phenytoin use is also problematic in this regard, its adverse effects are less troublesome, and thus many choose it for neuroprophylaxis in MG patients with severe preeclampsia. Because smooth muscle is unaffected, most women have normal labor. Oxytocin is given for the usual indications, and cesarean delivery reserved for obstetrical indications. Because narcotics may cause respiratory depression, close observation and respiratory support are essential during labor and delivery. Curariform drugs should be avoided—examples include magnesium sulfate discussed above, muscle relaxants used with general anesthesia, and aminoglycosides. Neuraxial analgesia is accomplished with amide-type local agents. Regional analgesia is preferred unless there is significant bulbar involvement or respiratory compromise (Almeida, 2010; Blichfeldt-Lauridsen, 2012). During second-stage labor, some women may have impaired voluntary expulsive efforts that may warrant operative vaginal delivery.

Neonatal Effects
As discussed above, 80 percent of mothers with myasthenia gravis have anti-acetylcholine-receptor IgG antibodies. These and anti-MuSK antibodies are transported transplacentally, and the fetus can be affected to cause hydramnios (Heaney, 2010). Similarly, 10 to 20 percent of neonates manifest MG symptoms (Murray, 2010; Niks, 2008). Transient symptoms usually include a feeble cry, poor suckling, and respiratory distress. Symptoms usually respond to cholinesterase inhibitors and resolve within a few weeks.

NEUROPATHIES

Peripheral neuropathy is a general term used to describe disorders of peripheral nerve(s) of any cause. Because neuropathy can result from a variety of sources, its discovery should prompt a search for an etiology. Polyneuropathies can be either axonal or demyelinating as well as acute, subacute, or chronic (Chaudhry, 2008). They are often associated with systemic diseases such as diabetes, with drug or environmental toxin exposure, or with genetic diseases.

Mononeuropathies are relatively common in pregnancy, and they signify focal involvement of a single nerve trunk and imply local causation such as trauma, compression, or entrapment. Traumatic pudendal, obturator, femoral, and common fibular mononeuropathies are usually caused by childbirth and are discussed in Chapter 36 (p. 676).

 Guillain-Barré Syndrome
In 75 percent of cases, this acute demyelinating polyradiculoneuropathy has clinical or serological evidence for an acute infection. Commonly associated are infection with Campylobacter jejuni, cytomegalovirus, and Epstein-Barr virus; surgical procedures; and immunizations (Haber, 2009; Hauser, 2012a). Guillain-Barré syndrome (GBS) is thought to be immune-mediated from
antibodies formed against nonself antigens. Demyelination causes sensory and motor conduction blockade, and recovery occurs with remyelination in most cases.

Clinical features include areflexic paralysis—usually ascending—with or without sensory disturbances. Autonomic dysfunction is common. The full syndrome develops over 1 to 3 weeks. Management is supportive, but in the worsening phase, patients should be hospitalized because at least a third will need ventilatory assistance. Intravenous high-dose immunoglobulin (IVIG) or plasmapheresis is beneficial if begun within 1 to 2 weeks of motor symptoms, however, neither decreases mortality rates (Cortese, 2011; Gwathmey, 2011; Hughes, 2011). Although most patients recover fully within several months to a year, up to 20 percent are severely disabled, and 5 percent die, despite treatment (Yuki, 2012). Some manifest as chronic inflammatory demyelinating polyneuropathy, and our experiences indicate that it may be relatively common in these young women.

**Pregnancy**

Guillain-Barré syndrome is not more common in pregnancy, although inconclusive data suggest rates are increased in the puerperium (Cheng, 1998). Its clinical course in pregnancy is the same as for nonpregnant individuals, and after an insidious onset, paresis and paralysis most often continue to ascend to cause ventilatory weakness. Hurley and colleagues (1991) reported that a third of pregnant women required ventilatory support, with a mortality rate of 13 percent. The acute syndrome is treated with either high-dose IVIG or plasmapheresis (Chan, 2004; Yuki, 2012).

**Bell Palsy**

This disfiguring palsy is usually a mononeuropathic acute facial paralysis that is relatively common in reproductive-aged women (Fig. 60-4). It has a female predominance, and pregnant women are at a fourfold risk compared with nonpregnant women (Cohen, 2000; Heaney, 2010). The disease is characterized by facial nerve inflammation and often is associated with reactivation of herpes virus or herpes zoster virus.
Bell facial nerve palsy usually has an abrupt and painful onset with maximum weakness by 48 hours. In some cases, hyperacusis and loss of taste accompany paralysis (Beal, 2012). Management includes supportive care with facial muscle massage and eye protection against corneal lacerations from drying. There is general consensus that prednisone, 1 mg per kg given orally daily for 5 days, will result in improved outcomes and a shortened recovery period (Salinas, 2010; Sullivan, 2007). It is controversial if addition of an antiviral medication will improve these outcomes (de Almeida, 2009; Lockhart, 2009; Quant, 2009).

**Pregnancy**

It is unclear if pregnancy alters the prognosis for spontaneous facial palsy recovery. Gillman and colleagues (2002) found that only half of pregnant women recovered to a satisfactory level after 1 year—this compared with approximately 80 percent of nonpregnant women and men. Some prognostic markers for incomplete recovery are bilateral palsy, recurrence in a subsequent pregnancy, greater percentage of nerve function loss, and a faster rate of loss (Cohen, 2000; Gilden, 2004). Corticosteroid therapy given early in the course of the disease significantly improves outcomes. Other than a fivefold increased rate for gestational hypertension or preeclampsia, women with Bell palsy do not have increased adverse pregnancy outcomes (Katz, 2011; Shmorgun, 2002).

**Carpal Tunnel Syndrome**

This syndrome results from compression of the median nerve and is the most frequent mononeuropathy in pregnancy (Padua, 2010). Symptoms include burning, numbness, or tingling
along the inner half of one or both hands. Also, wrist pain and numbness extend into the forearm and sometimes into the shoulder (Katz, 2002). Symptoms are bilateral in 80 percent of pregnant women, and 10 percent have evidence for severe denervation (Seror, 1998). Differential diagnosis includes cervical radiculopathy of C_6–C_7 and de Quervain tendonitis, which is caused by swelling of the conjoined tendons and their sheaths near the distal radius. Nerve conduction studies may be helpful (Alfonso, 2010).

**Pregnancy**

The reported incidence is 7 to 43 percent and varies greatly because the range of symptoms is marked (Finsen, 2006; Padua, 2010). Symptomatic treatment with a splint applied to the slightly flexed wrist during sleep relieves pressure and usually provides relief. Although symptoms typically are self-limited, occasionally surgical decompression and corticosteroid injections are necessary (Keith, 2009; Shi, 2011). Symptoms may persist in more than half of patients at one year and in a third at 3 years (Padua, 2010).

---

**SPINAL-CORD INJURY**

According to the National Spinal Cord Injury Statistical Center (2012), there are approximately 12,000 spinal cord injuries each year. At least half affect reproductive-age individuals, with a male-to-female predominance of 4 to 1. The severity of cord injury determines the short- and long-term prognosis as well as that for pregnancy. Incomplete neurological lesions are associated with at least some sensory and/or motor function below the level of injury, whereas there is none with complete cord transection. Many women develop sexual function alteration and transient hypothalamic pituitary hypogonadism, however, pregnancy is not uncommon if menstruation resumes (Bughi, 2008).

Women with spinal cord injury have an increased frequency of pregnancy complications that include preterm and low-birthweight infants. Most have asymptomatic bacteriuria with sporadic symptomatic urinary infections. Bowel dysfunction causes constipation in more than half, and anemia and pressure-necrosis skin lesions are also common. There are two serious and life-threatening complications with spinal cord injuries:

1. If the cord is transected above T_{10}, the cough reflex is impaired, respiratory function may be compromised, and pneumonitis from covert aspiration can be serious. Pulmonary function tests are considered, and some women may need ventilatory support in late pregnancy or in labor.
2. Women with lesions above T_5–T_6 are at risk for *autonomic dysreflexia*. With this, stimuli from structures innervated below the level of the spinal lesion results in massive disordered sympathetic stimulation. Abrupt catecholamine release can cause vasoconstriction with severe hypertension and symptoms that include throbbing headaches, facial flushing, sweating, bradycardia, tachycardia, arrhythmias, and respiratory distress. Dysreflexia can be precipitated by a variety of stimuli, such as urethral catheterization; bladder distention from retention; rectal or cervical distention with digital examinations; uterine contractions and cervical dilatation; or any other pelvic structure manipulation (American College of Obstetricians and Gynecologists, 2005; Krassioukov, 2009). In one report, 12 of 15 women at risk for autonomic dysreflexia suffered at least one episode during pregnancy (Westgren, 1993).

Because uterine contractions are not affected by spinal cord lesions, labor is usually easy—
even precipitous, and comparatively painless. If the lesion is below $T_{12}$, uterine contractions are felt normally. For lesions above $T_{12}$, the risk of out-of-hospital delivery is substantial and can be minimized by teaching women to palpate for uterine contractions. This is especially important because up to 20 percent of women deliver preterm (Westgren, 1993). Some recommend tocodynamometry and weekly cervical examinations beginning at 28 to 30 weeks. Another reasonable option that we frequently employ at Parkland Hospital is elective hospitalization after 36 to 37 weeks (Hughes, 1991).

Spinal or epidural analgesia extending to $T_{10}$ prevents autonomic dysreflexia and should be instituted at the start of labor. If there are severe symptoms before epidural placement, steps are taken to abolish the provoking stimulus. A parenteral antihypertensive agent such as hydralazine or labetalol is given. Labor and vaginal delivery with epidural or spinal analgesia are preferable and will minimize autonomic dysreflexia (Kuczkowski, 2006). Operative vaginal delivery is frequently necessary.

**IDIOPATHIC INTRACRANIAL HYPERTENSION**

Also known as *pseudotumor cerebri* or *benign intracranial hypertension*, this disorder is characterized by increased intracranial pressure without hydrocephalus. The cause is unknown, but it may be the result of either overproduction or underabsorption of cerebrospinal fluid. Symptoms include headache in at least 90 percent of cases, visual disturbances such as loss of a visual field or central visual acuity in 70 percent, and commonly occurring papilledema that may be sight-threatening (Evans, 2000; Heaney, 2010). Other complaints are stiff neck, back pain, pulsatile tinnitus, cranial nerve palsies such as facial palsy, ataxia, or paresthesias. The syndrome is commonly found in young women and is prevalent in those who are obese, who recently gained weight, or both (Fraser, 2011). Along with symptoms, other criteria for diagnosis include elevated intracranial pressure $> 250$ mm H$_2$O, normal cerebrospinal fluid (CSF) composition, normal cranial CT or MR imaging findings, and no evidence for systemic disease (International Headache Society, 2005).

Idiopathic intracranial hypertension is usually self-limited. Visual defects can be prevented by lowering the cerebrospinal fluid pressure. Drugs given to lower pressure include acetazolamide (*Diamox*) to reduce fluid production, furosemide (*Lasix*), or topiramate (*Topamax*). Corticosteroids are now rarely used. Surgical intervention is occasionally necessary and is accomplished by either lumboperitoneal shunting of spinal fluid or optic nerve sheath fenestration.

**Effects of Pregnancy**

It is controversial if pregnancy is a risk factor for idiopathic intracranial hypertension. Certainly, symptoms may first appear in pregnancy, and women previously diagnosed may become symptomatic. These usually develop by midpregnancy, tend to be self-limited, and usually resolve postpartum.

There is general agreement that pregnancy does not alter management. Some recommend serial visual field testing to prevent permanent vision loss. In a report of 16 pregnant women, visual field loss developed in four, and it became permanent in one (Huna-Baron, 2002). Visual field loss is often coincident with the development of papilledema, for which acetazolamide is given. Lee and associates (2005) reported successful treatment of 12 pregnant women. Although outmoded for
treatment of nonpregnant individuals, repeated lumbar punctures are generally successful in providing temporary relief throughout pregnancy. In some pregnant women, surgical therapy becomes necessary, and we and others have had promising results with optic nerve sheath fenestration (Thambisetty, 2007).

Pregnancy complications are likely due to associated obesity and not to intracranial hypertension. In a review of 54 pregnancies, there were no excessive adverse perinatal outcomes (Katz, 1989). The route of delivery depends on obstetrical indications, and conduction analgesia is safe (Aly, 2007; Karmaniolou, 2011).

MATERNAL VENTRICULAR SHUNTS

Pregnancies in women with previously placed ventricular shunts for obstructive hydrocephalus usually have satisfactory outcomes (Landwehr, 1994). Shunts may be ventriculoperitoneal, ventriculoatrial, or ventriculopleural. Partial obstruction of a shunt is common, especially late in pregnancy (Schiza, 2012). In one report of 17 such pregnancies, neurological complications were reported in 13 (Wisoff, 1991). Findings included headaches in 60 percent, nausea and vomiting in 35 percent, lethargy in 30 percent, and ataxia or gaze paresis, each in 20 percent. Most symptoms respond to conservative management. However, if CT scanning during symptom evaluation discloses acute hydrocephaly, then the shunt is tapped or pumped several times daily. In some cases, surgical revision is necessary and may be emergently required (Murakami, 2010).

Another shunting procedure involves placement of an endoscopic third ventriculostomy for hydrocephalus in children or adults (de Ribaupierre, 2007). One report described successful results in five pregnant women who underwent successful ventriculostomy placement (Riffaud, 2006). In a review, reproductive function and miscarriage rates were found to significantly worsen in these women (Bedaiwy, 2008).

Vaginal delivery is preferred in women with shunts, and unless there is a meningomyelocele, conduction analgesia is permitted. Antimicrobial prophylaxis is indicated if the peritoneal cavity is entered for cesarean delivery or tubal sterilization.

MATERNAL BRAIN DEATH

Brain death is rare in obstetrics. Life-support systems and parenteral alimentation for up to 15 weeks have been described while awaiting delivery (Hussein, 2006; Powner, 2003; Souza, 2006). Some women were treated with aggressive tocolysis and antimicrobial therapy. Chiossi and coworkers (2006) reviewed outcomes in 17 women with persistent vegetative state who were given various levels of support. At least five died after delivery, and most of the remainder continued to be in the vegetative state. There are no published reports of neurological recovery with a diagnosis of brain death using the uniform Determination of Death Act definition (Wijdicks, 2010). The ethical, financial, and legal implications, both civil and criminal, that arise from attempting or not attempting such care are profound (Farragher, 2005; Feldman, 2000). In some women, perimortem cesarean delivery is performed as discussed in Chapter 47 (p. 956).

Pregnancy and the puerperium are at times sufficiently stressful to provoke mental illness. Such illness may represent recurrence or exacerbation of a preexisting psychiatric disorder, or may signal the onset of a new disorder. Psychiatric disorders during pregnancy have been associated with less prenatal care, substance abuse, poor obstetrical and infant outcomes, and a higher risk of postpartum psychiatric illness (Frieder, 2008). Of pregnant women identified with psychiatric disorders, Andersson and colleagues (2003) in one Swedish study reported that more than 80 percent had a mood disorder. According to the Agency for Healthcare Research and Quality, the period prevalence of any depressive disorder during pregnancy in the United States is 18 percent (Yonkers, 2011). Unfortunately, most pregnant women with depressive disorders are not treated. In the Swedish study mentioned above, only 5 percent of women identified with psychiatric disorders received some form of treatment.

Suicide is the fifth leading cause of death in the United States among women during the perinatal period, and major depression is among the strongest predictors of suicidal ideation (Melville, 2010). In both the United Kingdom and Australia, psychiatric illness is a leading cause of mortality for late maternal deaths—those between 43 and 365 days postpartum (Austin, 2007). Suicide by violent means was responsible for 65 percent of these. In a 10-year case-control
analysis of Washington state hospitalizations, Comtois and associates (2008) studied 355 women with a postpartum suicide attempt. Significant risk factors and their associated rates included prior hospitalization for a psychiatric diagnosis—27-fold, and for substance abuse—sixfold. These rates were further increased if there were multiple hospitalizations.

PSYCHOLOGICAL ADJUSTMENTS TO PREGNANCY

Biochemical factors—including hormonal effects—and life stressors can markedly influence mental illness. Thus, intuitively, pregnancy exacerbates some coexisting mental disorders. Indeed, pregnancy-related shifts in sex steroids and monoamine neurotransmitter levels; dysfunction of the hypothalamic-pituitary-adrenal axis; thyroid dysfunction; and alterations in immune response are all associated with an increased risk for mood disorders (Yonkers, 2011). These changes, coupled with evidence of familiality of depression, suggest that there may be a subgroup of women at risk for developing a unipolar major depressive disorder during pregnancy.

Women respond in a variety of ways to stressors of pregnancy, and some express persistent concerns regarding fetal health, child care, lifestyle changes, or fear of childbirth pain. Anxiety, sleep disorders, and functional impairment are common (Morewitz, 2003; Romero, 2014; Vythilingum, 2008). According to Littleton and coworkers (2007), however, anxiety symptoms in pregnancy are associated with psychosocial variables similar to those for nonpregnant women. The level of perceived stress is significantly higher for women whose fetus is at high risk for a malformation, for those with preterm labor or delivery, and for those with other medical complications (Alder, 2007; Ross, 2006). Hippman (2009) screened 81 women for depression who had an increased risk for a fetus with aneuploidy. Half of these women had a positive depression screening score, whereas only 2.4 percent of those with a normal pregnancy did so.

A number of steps can be taken to diminish psychological stress in the event of a poor obstetrical outcome. For example, following a stillbirth, Gold (2007) encouraged parental contact with the newborn and provision of photographs and other infant memorabilia. Addressing associated sleep disorders also seems reasonable (Romero, 2014).

The Puerperium

The puerperium is a particularly stressful time and carries as increased risk for mental illness. Up to 15 percent of women develop a nonpsychotic postpartum depressive disorder within 6 months of delivery (Tam, 2007; Yonkers, 2011). A few have a more severe, psychotic illness following delivery, and half of these have a bipolar disorder (Yonkers, 2011). Depressive disorders are more likely in women with obstetrical complications such as severe preeclampsia or fetal-growth restriction, especially if associated with early delivery. However, among women with a history of bipolar disorder, these factors do not seem to play as great a role in the development of mania or depression (Yonkers, 2011).

Maternity Blues

Also called *postpartum blues*, this is a time-limited period of heightened emotional reactivity experienced by half of women within approximately the first week after parturition. Prevalence estimates for the blues range from 26 to 84 percent depending on criteria used for diagnosis (O’Hara, 2014). This emotional state generally peaks on the fourth or fifth postpartum day and
normalizes by day 10 (O’Keane, 2011). The predominant mood is happiness. However, affected mothers are more emotionally labile, and insomnia, weepiness, depression, anxiety, poor concentration, irritability, and affective lability may be noted. Mothers may be transiently tearful for several hours and then recover completely, only to be tearful again the next day. Supportive treatment is indicated, and sufferers can be reassured that the dysphoria is transient and most likely due to biochemical changes. They should be monitored for development of depression and other severe psychiatric disturbances.

**Prenatal Evaluation**

Screening for mental illness is generally done at the first prenatal visit. Factors include a search for psychiatric disorders, including hospitalizations, outpatient care, prior or current use of psychoactive medications, and current symptoms. Risk factors should be evaluated—for example, a prior personal or family history of depression conveys a significant risk for depression. Women with a history of sexual, physical, or verbal abuse; substance abuse; and personality disorders are also at greater risk for depression (Akman, 2007; Tam, 2007). Smoking and nicotine dependence have been associated with an increase in rates of all mental disorders in pregnancy (Goodwin, 2007). Finally, because eating disorders may be exacerbated by pregnancy, affected women should be followed closely.

According to the American College of Obstetricians and Gynecologists (2012a), there is currently insufficient evidence to make a firm recommendation for routine depression screening, either during or after pregnancy. At Parkland Hospital, all women are asked about depression and domestic violence at their first prenatal visit. They are also screened again during their first postpartum visit using the Edinburgh Postnatal Depression Scale (EPDS). In an analysis of more than 17,000 of these questionnaires, 6 percent had scores that indicated either minor or major depressive symptoms. Twelve of these 1106 women also had thoughts of self-harm (Nelson, 2013).

**Treatment Considerations**

A large number of psychotropic medications may be used for management of the myriad mental disorders encountered in pregnancy. For treatment options that include psychosocial and psychological interventions, treatment decisions are ideally shared between patients and their health-care providers. Women taking psychotropic medication should be informed of likely side effects. Many of these drugs are discussed in Chapter 12 as well as by the American College of Obstetricians and Gynecologists (2012b). Additionally, these drugs are discussed subsequently in this chapter. Babbitt (2014) and Pozzi (2014) and their colleagues have recently reviewed principles of antenatal and intrapartum care of women with major mental disorders.

**Pregnancy Outcomes**

There are only a few reports of psychiatric disorders and pregnancy outcomes. Some, but not all, link maternal psychiatric illness with untoward outcomes such as preterm birth, low birthweight, and perinatal mortality (Schneid-Kofman, 2008; Steinberg, 2014; Yonkers, 2009). In a population-based cohort of more than 500,000 California births, Kelly and colleagues (2002) assessed the perinatal effects of a psychiatric diagnosis that included all International Classification of Diseases 9th Edition Clinical Modification (ICD-9-CM) diagnostic codes. Women with thes
diagnoses had up to a threefold increased incidence of a very-low- or low-birthweight neonate or preterm delivery. In another study of more than 1100 women enrolled in a Healthy Start initiative, women with depression were found to be 1.5 times more likely to be delivered early compared with nondepressed women. Conversely, Littleton and associates (2007) reviewed 50 studies and concluded that anxiety symptoms—a common comorbidity in depression—had no adverse effect on outcomes.

CLASSIFICATION OF MENTAL DISORDERS

The Diagnostic and Statistical Manual-V is the most recent version by the American Psychiatric Association (2013). Its purpose is to assist in the classification of mental disorders, and it specifies criteria for each diagnosis. Shown in Table 61-1 are 12-month prevalences of mental disorders for adults.

Depressive Disorders

According to the National Institute of Mental Health (2010), the lifetime prevalence of depressive disorders in the United States is 21 percent. Women are 50 percent more likely than men to experience a major mood disorder during their lifetime. Historically, these include major depression—a unipolar disorder—and manic-depression—a bipolar disorder with both manic and depressive episodes. It also includes dysthymia, which is chronic, mild depression. When concurrent with medical complications such as diabetes, heart disease, and asthma, major mood disorders worsen medical outcomes, and as a group, contribute to two thirds of all suicides (Yonkers, 2011).

*aBased on Diagnostic and Statistical Manual-IV-R (DSM-IV-R) of the American Psychiatric Association, 2000b.

*bBased on 2004 census data.

From the National Institute of Mental Health, 2006, 2010.
This is the most common depressive disorder, and an estimated 12 million women each year in the United States are affected (Mental Health America, 2013a). The lifetime prevalence is 17 percent but only half ever seek care. The diagnosis is arrived at by identifying symptoms listed in Table 61-2.

*a* Not all patients experience the same symptoms, and their severity, frequency, and duration will vary among individuals.

From the National Institute of Mental Health, 2010.

Major depression is multifactorial and prompted by genetic and environmental factors. First-degree relatives have a 25-percent risk, and female relatives are at even higher risk. One genome-wide linkage analysis of more than 1200 mothers suggests that variation in chromosomes 1 and 9 increases susceptibility to postpartum mood symptoms (Mahon, 2009). Families of affected individuals also often have members with alcohol abuse and anxiety disorders. Provocative conditions leading to depression include life events that prompt grief reactions, substance abuse, use of certain medications, and other medical disorders. Although life events can trigger depression, genes influence the response to life events, making the distinction between genetic and environmental factors difficult.

### Pregnancy

It is unquestionable that pregnancy is a major life stressor that can precipitate or exacerbate depressive tendencies. In addition, there are likely various pregnancy-induced effects. Hormones certainly affect mood as evidenced by premenstrual syndrome and menopausal depression. Estrogen has been implicated in increased serotonin synthesis, decreased serotonin breakdown, and serotonin receptor modulation (Deecher, 2008). Concordantly, women who experience postpartum depression often have higher predelivery serum estrogen and progesterone levels and experience a greater decline postpartum (Ahokas, 1999).

Dennis and associates (2007) queried the Cochrane Database and reported the prevalence of antenatal depression to average 11 percent. Melville and coworkers (2010) found it in nearly 10
percent of more than 1800 women enrolled for prenatal care at a single university obstetrical clinic. Others have reported the incidence to be much higher (Lee, 2007; Westdahl, 2007). In another report, Luke and colleagues (2009) found major depressive symptoms in 25 percent of pregnant African American women. Hayes and associates (2012) reported that 13 percent of pregnant women in the Tennessee Medicaid program filled an antidepressant prescription either before or during pregnancy. In another report of almost 119,000 pregnancies in seven health plans, Andrade and coworkers (2008) found that only 6.6 percent received antidepressants at any time during pregnancy. These findings support to the notion that only half of pregnant women with depression receive treatment.

Postpartum depression—major or minor—develops in 10 to 20 percent of parturients (Centers for Disease Control and Prevention, 2008; Mental Health America, 2013b). Available data indicate that unipolar major depression may be slightly more prevalent during the puerperium than among women in the general population (Yonkers, 2011). In addition to antenatal depression, postpartum depression has been associated with young maternal age, unmarried status, smoking or drinking, substance abuse, hyperemesis gravidarum, preterm birth, and high utilization of sick leave during pregnancy (Endres, 2013; Lee, 2007; Marcus, 2009).

Depression is frequently recurrent. At least 60 percent of women taking antidepressant medication before pregnancy have symptoms during pregnancy. According to Hayes and colleagues (2012), approximately three fourths of women taking antidepressants before pregnancy stopped taking them before or during the first trimester. For those who discontinue treatment, almost 70 percent have a relapse compared with 25 percent who continue therapy. Up to 70 percent of women with previous postpartum depression have a subsequent episode. Women with both prior puerperal depression and a current episode of “maternity blues” are at inordinately high risk for major depression. Indeed, the need for postpartum depression help was the fourth most common challenge identified at 2 to 9 months postpartum by the Pregnancy Risk Assessment Monitoring System—PRAMS (Kanotra, 2007).

Postpartum depression is generally underrecognized and undertreated. Major depression during pregnancy or after delivery can have devastating consequences for affected women, their children, and families. Among new mothers, one of the most significant contributions to their mortality rate is suicide, which is most common among women with mental illness (Koren, 2012; Palladino, 2011). If left untreated, up to 25 percent of women with postpartum depression will be depressed 1 year later. As the duration of depression increases, so too do the number of sequelae and their severity. In addition, maternal depression during the first weeks and months after delivery can lead to insecure attachment and later behavioral problems in the child.

Treatment

Antidepressant medications, along with some form of psychotherapy, are indicated for severe depression during pregnancy or the puerperium (American College of Obstetricians and Gynecologists, 2012b). Shown in Figure 61-1 is one algorithm regarding initiation of treatment of mood disorders and management with a mental health professional. In women with severe depression a selective serotonin-reuptake inhibitor—SSRI—should be tried initially (Table 61-3). Tricyclic antidepressants and monoamine oxidase inhibitors are infrequently used in contemporary practice. If depressive symptoms improve during a 6-week trial, the medication should be continued for a minimum of 6 months to prevent relapse (Wisner, 2002). If the response is suboptimal or a relapse occurs, another SSRI is substituted, or psychiatric referral is considered. Mozurkewich and associates (2013) reported no salutary effects of docosahexaenoic acid (DHA) to prevent perinatal depression.
FIGURE 61-1 Treatment algorithm of pregnant women with mood disorders. (Modified from Yonkers, 2011.)

TABLE 61-3. Some Drugs Used for Treatment of Major Mental Disorders in Pregnancy
Importantly, in a recent metaanalysis by Huang and colleagues (2014), women using antidepressants during pregnancy were found to be at increased risk for preterm birth and low-birthweight neonates. Nevertheless, in their review of antidepressant medication use in pregnancy, Ray and Stowe (2014) concluded that the relative reproductive safety data is reassuring and that antidepressants remain a viable treatment option.

Recurrence some time after medication is discontinued develops in 50 to 85 percent of women with an initial postpartum depressive episode. Women with a history of more than one depressive episode are at greater risk (American Psychiatric Association, 2000a). Surveillance should include monitoring for thoughts of suicide or infanticide, emergence of psychosis, and response to therapy. For some women, the course of illness is severe enough to warrant hospitalization.

**Fetal Effects of Therapy**

Some known and possible fetal and neonatal effects of treatment are listed in Table 61-3. Studies
implicating SSRIs with an increased teratogenic risk for fetal cardiac defects were isolated to paroxetine and were most consistent for ventricular septal defects (VSDs). It is estimated that the risk is no greater than 1 in 200 exposed infants (Koren, 2012). Nevertheless, the American College of Obstetricians and Gynecologists (2012b) has recommended that paroxetine be avoided in women who are either pregnant or planning pregnancy. Fetal echocardiography should be considered in women exposed to paroxetine in the first trimester.

In a case-control study, there was a sixfold increased risk of persistent pulmonary hypertension of the newborn (PPHN) in infants exposed to SSRIs after 20 weeks (Chambers, 2006). This translates to an overall risk of pulmonary hypertension that would be less than 1 in 100 exposed infants (Koren, 2012). In contrast, a population-based cohort study of 1.6 million pregnancies from Nordic countries identified a twofold increased risk in exposed neonates. It was estimated that this yields an attributable risk of 2 per 1000 births (Kieler, 2012). This marginally increased risk must be weighed against the risk associated with discontinuing or tapering medication during pregnancy.

Women who abruptly discontinue either serotonin- or norepinephrine-reuptake inhibitor therapy typically experience some form of withdrawal. Not surprisingly, up to 30 percent of exposed neonates may also exhibit withdrawal symptoms. Symptoms are similar to opioid withdrawal, but typically are less severe. This condition—neonatal behavioral syndrome—is self-limited, and the newborn rarely remains in the nursery more than 5 days (Koren, 2009). Currently, convincing evidence of long-term neurobehavioral effects of fetal exposure to these medications is lacking (Koren, 2012).

Some psychotropic medications pass into breast milk. However, in most cases, levels are very low or undetectable. Importantly, the average amount of drug detected in breast milk is higher with fluoxetine than most other reuptake inhibitors (National Library of Medicine, 2012). Adverse effects include transient irritability, sleep disturbances, and colic. Agents with lower excretion into breast milk may therefore be preferred.

Electroconvulsive Therapy

This form of depression treatment is occasionally necessary during pregnancy for women with major mood disorders unresponsive to pharmacotherapy. With proper preparation, the risks to both mother and fetus appear to be reasonable (Pinette, 2007). O’Reardon and coworkers (2011) reported a woman who underwent 18 electroconvulsive therapy (ECT) sessions during the second and third trimesters. She was delivered of a normal child without evidence of developmental delay up to 18 months of age. That said, adverse maternal and perinatal outcomes have been described from complications of convulsive therapy. Balki and associates (2006) reported a pregnancy in which fetal brain damage likely was caused by sustained maternal hypotension associated with treatment of status epilepticus stimulated by electroshock.

Women undergoing ECT should be fasting for at least 6 hours. They should be given a rapid-acting antacid before the procedure, and their airway should be protected to decrease the likelihood of aspiration. A wedge should be placed under the right hip to prevent sudden maternal hypotension from aortocaval compression. Other important preparatory steps include cervical assessment, discontinuation of nonessential anticholinergic medication, uterine and fetal heart rate monitoring, and intravenous hydration. During the procedure, excessive hyperventilation should be avoided. In most cases, maternal and fetal heart rate and maternal blood pressure and oxygen saturation remain normal throughout the procedure.

There have been at least two reviews of ECT outcomes in pregnancy. In the earlier one, Miller (1994) found 300 cases and reported complications in 10 percent. These included fetal arrhythmias, vaginal bleeding, abdominal pain, and self-limited contractions. Women not
adequately prepared had increased risks for aspiration, aortocaval compression, and respiratory alkalosis. In the more recent review, Andersen and Ryan (2009) described 339 cases, undoubtedly with some homology with the earlier study. In most cases, ECT therapy was done to treat depression, and it was 78-percent effective. They reported a 5-percent maternal ECT-related complication rate and a 3-percent associated perinatal complication rate that included two fetal deaths. For all of these reasons, we agree with Richards (2007) that ECT in pregnancy is not “low risk” and that it should be reserved for women whose depression is recalcitrant to intensive pharmacotherapy.

### Bipolar and Related Disorders

According to the National Institute of Mental Health (2010), the lifetime prevalence for manic-depression illness is 3.9 percent. There is no difference in the prevalence of bipolar disorder between pregnant women and nonpregnant reproductive-aged women (Yonkers, 2011). It has a strong genetic component and has been linked to possible mutations on chromosomes 16 and 8 (Jones, 2007). The risk that monozygotic twins are both affected is 40 to 70 percent, and the risk for first-degree relatives is 5 to 10 percent (Muller-Oerlinghausen, 2002). Periods of depression last at least 2 weeks. At other times, there are manic episodes, distinct periods during which there is an abnormally raised, expansive, or irritable mood. Potential organic causes of mania include substance abuse, hyperthyroidism, and central nervous system tumors. Importantly, however, pregnancy frequently prompts medication discontinuation, and this translates to a twofold increased risk for relapse during pregnancy (Viguera, 2007). Up to 20 percent of patients with manic-depression illness commit suicide.

Typical therapy for bipolar disorder includes mood stabilizers such as lithium, valproic acid, and carbamazepine, as well as antipsychotic medications (see Table 61-3). As depicted in Figure 61-1, treatment of bipolar disorder in pregnancy is complex and should be co-managed with a psychiatrist. Treatment decisions include risks versus benefits of using mood stabilizers, some of which are teratogenic. For example, lithium has been linked to Ebstein anomaly in exposed infants (Chap. 12, p. 250). More recent data, however, suggest a lower risk of cardiac malformations than previously indicated (Reprotox, 2012). Nevertheless, fetal echocardiography is recommended by many for exposed fetuses. There is some limited evidence suggesting that lithium in breast milk can adversely affect the infant when its elimination is impaired as in dehydration or immaturity (Davanzo, 2011). Lithium use in mothers with a healthy term fetus, however, is considered moderately safe. A more detailed discussion of other mood stabilizers and antipsychotic medications side effects can be found in Chapter 12 (p. 250).

### Postpartum Psychosis

This severe mental disorder is usually a bipolar disorder, but it may be due to major depression (American Psychiatric Association, 2013). Its incidence is estimated to be 1 in every 1000 deliveries, and it is more common in primiparas, especially those with obstetrical complications (Bergink, 2011; Blackmore, 2006). In most cases, illness manifests within 2 weeks of delivery. In a case-control study of postpartum women with their first lifetime episode of psychosis, the median onset of psychiatric symptoms was 8 days after delivery, and the median duration of the episode was 40 days (Bergink, 2011).

The most important risk factor for postpartum psychosis is a history of bipolar disease. These women typically exhibit symptoms sooner—1 to 2 days after delivery (Heron, 2007, 2008). Manic symptoms include feeling excited, elated, “high”; not needing sleep or unable to sleep; feeling
active or energetic; and feeling “chatty.” Affected women have signs of confusion and disorientation but may also have episodes of lucidity. Because those with underlying disease have a 10- to 15-fold risk for recurrence postpartum, close monitoring is imperative. Postpartum psychosis has a 50-percent recurrence risk in the next pregnancy. As a result, Bergink and colleagues (2012) recommend initiating lithium therapy immediately postpartum in women with a history of postpartum psychosis.

The clinical course of bipolar illness with postpartum psychosis is comparable with that for nonpregnant women. Patients usually require hospitalization, pharmacological treatment, and long-term psychiatric care. Psychotic women may have delusions leading to thoughts of self-harm or harm to their infants. Unlike women with nonpsychotic depression, these women commit infanticide, albeit uncommonly (Kim, 2008). In most instances, women with postpartum psychosis ultimately develop relapsing, chronic psychotic manic-depression.

### Anxiety Disorders

These relatively common disorders—18 percent prevalence overall—include panic attack, panic disorder, social anxiety disorder, specific phobia, separation anxiety disorder, and generalized anxiety disorder. All are characterized by irrational fear, tension, and worry, which are accompanied by physiological changes such as trembling, nausea, hot or cold flashes, dizziness, dyspnea, insomnia, and frequent urination (Schneier, 2006). They are treated with psychotherapy and medication, including selective serotonin-reuptake inhibitors, tricyclic antidepressants, monoamine oxide inhibitors, and others.

### Pregnancy

Despite their relative high prevalence in childbearing-aged women as shown in Table 61-1, little specific attention has been directed to anxiety disorders in pregnancy. Most reports conclude that there is no difference in rates in between pregnant and nonpregnant women. One recent analysis of 268 pregnant women with generalized anxiety disorder demonstrated that both symptoms and severity of anxiety decrease across pregnancy (Buist, 2011). Older studies indicate increased risks for adverse pregnancy outcomes with some of these disorders (American College of Obstetricians and Gynecologists, 2012b).

From their review, Ross and McLean (2006) concluded that some of the anxiety disorders may have important maternal-fetal implications. Some have been linked to preterm birth and fetal-growth restriction as well as poor neurobehavioral development (Van den Bergh, 2005). Children with a history of in utero exposure to maternal anxiety are felt to be at increased risk for a variety of neuropsychiatric conditions such as attention deficit/hyperactivity disorder (ADHD). Hunte and coworkers (2012) analyzed infants of 60 mothers with an anxiety disorder and found that auditory sensory gating—a reflection of inhibitory neurotransmission—was impaired, particularly in offspring of untreated women. Conversely, Littleton and associates (2007) found no excessive adverse pregnancy outcomes with “anxiety symptoms.” One important exception is their link with postpartum depression (Vythilingum, 2008).

### Treatment

Mood and anxiety disorders coexist in more than half of women identified with either diagnosis (Frieder, 2008). Anxiety disorders can be effectively treated during pregnancy with psychotherapy, cognitive behavioral therapy, or medications. Antidepressants listed in Table 61-3 are often the first line of pharmacotherapy. Benzodiazepines are also commonly used to treat
anxiety or panic disorders before and during pregnancy. Earlier case-control studies linked use of these central nervous system depressants to an increased risk for cleft lip and palate. However, a recent metaanalysis that included more than 1 million exposed pregnancies did not identify a teratogenic risk (Enato, 2011). Benzodiazepines, especially when taken during the third trimester, can cause neonatal withdrawal syndrome, which persists for days to weeks after delivery.

Schizophrenia Spectrum Disorders

This major form of mental illness affects 1.1 percent of adults (see Table 61-1). Schizophrenia spectrum disorders are defined by abnormalities in one or more of the following domains: delusions, hallucinations, disorganized thinking, grossly disorganized or abnormal motor behavior, and negative symptoms. Brain-scanning techniques such as positron-emission tomography (PET) and functional magnetic resonance imaging (fMRI) have shown that schizophrenia is a degenerative brain disorder. Subtle anatomical abnormalities are present early in life and worsen with time.

Schizophrenia has a major genetic component, and there is a 50-percent concordance in monozygotic twins. If one parent has schizophrenia, the risk to offspring is 5 to 10 percent. Some data, including a strong association between schizophrenia and the velocardiofacial syndrome, suggest that associated genes are located on chromosome 22q11 (Murphy, 2002). But sophisticated gene mapping studies have shown clearly that schizophrenia is not related to a single gene or mutation. Instead, there are multiple DNA variants that likely interact to lead to schizophrenia (Kukshal, 2012). Other putative risk factors for subsequent schizophrenia in an exposed fetus include maternal iron deficiency anemia, diabetes, and acute maternal stress (Insel, 2008; Malaspina, 2008; Van Lieshout, 2008). These remain unproven, as does the association with maternal influenza A (Chap. 64, p. 1241).

Signs of illness begin approximately at age 20 years, and commonly, work and psychosocial functioning deteriorate over time. Women have a slightly later onset than men and are less susceptible to autism and other neurodevelopmental abnormalities. Thus, many investigators theorize that estrogen is protective. Affected women may marry and become pregnant before symptoms manifest. With appropriate treatment, patients may experience a decrease or cessation of symptoms. Within 5 years from the first signs of illness, 60 percent have social recovery, 50 percent are employed, 30 percent are mentally handicapped, and 10 percent require continued hospitalization (American Psychiatric Association, 2013).

Pregnancy

There has been an apparent increase in relative fertility in schizophrenic women (Solari, 2009). Most studies have not found adverse maternal outcomes, although researchers in a Swedish study noted increased risks of low birthweight, fetal-growth restriction, and preterm delivery (Bennedsen, 1999). In an Australian study of more than 3000 pregnancies in schizophrenic women, Jablensky and colleagues (2005) reported that placental abruption was increased threefold and “fetal distress”—vaguely defined—was increased 1.4-fold.

Treatment

Because schizophrenia has a high recurrence if medications are discontinued, it is advisable to continue therapy during pregnancy. After 40 years of use, there is no evidence that conventional or “typical” antipsychotic drugs listed in Table 61-3 cause adverse fetal or maternal sequelae (McKenna, 2005; Robinson, 2012; Yaeger, 2006). Because less is known about “atypical”
antipsychotics, the American College of Obstetricians and Gynecologists (2012b) recommends against their routine use in pregnant and breast-feeding women. In response to adverse event reports, the Food and Drug Administration (2011) issued a safety communication alerting healthcare providers concerning some antipsychotic medications. These have been associated with neonatal extrapyramidal and withdrawal symptoms similar to the neonatal behavioral syndrome seen in those exposed to selective serotonin-reuptake inhibitors.

Feeding and Eating Disorders

These severe disturbances in eating behavior largely affect adolescent females and young adults with a lifetime prevalence of 2 to 3 percent each (see Table 61-1). They include anorexia nervosa, in which the patient refuses to maintain minimally normal body weight. With bulimia nervosa, there usually is binge eating followed by purging or by excessive fasting to maintain normal body weight (Zerbe, 2008). Bulik and coworkers (2009) studied pregnancy outcomes in almost 36,000 Norwegian women screened for eating disorders. Approximately 0.1 percent—1 in 1025—had anorexia nervosa; 0.85 percent—1 in 120—had bulimia nervosa; and 5.1 percent reported a binge-eating disorder—a 6-percent pregnancy prevalence similar to the 6-month prevalence for nonpregnant individuals (see Table 61-1). The last subtype had a higher risk for large-for-gestational age infants with a concomitantly increased cesarean delivery rate. All eating disorders begin with the desire to be slim, and women with chronic eating disorders may migrate between subtypes (Andersen, 2009).

Pregnancy

As discussed in Chapter 18 (p. 352), there is an increased risk for pregnancy complications with both eating disorders, but especially in women with bulimia nervosa (Andersen, 2009; Hoffman, 2011; Sollid, 2004). Generally, eating disorder symptoms improve during pregnancy, and remission rates may reach 75 percent. In contrast, what may appear as a typical case of hyperemesis gravidarum could actually be a new or relapsing case of bulimia nervosa or of anorexia nervosa, binge-purge type (Torgerson, 2008). As perhaps expected, anorexia is associated with low-birthweight infants (Micali, 2007). Additional risks associated with eating disorders include poor wound healing and difficulties with breast feeding (Andersen, 2009). At a minimum, closely monitoring gestational weight gain in women with a suspected history of an eating disorder seems prudent.

Personality Disorders

These disorders are characterized by the chronic use of certain coping mechanisms in an inappropriate, stereotyped, and maladaptive manner. They are rigid and unyielding personality traits. The American Psychiatric Association (2013) recognizes three clusters of personality disorders:

1. Paranoid, schizoid, and schizotypal personality disorders, which are characterized by oddness or eccentricity.
2. Histrionic, narcissistic, antisocial, and borderline disorders, which are all characterized by dramatic presentations along with self-centeredness and erratic behavior.
3. Avoidant, dependent, compulsive, and passive-aggressive personalities, which are characterized by underlying fear and anxiety.
Genetic and environmental factors are important in the genesis of these disorders, whose prevalence may be as high as 20 percent. Although management is through psychotherapy, most affected individuals do not recognize their problem, and thus only 20 percent seek help. In an observational study of 202 women with borderline personality disorder, De Genna and associates (2012) demonstrated that such women become pregnant during the most severe trajectory of their illness. They are at increased risk for teen and unintended pregnancies, however, it was not a risk factor for elective or spontaneous abortion.

Pregnancy

Personality disorders during pregnancy are probably no different than in nonpregnant women. Management of women with some of these disorders may be vexing. Akman and colleagues (2007) reported that avoidant, dependent, and obsessive-compulsive disorders are associated with an excessive prevalence of postpartum major depression. Magnusson and associates (2007) found a link between some personality traits—not disorders—and excessive alcohol consumption, but not necessarily addiction or dependence. Conroy and coworkers (2010) found that a mother’s ability to care for her newborn was obviously impaired only when a personality disorder was coupled with depression.

National Institute of Mental Health: The numbers count: mental disorders in America. NIH Publication No. 06-4584, 2006
Normal physiological changes of pregnancy include alterations to skin, hair, and nails as discussed in Chapter 4 (p. 51). In addition, several dermatoses are seen only in pregnancy. Finally, it is axiomatic that skin diseases that affect childbearing-age women are commonly encountered in pregnancy.

### PREGNANCY-SPECIFIC DERMATOSES

Four dermatoses considered unique to pregnancy include intrahepatic cholestasis of pregnancy, pruritic urticarial papules and plaques of pregnancy (PUPPP), atopic eruption of pregnancy (AEP), and pemphigoid gestationis (Table 62-1). As a group, these are diagnosed in up to 5 percent of pregnancies with the following relative occurrences: intrahepatic cholestasis 1 in 100; PUPPP, 1 in 130 to 350; atopic eruptions, 1 in 300 to 450, and pemphigoid, 1 in 50,000 (Chander, 2011). Their gross appearance may be similar to each other or to other skin disorders, and pruritus is a common feature of all four. Only intrahepatic cholestasis and pemphigoid gestationis have been linked with adverse fetal outcomes.

### TABLE 62-1. Pregnancy-specific Dermatoses

- Intrahepatic cholestasis
- Pruritic urticarial papules and plaques of pregnancy (PUPPP)
- Atopic eruption of pregnancy (AEP)
- Pemphigoid gestationis

Their gross appearance may be similar to each other or to other skin disorders, and pruritus is a common feature of all four. Only intrahepatic cholestasis and pemphigoid gestationis have been linked with adverse fetal outcomes.
Intrahepatic Cholestasis of Pregnancy

Previously termed pruritus gravidarum and in contrast to the other pregnancy-specific dermatoses, intrahepatic cholestasis of pregnancy generally has no primary skin lesions. Rarely, a rash preceded pruritus (Chao, 2011). Pruritus is associated with abnormally elevated serum bile acid levels, and hepatic aminotransferase levels may also be mildly increased. Adverse fetal affects have been linked to this condition, and it is discussed in detail in Chapter 55 (p. 1084).

Pemphigoid Gestationis

This rare autoimmune bullous disease is notable for its maternal and fetal effects. Initially, pruritic papules and urticarial plaques form and are then followed in most cases after 1 to 2 weeks by vesicles or bullae. Lesions are frequently distributed periumbilically, and they often develop on other skin surfaces with sparing of mucous membranes, scalp, and face (Fig. 62-1).
Previously termed *herpes gestationis*, pemphigoid gestationis is not related to the herpesvirus. It is a result of a primary reaction between maternal immunoglobulin G (IgG) antibodies directed against collagen XVII found in the basement membrane of skin as well as amnionic epithelium (Kelly, 1988; Shimanovich, 2002). Collagen XVII is also termed bullous pemphigoid 180 (BP180). Autoantibody binding to collagen XVII, either in the amnion or in the skin, activates complement to promote eosinophil chemotaxis to the antigen-antibody complexes on the basement membrane. Eosinophilic degranulation damages the dermal-epidermal junction with blister formation (Engineer, 2000).

**Pregnancy**

In most cases, pemphigoid gestationis develops during a first pregnancy, and it may rarely be associated with gestational trophoblastic disease (Takatsuka, 2012). Most subsequent pregnancies are also affected and usually earlier and more severely. Whites have a higher incidence, and other autoimmune diseases are common in affected women (Shornick, 1984, 1992).

Pemphigoid gestationis usually begins during the second or third trimester. The disease course is frequently marked by antepartum exacerbations and remissions and by intrapartum flares (Shornick, 1998). It is possible that there is an association of pemphigoid gestationis with preterm birth and fetal-growth restriction, especially with early-onset disease and with blistering (Chi, 2009). These theoretically may result from mild placental insufficiency stemming from IgG and complement deposition along the amnionic basement membrane (Huilaja, 2013). Because of this, antepartum surveillance of affected pregnancies may be prudent.

In approximately 10 percent of neonates, IgG antibodies passively transferred from the mother will cause similar skin lesions in the newborn (Erickson, 2002). These eruptions require only wound care and clear spontaneously within a few weeks as the passively acquired IgG levels decrease.

Slowly following delivery, maternal lesions resolve without scarring, and most women are disease-free after 6 months (Jenkins, 1999). In some, however, resolution is protracted, and
disease may be exacerbated during menses or by oral contraceptives (Semkova, 2009).

### Diagnosis and Treatment

Before bullae form, these lesions may resemble PUPPP (p. 1216). Other diagnoses include pustular psoriasis of pregnancy, dermatitis herpetiformis, erythema multiforme, linear IgA bullous dermatosis, urticaria, allergic contact dermatitis, bullous pemphigoid, and atopic eruptions of pregnancy (Lipozenčić, 2012). Drug-induced blistering syndromes must also be excluded, as some are life-threatening. Examples include Stevens-Johnson syndrome and toxic epidermal necrolysis (Stern, 2012).

Skin biopsy and serum antibody assays may be informative (Semkova, 2009). Immunofluorescent skin tissue staining is the gold standard, and C3 complement and sometimes IgG are seen deposited along the basement membrane between the epidermis and the dermis (Katz, 1976). Also, in many cases, circulating IgG antibodies against collagen XVII may be detected in patient serum (Powell, 2005; Sitaru, 2004).

Pruritus can be severe. Early in its course, topical high-potency corticosteroids and oral antihistamines may be effective. Oral prednisone, 0.5 to 1 mg/kg daily gradually tapered to a maintenance dose, may be needed for relief and also inhibition of new lesions. Plasmapheresis or high-dose intravenous immunoglobulin (IVIG) therapy has been used in intractable cases (Gan 2012; Van de Wiel, 1980).

### Pruritic Urticarial Papules and Plaques of Pregnancy (PUPPP)

This relatively common pregnancy-specific dermatosis is characterized by its intensely pruritic 1- to 2-mm erythematous papules that coalesce to form urticarial plaques and by its benign effects on pregnancy (Rudolph, 2005). Its cause is unknown, but it is not an autoimmune dermatosis. Also known as polymorphic eruption of pregnancy, PUPPP usually appears late in pregnancy, but 15 percent begin postpartum (Buccolo, 2005). The rash affects the abdomen and proximal thighs in 97 percent of women (Fig. 62-2). Lesions often initially form within striae but show periumbilical sparing. Rarely, the face, palms, and soles may be involved (High, 2005). It is more frequently seen in white and nulliparous women, those with multifetal gestation, and those carrying a male fetus (Regnier, 2008). It seldom recurs in subsequent pregnancies (Ahmadi, 2005).
FIGURE 62-2 Pruritic urticarial papules and plaques of pregnancy (PUPPP) shows small papules within abdominal striae.

Diagnosis and Treatment
PUPPP may be compared with a number of skin eruptions. Some include contact dermatitis, drug eruption, viral exanthem, insect bites, scabies infestation, pityriasis rosea, and the other pregnancy-specific dermatoses. It also may appear similar to early pemphigoid gestationis that has not yet blistered. In unclear cases, skin biopsy and negative serum collagen XVII antibody levels help to differentiate the two. Pruritus will usually respond to treatment with oral antihistamines, skin emollients, and topical corticosteroids. A small number of women will need systemic corticosteroids to relieve severe itching (Scheinfeld, 2008).

PUPPP usually resolves within several days following delivery and leaves no scarring. In 15 to 20 percent of women, however, symptoms persist for 2 to 4 weeks postpartum (Vaughan Jones, 1999).

Atopic Eruption of Pregnancy (AEP)
This umbrella term is thought by some authorities, but not all, to encompass three conditions previously considered separate: eczema in pregnancy, prurigo of pregnancy, and pruritic folliculitis of pregnancy (Ambros-Rudolph, 2006; Cohen, 2007; Ingber, 2010). Two thirds of women with AEP have widespread eczematous changes, whereas the other third have papular lesions. As a group, these pose no adverse risk to the fetus. Diagnosis is greatly aided by a history of atopy and by rash characteristics.

Eczema in pregnancy has the appearance of traditional eczema but with a pregnancy onset. It is the most common pregnancy-specific dermatosis, and affected skin shows dry, thickened, scaly, red patches involving extremity flexures, nipples, neck, and face. In contrast, prurigo of pregnancy, also known as prurigo gestationis, is characterized by 5- to 10-mm, itchy, erythematous papules or nodules commonly found on the extensor surfaces and trunk. Last, pruritic folliculitis of pregnancy is rare and notable for small, erythematous follicular papules and sterile
Pustules predominantly on the trunk. Onset for all is during the second or third trimester, although eczema in pregnancy may develop earlier than the other two. All lesions commonly resolve with delivery, but may persist for up to 3 months postpartum. Recurrence with subsequent pregnancies is variable but common.

Diagnosis is one of exclusion. Serum bile acid levels are elevated to concentrations expected for normal pregnancy, and aminotransferase levels are normal. Serology specific for pemphigoid gestationis is negative. Many women with eczema of pregnancy have elevated serum IgE levels, which are not seen with the two other AEP dermatoses (Ambros-Rudolph, 2011).

For all three manifestations, skin lesions and pruritus are usually controlled with low- or moderate-potency topical corticosteroids and oral antihistamines. For severe eczema, second-line agents include short-course ultrapotent topical corticosteroids. However, oral corticosteroids, narrow-band ultraviolet B, or cyclosporine are occasionally required (Koutroulis, 2011).

DERMATOLOGICAL CONDITIONS NOT SPECIFIC TO PREGNANCY

Any chronic dermatological disorders can complicate pregnancy. Acne is unpredictably affected by pregnancy and if necessary, is treated with benzoyl peroxide, azelaic acid, or topical erythromycin, which are category B drugs (Krautheim, 2003). Topical retinoids, which include tretinoin, adapalene, and tazarotene, also appear safe, but are probably best avoided during pregnancy, especially during the first trimester (Akhavan, 2003). If topical antibiotics are required, benzoyl peroxide plus erythromycin is advocated to minimize *Propionibacterium acnes* drug resistance (Strauss, 2007; Thiboutot, 2009). With topical salicylic acid, systemic absorption is variable, and efforts to minimize absorption are encouraged (Lam, 2008).

Psoriasis also has a variable course during pregnancy, however, postpartum flares are common with nonsevere disease (Oumeish, 2006). Emollients and low- or moderate-potency topical corticosteroids are given initially. Anthralin and ultraviolet B phototherapy can also be used (Weatherhead, 2007). In resistant cases, restrained use of topical preparations such as high-potency or ultrapotent corticosteroids, calcipotriene, and coal tar appear to be safe in the second and third trimesters, and cyclosporine also may be used (Rosmarin, 2010; Ryan, 2010). With severe disease, a small increased risk for low-birthweight neonates has been shown by some (Lima, 2012; Yang, 2011). Also, in general, psoriatic patients have higher associated rates of depression (Rieder, 2012).

Psoriasis is most commonly of the chronic plaque variety. In contrast, with *generalized pustular psoriasis of pregnancy*—formerly called impetigo herpetiformis—severe systemic symptoms may develop. This rare pustular form has erythematous, sometimes pruritic, plaques ringed by sterile pustules that enlarge and then crust. Lesions initially involve intertriginous areas but may spread to the torso, extremities, and oral mucosa. Constitutional symptoms are common. For accurate diagnosis, skin biopsy is typically required (Roth, 2011). Extensive lesions can lead to sepsis from secondary infection and to massive fluid loss with hypovolemia and placental insufficiency. Treatment is with systemic corticosteroids along with antimicrobials for secondary infection, and cyclosporine is used in refractory cases (Geraghty, 2011; Huang, 2011). Pustular psoriasis typically resolves quickly in the puerperium, but recurrences have been reported in subsequent pregnancies and with menstruation or oral contraceptive use.

*Erythema nodosum* is a cutaneous reaction associated with numerous disorders that include...
pregnancy, but typically it is caused by infections, sarcoidosis, drugs, Behçet’s syndrome, inflammatory bowel disease, or a malignancy (Mert, 2007; Papagrigoraki, 2010). Characteristically, 1- to 5-cm tender, red, warm nodules and plaques develop rapidly on the extensor surface of the legs and arms. Within a few days, lesions flatten and undergo the color evolution of a bruise—from dark red and purple to yellow green. Constitutional symptoms may also be present (Requena, 2007). Initial evaluation and treatment focuses on the underlying etiology.

Pyogenic granuloma are frequently seen in pregnancy. This is a lobular capillary hemangioma commonly forming on the mouth or hand in response to low-grade local irritation or traumatic injury (Fig. 62-3). They grow quickly and bleed with minimal provocation. Active bleeding can be controlled with pressure and application of a silver nitrate stick or Monsel paste (ferric subsulfate). These growths often resolve within months postpartum. But with symptomatic or postpartum lesions, or with unclear diagnosis, excision can be done using suture and scalpel, electrosurgical curettage, laser photocoagulation, or cryotherapy. Oral lesions are best referred to oral health-care specialists.

**FIGURE 62-3** Pyogenic granuloma is characterized grossly by a lobulated red growth on a pedunculated or sessile base. (Photograph contributed by Dr. Abel Moron.)

*Rosacea fulminans*—also known as pyoderma faciale—is characterized by facial pustules and coalescing draining sinuses. It may rarely complicate pregnancy. Topical or oral antimicrobials are primary treatment, although surgical drainage and corticosteroids have also been used (Fuentelsaz, 2011; Jarrett, 2010). *Hidradenitis suppurativa* has been said to improve with pregnancy, but in our experiences, it is not appreciably changed. Oral antimicrobials or clindamycin gel are initial choices. *Neurofibromatosis* lesions may increase in size and number as a result of pregnancy. Other skin conditions that are discussed include hirsutism and melanoma (Chap. 63, p 1233), cutaneous lupus (Chap. 59, p. 1169), and skin lesions seen with infections
DERMATOLOGICAL TREATMENT

Local skin care, oral antihistamines, and topical corticosteroids are commonly used for many dermatoses. Oral antihistamines are given for pruritus. Suitable options include first-generation agents such as diphenhydramine (Benadryl), 25 to 50 mg every 6 hours, or chlorpheniramine (Chlor-Trimeton), 4 mg every 6 hours. Second-generation agents—loratadine (Claritin) 10 mg daily and cetirizine (Zyrtec) 5 or 10 mg daily—may produce less sedation and are also pregnancy category B.

Hundreds of topical corticosteroid preparations are available, and in the United States, these are categorized by potency into seven groups. For initial treatment of dermatological disorders, low- or moderate-potency agents are preferred. Low-potency agents include those in groups 6 and 7, such as 1-percent hydrocortisone or 0.05-percent desonide (DesOwen). Moderate-potency drugs are in groups 5, 4, and 3—such as 0.1-percent triamcinolone acetonide (Aristocort) or 0.1-percent mometasone furoate (Elocon). High-potency medications are in group 2, such as 0.05-percent betamethasone dipropionate (Diprolene). Ultrapotent agents in group 1, such as 0.05-percent clobetasol propionate (Temovate), are best reserved for refractory disorders and used for only 2 to 4 weeks on small surface areas.

Mild and moderate strengths are not associated with adverse pregnancy outcomes, whereas high- and ultrapotent agents pose a small risk for fetal-growth restriction if used long-term. Even then, this risk is less than that with systemic corticosteroids (Chi, 2011). Importantly, with any topical agent, factors that increase systemic absorption include a large surface area treated, compromised epidermal barrier, occlusive dressings, prolonged treatment duration, and coadministration of topical agents that increase absorption.

With some severe skin diseases, systemic immune modulating agents, such as corticosteroids and cyclosporine, may be required. Although these are not contraindicated in pregnancy, their risks must be balanced against therapeutic benefits. Of these, cyclosporine is not recommended with breast feeding (Rosmarin, 2010). Bacterial infections are a potential secondary complication of skin disorders and are treated promptly with oral antimicrobial agents with gram-positive coverage. Therapeutic agents to be avoided during pregnancy include methotrexate, psoralen plus ultraviolet A, biological agents, mycophenolate mofetil, and systemic retinoids (Lam, 2008). These are discussed in more detail in Chapter 12 (p. 250).

MISCELLANEOUS TUMORS

Neoplasms are commonly found in pregnant women. Although most are benign, if a malignancy complicates pregnancy, then usual management schemes become problematic. Uterine leiomyomas and ovarian cysts are the most frequently encountered benign neoplasms during pregnancy. Malignancies have an incidence of approximately 1 per 1000 pregnancies (Brewer, 2011). One third are diagnosed prenatally and the others within 12 months of delivery. Some of the more common cancers found in pregnant women are shown in Figure 63-1. Of these, the three most common are breast—1 per 5000 pregnancies, thyroid—1 per 7000, and cervical—1 per 8500 (Smith, 2003). These, along with lymphoma and melanoma, account for 65 percent of cancer cases in pregnancy (Eibye, 2013).
PRINCIPLES OF CANCER THERAPY RELATED TO PREGNANCY

Management of the pregnant woman with cancer poses unique problems related to fetal concerns. Because of these, treatment must be individualized. Considerations include the type and stage of cancer and the desire for pregnancy continuation with the inherent risks associated with modifying or delaying treatment.

Surgery

Operative procedures indicated for cancer include those for diagnosis, staging, or therapy. Fortunately, most procedures that do not interfere with the reproductive tract are well tolerated by both mother and fetus (Chap. 46, p. 927). Although many procedures have classically been deferred until after 12 to 14 weeks’ gestation to minimize abortion risks, this probably is not necessary. We are of the opinion that surgery should be performed regardless of gestational age if maternal well-being is imperiled.

Both pregnancy and malignancy are risk factors for venous thromboembolism. There are no guidelines specific for thromboprophylaxis in pregnant women undergoing surgical procedures for
cancer. Thus, depending on the complexity of the planned procedure, it seems reasonable to use mechanical prophylaxis compression or pneumatic stockings, low-molecular-weight heparin, or both (Chap. 52, p. 1044). There are general evidenced-based practice guidelines available from the American College of Chest Physicians (Guyatt, 2012).

Diagnostic Imaging
Sonography is a preferred imaging tool during pregnancy when appropriate. In addition, according to the American College of Obstetricians and Gynecologists (2009), most diagnostic radiographic procedures have very low x-ray exposure and should not be delayed if they would directly affect therapy (Chap. 46, p. 932). Computed tomography is useful for imaging extraabdominal tumors, and abdominal shielding usually helps to decrease fetal exposure. Routine magnetic resonance (MR) imaging use is not recommended, and if needed, is used preferentially after the first trimester. Gadolinium contrast administered with MR imaging crosses the placenta, resulting in high fetal concentrations. It should not be used in the first trimester and should be used later in pregnancy only when the benefits overwhelmingly outweigh the risks (Kanal, 2007). Some radioisotopes are relatively safe, but positron emission tomography (PET) scanning is usually not performed during pregnancy. Moreover, $^{18}$F-FDG (fludeoxyglucose) is concentrated in both breast tissue and milk. Thus, in the puerperium, breast feeding should be discontinued for 72 hours following a procedure (Rizack, 2009).

Radiation Therapy
Therapeutic radiation often results in significant fetal exposure depending on the dose, tumor location, and field size. The most susceptible period is organogenesis, although there is no gestational age considered safe for therapeutic radiation exposure. Adverse effects include cell death, carcinogenesis, and mutagenic changes in future generations (Brent, 1999; Hall, 1991). Characteristic fetal effects are microcephaly and mental retardation, and even late exposure can cause growth restriction and brain damage. Thus, radiotherapy to the maternal abdomen is contraindicated. With some head and neck cancers, however, radiotherapy to supradiaphragmatic areas can be used relatively safely with abdominal shielding. In others, such as breast cancer, significant scatter doses can accrue to the fetus.

Chemotherapy
Various antineoplastic drugs may be given for primary treatment or for adjunctive therapy. Although chemotherapy often improves long-term maternal outcomes, many are reluctant to employ it during pregnancy. As discussed in Chapter 12 (p. 248), fetal concerns include malformations, growth restriction, mental retardation, and the risk of future malignancies. Risks are dependent primarily on fetal age at exposure, and most agents are potentially detrimental given in the first trimester during organogenesis. Indeed, embryonic exposure to cytotoxic drugs may cause major malformations in up to 20 percent of cases (Pavlidis, 2011).

After organogenesis, most antineoplastic drugs are without immediate obvious adverse sequelae (Abdel-Hady, 2012; Cardonick, 2004). Similarly, late mutagenic effects appear limited. Children born to 68 women receiving chemotherapy and who were assessed at 18 months had no excessive adverse effects to their central nervous system, heart, or hearing or to their general health or growth (Amant, 2012b).
Although not always practicable, some recommend that chemotherapy be withheld in the 3 weeks before expected delivery because neutropenia or pancytopenia might cause undue risk for maternal infection or hemorrhage. Another concern is that neonatal hepatic and renal clearance of chemotherapy metabolites is limited (Ko, 2011). For these reasons, chemotherapy is also contraindicated with breast feeding.

**Molecular Therapy**

Drugs designed to stimulate hemopoiesis are commonly used with cancer treatments. Some of these include the granulocyte colony-stimulating factors filgrastim (Neupogen) and pegfilgrastim (Neulasta). If required in pregnancy, limited data support the safety of these factors (Dale, 2003). Red blood cells can be stimulated by erythropoietin alfa (Procrit), which likely is also safe in pregnancy (Briggs, 2011).

**Immunotherapy**

Hybridized monoclonal antibodies directed against tumor-specific antigens are designed to treat an ever-increasing list of malignant neoplasms. Some of these drugs are described in the discussion of tumors for which they are used. Little is known regarding their fetal effects, but concerns for teratogenicity by tyrosine kinase inhibitors—for example, imatinib (Gleevec)—have been raised (Ali, 2009).

**Fertility and Pregnancy after Cancer Therapy**

The number of cancer survivors continues to increase. From the Childhood Cancer Survival Study (CCSS), a fourth of survivors have significant morbidity at 25 years (Diller, 2011). One is that subsequent fertility may be diminished after chemotherapy or radiotherapy, and couples should be counseled regarding potential risks (American Society for Reproductive Medicine, 2013). Guidelines for this counseling have been developed by the American Society of Clinical Oncology (Loren, 2013).

Embryo cryopreservation is standard and widely available, however, other methods are considered investigational and limited to referral centers. Some are oocyte or ovarian cryopreservation, preradiotherapy ovarian transposition, and/or ovarian suppression with gonadotropin-releasing hormone agonists before therapy. Educational materials concerning these methods have been provided by a National Institutes of Health (NIH) interdisciplinary group—the Oncofertility Consortium (Woodruff, 2010). This is available online at: http://oncofertility.northwestern.edu.

Not surprisingly, abdominopelvic radiation impairs subsequent reproductive function (Wo, 2009). Data from the CCSS are informative for women who conceive following cancer therapy. Since the database was established in 1994, 4029 pregnancies have been reported in 1953 women. A number of reports have described increased adverse pregnancy outcomes by type of cancer treatment given. For example, fetuses born to women who had undergone prior pelvic radiation were more likely to have a birthweight < 2500 g (Green, 2002; Robison, 2005). There was a higher rate of preterm birth in cancer survivors—especially those given pelvic radiotherapy—compared with their siblings (Signorello, 2006). In another study of 917 pregnancies, cancer survivors had slightly higher rates of preterm birth and postpartum hemorrhage (Clark, 2007). In yet another study of 1657 women from the CCSS, Signorello and colleagues (2010) reported that
uterine or ovarian irradiation significantly increased the risk of stillbirth and neonatal death. One possible explanation for adverse reproductive effects is that radiotherapy, but not chemotherapy, at a young age irreversibly reduces the uterine volume in survivors (Larsen, 2004). Perhaps the most reassuring findings from all of these studies are that fetuses of women who were treated in childhood with radiotherapy did not have significantly increased risks for congenital malformations (Lawrenz, 2012; Winther, 2009).

### Placental Metastases

Tumors infrequently metastasize to the placenta. The most common types are malignant melanomas, leukemias, lymphomas, and breast cancer (Al-Adnani, 2007). Placentas from pregnancies in these and all other women with a malignancy should be sent for histological evaluation. Because tumor cells are usually confined within the intervillous spaces, fetal metastases are infrequent. Melanoma is the most common example, and typically fetal metastases are found in the liver or subcutaneous tissue with an 80-percent associated mortality rate (Alexander, 2003; Altman, 2003; Gottschalk, 2009).

### REPRODUCTIVE TRACT NEOPLASMS

Benign neoplasms are common in the female reproductive tract and include leiomyomas, ovarian neoplasms, and endocervical polyps. Malignancies of these organs are the most frequent cancers encountered in pregnant women, and of these, cervical cancers make up the majority (Fig. 63-2).
A number of benign, premalignant, and malignant cervical neoplasms are frequently recognized during pregnancy. Endocervical polyps are overgrowths of benign endocervical stroma covered by epithelium. If asymptomatic, these polyps are usually seen at the time of the initial pelvic examination, although they can cause bleeding at any time. They typically appear as single, red, smooth, elongated fleshy masses of variable size that extend outward from the endocervical canal. Typically benign, they can however be a source of Pap smear results describing atypical glandular cells of undetermined significance—AGUS. And although malignant transformation in these growths is uncommon, polypoid cervical cancers can mimic these (Chin, 2002; Younis, 2010). Thus, most recommend their removal and evaluation. Polyps with a slender stalk are removed by grasping the tumor with ring or polyp forceps. It is then twisted repeatedly about its base to strangulate feeding vessels. With repeated twisting, the base narrows and avulses. Monsel solution, which is ferric subsulfate, can be applied with pressure to the stalk stub for hemostasis. A thick-pedicle polyp may sometimes warrant surgical excision.

**Epithelial Neoplasia**
Pregnancy provides an opportune time to screen for premalignant and malignant cervical epithelial neoplasia, especially in women without regular access to health care. With prenatal Pap smear screening, the pregnancy status is noted on the requisition form because interpretation may be hindered by pregnancy-associated physiological changes (Connor, 1998). Some changes include glandular epithelial hyperplasia, Arias-Stella reaction, and presence of decidual cells.

Screening guidelines also applicable in pregnant women were updated in 2012 by the American Society for Colposcopy and Cervical Pathology (ASCCP). These include: (1) no screening until age 21, (2) cytology alone every 3 years in those aged 21 to 29 years, and (3) in those older than 30, human papillomavirus (HPV) and cytology co-testing every 5 years, or cytology alone every 3 years. Importantly, these broad guidelines do not cover women in high-risk populations who may need more intensive screening. Examples include diethylstilbestrol (DES)-exposed women, cervical cancer survivors, and the immunocompromised (Saslow, 2012).

**Oncogenic Human Papillomaviruses.** Certain serovars of HPV are associated with high-grade intraepithelial lesions and invasive cancer. Some of these high-risk viruses—HPV types 16, 18, 31, 35, 45, 51, 52, and 56—may have an increased incidence in pregnant compared with nonpregnant women (Fife, 1996). Cotesting for such high-risk serotypes at the time of the Pap test is now incorporated into the recent screening guidelines for women 30 years and older. Cells can be collected directly into liquid-based cytology medium, namely, PreservCyt Solution of the ThinPrep Pap Test. Additionally, the cobas HPV Test and Digene HC2 HPV DNA test also allow collection into a specific collection medium if traditional cytology is performed.

**HPV Vaccination.** The clear link between HPV infection and cervical neoplasia has prompted development of two Food and Drug Administration-approved vaccines. These are available for girls and women aged 9 to 26 years. The quadrivalent HPV-6/11/16/18 vaccine (Gardasil) and the bivalent HPV-16/18 vaccine (Cervarix) decrease the incidence of high-grade dysplasia, and thus, cervical carcinoma (American College of Obstetricians and Gynecologists, 2012b; FUTURE II Study Group, 2007; Paavonen, 2009).

Vaccination is not recommended during pregnancy, and contraception during the series is recommended by the American College of Obstetricians and Gynecologists (2010) and the Centers for Disease Control and Prevention (2010). That said, both vaccines are considered safe and are not associated with higher rates of adverse pregnancy outcomes if conception occurs during the series (Dana, 2009; Descamps, 2009; Garland, 2009). Completion of the series should be delayed until after delivery. Both of these inactivated vaccines can be given postpartum in a typical regimen of three doses, with injections given at 0, at 1 to 2, and at 6 months. The vaccines are safe for use in breast-feeding women.

**Abnormal Cytological Results.** The incidence of abnormal cervical cytology during pregnancy is at least as high as that reported for nonpregnant women. Abnormal cytological findings and their suggested management according to consensus guidelines are summarized in Table 63-1. Many of these cytological abnormalities should prompt colposcopy to exclude invasive cancer. Accordingly, lesions suspicious for high-grade disease or cancer should undergo biopsy (American College of Obstetricians and Gynecologists, 2013a). These may actively bleed because of hyperemia, but this can be stopped with Monsel paste and pressure, silver nitrate application, vaginal packing, or suture.

| TABLE 63-1. American Society for Colposcopy and Cervical Pathology (ASCCP) Guidelines for Initial Management of Epithelial Cell Abnormalities in Pregnancy |
Unsatisfactory colposcopic evaluation is less common during pregnancy because the transformation zone is better exposed due to cervical eversion. With unsatisfactory visualization, colposcopy is repeated in 6 to 8 weeks, during which time the squamocolumnar junction will further evert (Randall, 2009). Once satisfactory examination is possible and advanced disease is excluded, additional colposcopic and cytological examinations during pregnancy are not encouraged. After delivery, repeat cytology and colposcopy should generally be delayed for at least 6 weeks to allow reparative healing.

Cervical Intraepithelial Neoplasia. Women with histologically confirmed intraepithelial neoplasia during pregnancy may be allowed to deliver vaginally, with further evaluation planned after delivery. For those with cervical intraepithelial neoplasia (CIN) 1, the recommended management is reevaluation postpartum. For those with CIN 2 or 3 in which invasive disease has been excluded, or with advanced pregnancy, repeat colposcopic and cytological evaluations are performed at intervals no more frequent than 12 weeks. Repeat biopsy is recommended if appearance of the lesion worsens or if cytology suggests invasive cancer. Alternatively, deferring reevaluation until at least 6 weeks postpartum is acceptable (Wright, 2007b).
Regression of CIN lesions is common during pregnancy or postpartum. In a study of 1079 pregnant women with cervical dysplasia in which biopsy correlated with colposcopic findings, 61 percent reverted to normal postpartum (Fader, 2010). In another study, Yost and colleagues (1999) reported postpartum regression in 70 percent of women with CIN 2 and CIN 3 lesions. Although 7 percent of women with CIN 2 lesions progressed to CIN 3, none progressed to invasive carcinoma. In another study of 77 women with carcinoma in situ (CIS) diagnosed during pregnancy, a third had postpartum regression, two thirds had persistent CIS, and only two women had microinvasive cancer on cone biopsy after delivery (Ackermann, 2006).

Adenocarcinoma in situ (AIS) is managed similarly to CIN 3 (Dunton, 2008). Thus, unless invasive cancer is identified, treatment of AIS is not recommended until 6 weeks postpartum (Wright, 2007b).

Cervical Conization. If invasive epithelial lesions are suspected, conization is indicated and may be done with loop electrosurgical excisional procedure (LEEP) or by cold knife conization. If possible, conization is avoided in pregnancy because of increased risks for abortion, membrane rupture, hemorrhage, and preterm delivery. The epithelium and underlying stroma within the endocervical canal cannot be extensively excised without the risk of membrane rupture. Residual disease is common. Of 376 conization procedures during pregnancy, Hacker and colleagues (1982) found residual neoplasia in 43 percent of subsequent specimens. In addition, nearly 10 percent of 180 pregnant women required transfusion after conization (Averette, 1970).

Women with CIN treated before pregnancy may encounter pregnancy complications. Cicatricial cervical stenosis is uncommon, but it may follow cervical trauma from conization, the loop electrosurgical excision procedure (LEEP), and laser surgery. Cervical stenosis almost always yields during labor. A so-called conglutinated cervix may undergo almost complete effacement without dilation, with the presenting part separated from the vagina by only a thin layer of cervical tissue. Dilatation usually promptly follows pressure with a fingertip, although manual dilatation or cruciate incisions may be required.

For decades, cold-knife conization has been associated with cervical incompetence and preterm birth. However, the relationship between preterm birth and LEEP continues to be debated, with some studies showing increased risk, but others not (Castanon, 2012; Jakobsson, 2009; Samson, 2005; Werner, 2010). An important study confounder is the increased risk of preterm birth in women with CIN compared with the general population even if they have not undergone an excisional procedure (Bruinsma, 2007; Shanbhag, 2009).

Invasive Cervical Cancer
The incidence of invasive cervical carcinoma has dramatically declined and approximates 1 in 8500 pregnancies in the United States (Pettersson, 2010; Smith, 2003). The diagnosis is confirmed with biopsies taken during colposcopy, with conization, or from a grossly abnormal lesion. Of the histological types, squamous cell carcinomas comprises 75 percent of all cervical cancers, whereas adenocarcinomas account for 20 to 25 percent. Cancers may appear as exophytic or endophytic growth; as a polypoid mass, papillary tissue, or barrel-shaped cervix; as a cervical ulceration or granular mass; or as necrotic tissue. A watery, purulent, foul, or bloody discharge may also be present. Biopsy with Tischler forceps is warranted for suspicious lesions.

Cervical cancer is staged clinically, and 70 percent of cases that are diagnosed in pregnancy are stage I (Morice, 2012). Physiological pregnancy changes may impede accurate staging, and the extent of cancer is more likely to be underestimated in pregnant women (Oto, 2007). Specifically, induration of the broad ligament base, which characterizes tumor spread beyond the cervix, may be
less prominent due to cervical, paracervical, and parametrial pregnancy-induced softening. Staging is modified and typically incorporates findings from pelvic examination and from renal sonography, chest radiography, cystoscopy, proctoscopy, and perhaps cone biopsy. Although MR imaging is not formally considered for clinical staging, it can be used without gadolinium contrast, ideally after the first trimester, to ascertain disease involvement of the urinary tract and lymph nodes (Fig. 63-3).

FIGURE 63-3 Sagittal T-2 weighted magnetic resonance image of a gravid uterus at 32 weeks’ gestation with a large cervical carcinoma (arrows).

Management and Prognosis. Treatment of cervical cancer in pregnant women is individualized and depends on the clinical stage, fetal age, and individual desire to continue pregnancy (Hunter, 2008). Stage IA1 is termed microinvasive disease and describes lesions with deepest invasion ≤ 3 mm and widest lateral extension ≤ 7 mm (FIGO Committee on Gynecologic Oncology, 2009b). If diagnosed by cone biopsy, treatment follows guidelines similar to those for intraepithelial disease. In general, continuation of pregnancy and vaginal delivery are considered safe, and definitive therapy is reserved until 6 weeks postpartum.

Truly invasive cancer demands relatively prompt therapy. During the first half of pregnancy, immediate treatment is advised by most, but this depends on the decision whether to continue
pregnancy. With diagnosis during the latter half of pregnancy, most agree that pregnancy can safely be continued not only until fetal viability is reached, but also until fetal lung maturity is attained (Greer, 1989). In two studies with a total of 40 women past 20 weeks with either stage I or stage IIA carcinoma, it was concluded that delayed treatment was reasonable in women without bulky lesions (Takushi, 2002; van Vliet, 1998). Another option is to complete staging using laparoscopic lymphadenectomy and to delay treatment if metastases are excluded (Alouini, 2008; Favero, 2010). In a recent metaanalysis, neoadjuvant chemotherapy with platinum derivatives was found to be promising for treatment in pregnancy (Zagouri, 2013).

Although surgical therapy and radiation are equally effective, radical hysterectomy plus pelvic lymphadenectomy is the preferred treatment for invasive carcinoma in most women with stage I and early stage IIA lesions (American College of Obstetricians and Gynecologists, 2010a). Before 20 weeks, hysterectomy is usually performed with the fetus in situ. In later pregnancy, however, hysterotomy is often performed first. Radiotherapy for cervical cancer destroys ovarian and possibly sexual function, and frequently causes intestinal and urinary tract injury. In 49 women with pregnancy-associated stage IB cancer, there was a 30-percent severe complication rate from radiotherapy compared with only 7 percent with surgery (Nisker, 1983).

Although less commonly selected, fertility-preserving procedures for early-stage cervical cancers have been investigated. Ungár and colleagues (2006) performed abdominal radical trachelectomy before 20 weeks for stage IB1 carcinoma in five pregnant women. Yahata and associates (2008) treated four women at 16 to 23 weeks for stage IA1 adenocarcinoma with laser conization, and all delivered at term. Van Calsteren and coworkers (2008) reported similar success in a woman at 8 weeks with stage IB2 adenocarcinoma.

Radiotherapy is given for more advanced-stage cancer. External beam radiation is given for treatment early in pregnancy, and then if spontaneous abortion does not ensue, curettage is performed. During the second trimester, spontaneous abortion may not promptly occur and may necessitate hysterotomy in up to a fourth of cases.

Stage-for-stage, the survival rate for invasive cervical carcinoma is similar in pregnant and nonpregnant women (Sood, 1998). In a case-control study of 44 women with pregnancy-associated cervical cancer, the overall 5-year survival rate was approximately 80 percent in both pregnant women and nonpregnant controls (Van der Vange, 1995).

Delivery. Any adverse prognostic effects that vaginal delivery through a cancerous cervix might have are unknown. For this reason, the mode of delivery is controversial, especially for small, early-stage lesions. In some cases of bulky or friable lesions, there may be significant hemorrhage with vaginal delivery. Also, recurrences in the episiotomy scar, which result from tumor cells apparently “seeding” the episiotomy, have been reported (Goldman, 2003). Thus, most favor cesarean delivery and use a classical hysterotomy incision to avoid the risk of cutting through tumor.

Pregnancy after Radical Trachelectomy. There is growing experience with pregnancy in women who have previously undergone fertility-sparing radical trachelectomy for stage IB1 and IB2 cervical cancer before conception. During the typically vaginal procedure, the cervix is amputated at the level of the internal os, and a permanent-suture cerclage is placed around the isthmus for support in future pregnancies. The uterine isthmus is then reconstructed to the vagina. Because of the permanent cerclage, a classical cesarean incision is required for delivery.

Shepherd and colleagues (2006) presented outcomes for 123 such women cared for at their institution. Of 63 women who attempted pregnancy, 19 had 28 live births. All had classical
cesarean deliveries, and a fourth were before 32 weeks. Similar findings were reported by Kim (2012) and Park (2014) and their colleagues.

Uterus

Leiomyomas

Also known as myomas and somewhat erroneously called fibroids, uterine leiomyomas are common benign smooth muscle tumors. Their incidence during pregnancy is approximately 2 percent, and the cited range depends on the frequency of routine sonography and population characteristics (Qidwai, 2006; Stout, 2010). For example, in a study of 4271 women, Laughlin and coworkers (2009) reported that first-trimester leiomyoma prevalence was highest in black women—18 percent—and lowest in whites—8 percent.

Leiomyomas vary in location and may develop as submucous, subserosal, or intramural growths. Less frequently, these develop in the cervix or broad ligament. Some become parasitic and their blood supply is derived from adjacent structures such as the highly vascularized omentum. In the rare manifestation of leiomyomatosis peritonealis disseminata, numerous subperitoneal benign smooth muscle tumors may appear similar to disseminated carcinomatosis. The tumors are likely caused by estrogen stimulation of multicentric subcoelomic mesenchymal cells to become smooth-muscle cells (Bulun, 2013). In their review of 45 cases, Lashgari and colleagues (1994) found that half were discovered during pregnancy. Often, these tumors regress after pregnancy.

The stimulatory effects of pregnancy on myoma growth are unpredictable and can be impressive. These tumors respond differently in individual women and may grow, regress, or remain unchanged in size during pregnancy (Laughlin, 2009; Neiger, 2006).

Especially during pregnancy, myomas can be confused with other adnexal masses, and sonographic imaging is indispensable (Fig. 63-4). In women in whom sonographic findings are unclear, MR imaging performed after the first trimester may be necessary (Torashima, 1997). Once diagnosed, leiomyomas do not require surveillance with serial sonography unless associated complications are anticipated.
FIGURE 63-4 Sonogram of a pregnant uterus with a large uterine leiomyoma. The heterogeneous mass (arrows) lies beside the fetus (seen in cross section) and has the classic appearance of a leiomyoma in pregnancy. The placenta is located anteriorly, and the mass originates from the posterior lower uterine segment and occupies more than half of the total uterine volume.

**Symptoms.** Most leiomyomas are asymptomatic, but acute or chronic pain or pressure may develop. For chronic pain secondary to large tumor size, nonnarcotic analgesic drugs may be given. More acutely, in some cases, myomas outgrow their blood supply and hemorrhagic infarction follows, which is termed red or carneous degeneration. Clinically, there is acute focal abdominal pain and tenderness, and sometimes a low-grade fever and leukocytosis is noted. As such, tumor degeneration may be difficult to differentiate from appendicitis, placental abruption, ureteral stone, or pyelonephritis. Sonographic imaging may be helpful, but close observation is requisite because an infarcted myoma is essentially a diagnosis of exclusion. In some women, preterm labor is stimulated by associated inflammation.

Treatment is analgesic medications, and most often, symptoms abate within a few days. If further treatment is given to forestall preterm labor, then close observation to exclude a septic cause is imperative. Although surgery is rarely necessary during pregnancy, myomectomy in highly selected cases has resulted in good outcomes (Celik, 2002; De Carolis, 2001). Most of 23 reported women were 14 to 20 weeks, and in almost half, surgery was performed because of pain. In some, an intramural leiomyoma was in contact with the implantation site. Except for one loss immediately following surgery at 19 weeks, most underwent cesarean delivery later at term.

Occasionally, pedunculated subserosal myomas will undergo torsion with subsequent painful necrosis. In such cases, laparoscopy or laparotomy can be used to ligate the stalk and resect the necrotic tumor. That said, we are of the opinion that surgery should be limited to tumors with a discrete pedicle that can be easily clamped and ligated.

**Pregnancy Complications.** Myomas are associated with a number of complications including
preterm labor, placental abruption, fetal malpresentation, obstructed labor, cesarean delivery, and postpartum hemorrhage (Klatsky, 2008; Qidwai, 2006; Sheiner, 2004). In a review of pregnancy outcomes in 2065 women with leiomyomas, Coronado and coworkers (2000) reported that placental abruption and breech presentation were each increased fourfold; first-trimester bleeding and dysfunctional labor, twofold; and cesarean delivery, sixfold. Salvador and associates (2002) reported an eightfold increased second-trimester abortion risk in these women but found that genetic amniocentesis did not increase this risk.

The two factors most important in determining morbidity in pregnancy are leiomyoma size and location (Shavell, 2012). The proximity of myomas to the placental implantation site is also a factor. Specifically, abortion, preterm labor, placental abruption, and postpartum hemorrhage all are increased if the placenta is adjacent to or implanted over a leiomyoma. Tumors in the cervix or lower uterine segment may obstruct labor, as did the one shown in Figure 63-5. Despite these complications, Qidwai and colleagues (2006) reported a 70-percent vaginal delivery rate in women in whom myomas were ≥ 10 cm. These data argue against empirical cesarean delivery for leiomyomas, and we allow a trial of labor unless myomas clearly obstruct the birth canal. If cesarean delivery is indicated, myomas are generally left alone unless they cause recalcitrant bleeding. An important caveat is that cesarean hysterectomy may be technically difficult because of lateral ureteral displacement by the tumors.

**FIGURE 63-5** Cesarean delivery performed because of a large leiomyoma in the lower uterine segment. A classical vertical uterine incision, seen to the left of the myoma, was required for delivery of the fetus.

Bleeding due to myomas may develop during pregnancy from any of several factors. Especially common is bleeding with miscarriage, preterm labor, or placenta previa and abruption. Much less frequently, bleeding may result from a submucous myoma that has prolapsed from the uterus and into the cervix or vagina. In these unusual cases, although heavy or persistent bleeding may require earlier intervention, the stalk can be ligated vaginally near term if accessible to avoid tumor
avulsion during delivery.

Fortunately, myomas rarely become infected (Genta, 2001). This is most frequent postpartum, especially if the tumor is located immediately adjacent to the implantation site (Lin, 2002). They also may become infected with an associated septic abortion and myoma perforation by a sound, dilator, or curette.

**Fertility Considerations.** Despite the relatively high prevalence of myomas in young women, it is not clear whether they diminish fertility, other than by possibly causing miscarriage as discussed in Chapter 18 (p. 359). In a review of 11 studies, Pritts (2001) concluded that submucous myomas did significantly affect fertility. He also found that hysteroscopic myomectomy improved infertility and early miscarriage rates in these women. Infertility-related myomas in other locations may require laparoscopy or laparotomy for excision.

Some of these methods of treatment for infertility may affect successful pregnancies. For example, after myomectomy, there is concern for uterine rupture before and during labor (American College of Obstetricians and Gynecologists, 2012a). Management is individualized and review of the prior operative report is prudent. If resection resulted in a defect into or immediately adjacent to the endometrial cavity, then cesarean delivery is usually done before labor begins.

Although less effective than surgery, uterine artery embolization of myomas has also been used to treat infertility or myoma symptoms (Mara, 2008). Women so treated have increased rates of miscarriage, cesarean delivery, and postpartum hemorrhage (Homer, 2010). At this time, the Society of Interventional Radiology (Stokes, 2010) considers myoma embolization relatively contraindicated in women who plan future pregnancies.

**Endometriosis and Adenomyosis**

Rarely do endometriomas cause problems in pregnancy. If they are identified sonographically, they can be resected if cesarean delivery is performed. With vaginal delivery, endometriotic tumors or cysts may be removed after the puerperium or followed clinically depending on symptoms and cyst characteristics (Levine, 2010). Occasionally, endometriosis can develop after delivery from endometrial implants within abdominal incisions made at cesarean delivery or within episiotomy scars (Bumpers, 2002).

**Adenomyosis is traditionally found in older women. Its acquisition may be at least partially related to disruption of the endometrial-myometrial border during sharp curettage for abortion (Curtis, 2002). Although problems during pregnancy are rare, in an 80-year review, Azziz (1986) reported concurrent adenomyosis to be associated with uterine rupture, ectopic pregnancy, uterine atony, and placenta previa.**

**Endometrial Carcinoma**

This estrogen-dependent neoplasia is usually found in women older than 40 years. Thus, it is seen only rarely with pregnancy. Hannuna and colleagues (2009) found 27 cases that were identified during pregnancy or within the first 4 months postpartum. Most were found in first-trimester curettage specimens.

These are usually early-stage well-differentiated adenocarcinomas for which treatment consists primarily of total abdominal hysterectomy and bilateral salpingo-oophorectomy. Much less commonly, to preserve future fertility, curettage with or without postprocedural progestational therapy has been used for the rare patient with cancer identified in a miscarriage curettage.
specimen (Schammel, 1998).

Many more studies describe a conservative approach for well-selected nonpregnant women diagnosed with endometrial cancer who wish to preserve fertility. In one study of 13 women treated with progestins for early-stage well-differentiated adenocarcinoma, nine had liveborn infants, and four of six women with a recurrence responded to another course of therapy (Gotlieb, 2003). Similar outcomes were described in 12 women by Niwa and associates (2005) and in 21 women by Signorelli and coworkers (2009). Despite these acceptable pregnancy rates, recurrences and death have been reported, and conservative management is not considered standard (Erkanli, 2010).

Ovary

Ovarian masses found during pregnancy are relatively common, and the reported incidences are population- and investigation-dependent. Factors include whether studies are referral or primary care sources, the frequency of prenatal sonography, and what size constitutes a “mass.” It is thus not surprising that the incidence has been reported as 1 in 100 to 1 in 2000 pregnancies (Whitecar, 1999; Zanetta, 2003). Of ovarian malignancies, the absolute incidence in the California Cancer Registry was 1 in 19,000 pregnancies (Smith, 2003).

The most frequent types of ovarian masses are corpus luteum cysts, endometriomas, benign cystadenomas, and mature cystic teratomas, colloquially termed dermoids. Because pregnant women are usually young, malignant tumors and those of low malignant potential are proportionately uncommon and vary from 4 to 13 percent (Hoffman, 2007; Sherard, 2003). Our experiences from Parkland Hospital are similar to those reported by Leiserowitz and colleagues (2006), who found that 1 percent of 9375 ovarian masses were frankly malignant and that another 1 percent was of low malignant potential.

Most ovarian masses are asymptomatic in pregnant women. Some cause pressure or chronic pain, and acute abdominal pain may be due to torsion, rupture, or hemorrhage. Seldom is blood loss significant enough to cause hypovolemia.

Sonography

Many ovarian masses are detected during routine prenatal sonography or during imaging done for other indications, including evaluation of symptoms. The typical sonographic appearance of these masses is shown in Figure 63-6. In some instances, MR imaging can be used to evaluate complicated anatomy (American College of Obstetricians and Gynecologists, 2013b).
FIGURE 63-6 Sonographic characteristics of common adnexal masses in pregnancy. **A.** A simple anechoic cyst with smooth walls is characteristic of a physiological corpus luteum cyst or benign cystadenoma. **B.** Cystic structure with diffuse internal low-level echoes suggestive of an endometrioma or hemorrhagic corpus luteum. **C.** Mature cystic teratoma appears as an adnexal cyst (*marked by calipers*) with accentuated lines and dots that represent hair in both longitudinal and transverse planes. At the central inferior aspect of this cyst, a mural nodule—Rokitansky protuberance—is seen. These typically rounded protuberances range in size from 1 to 4 cm, they are predominantly hyperechoic, and they create an acute angle with the cyst wall. Although not seen here, fat-fluid levels are often identified with cystic teratomas. (Image contributed by Dr. Elysia Moschos.)

**Tumor Markers**

Cancer antigen 125 (CA125) levels are frequently elevated with ovarian malignancy. Importantly, concentrations in early pregnancy and early puerperium are normally elevated, possibly from the decidua (Aslam, 2000; Haga, 1986; Spitzer, 1998). From the second trimester until term, levels are not normally higher than those in the nonpregnant woman (*Appendix*, p. 1289). Other tumor markers that have not been proven for diagnosis or posttreatment surveillance in pregnancy include OVA1, human chorionic gonadotropin (hCG), alpha-fetoprotein, and inhibins A and B (Liu, 2011). Of these, OVA1 is a biomarker blood test that measures five analytes, one of which is CA125.

**Complications**

The two most common complications of any ovarian mass are torsion and hemorrhage. Torsion usually causes acute constant or episodic lower abdominal pain that frequently is accompanied by nausea and vomiting. Sonography often aids the diagnosis. With color Doppler, presence of an ovarian mass with absent flow strongly correlates with torsion. However, minimal or early twisting may compromise only venous flow, thus leaving arterial supply intact. If torsion is suspected, laparoscopy or laparotomy is warranted. Contrary to prior teaching, adnexectomy is generally unnecessary to avoid clot release, thus, most recommend attempts at untwisting (McGovern, 1999; Zweizig, 1993). With a salvageable ovary, within minutes, congestion is relieved, and ovarian volume and cyanosis diminish. If cyanosis persists, however, then removal of the infarcted adnexa is typically indicated.

If the adnexa is healthy, there are options. First, neoplasms are resected. However, ovarian
cystectomy in an ischemic, edematous ovary may be technically difficult, and adnexectomy may be necessary. Second, unilateral or bilateral oophoropexy has been described to minimize the risk of repeated torsion (Djavadian, 2004; Germain, 1996). Techniques described include shortening of the uteroovarian ligament or fixing the uteroovarian ligament to the posterior uterus, the lateral pelvic wall, or the round ligament (Fuchs, 2010; Weitzman, 2008).

The most common case of ovarian hemorrhage follows rupture of a corpus luteum cyst. If the diagnosis is certain and symptoms abate, then observation and surveillance is usually sufficient. Concern for ongoing bleeding will typically prompt surgical evaluation. If the corpus luteum is removed before 10 weeks’ gestation, progestational support is recommended to maintain the pregnancy. Suitable regimens include: (1) micronized progesterone (Prometrium) 200 or 300 mg orally once daily; (2) 8-percent progesterone vaginal gel (Crinone) one premeasured applicator vaginally daily plus micronized progesterone 100 or 200 mg orally once daily; or (3) intramuscular 17-hydroxyprogesterone caproate, 150 mg. For the last, if given between 8 and 10 weeks’ gestation, only one injection is required immediately after surgery. If the corpus luteum is excised between 6 and 8 weeks’ gestation, then two additional doses should be given 1 and 2 weeks after the first.

Management of an Asymptomatic Adnexal Mass

Because most of these are incidental findings, management considerations include whether resection is necessary and its timing. A cystic benign-appearing mass that is < 5 cm often requires no additional antepartum surveillance. Early in pregnancy, this is likely a corpus luteum cyst, which typically resolves by the early second trimester. For cysts ≥ 10 cm, because of the substantial risk of malignancy, torsion, or labor obstruction, surgical removal is reasonable. Tumors between 5 and 10 cm should be carefully evaluated by sonography along with color Doppler and possibly MR imaging. If they have a simple cystic appearance, these cysts can be managed expectantly with sonographic surveillance (Schmeler, 2005; Zanetta, 2003). Resection is done if cysts grow, begin to display malignant qualities, or becomes symptomatic. However, if there are sonographic characteristics that suggest a cancer—thick septa, nodules, papillary excrescences, or solid components—then immediate resection is indicated (Caspi, 2000; Fleischer, 1990). Approximately 1 in 1000 pregnant women undergoes surgical exploration for an adnexal mass (Boulay, 1998). In general, we plan resection at 14 to 20 weeks because most masses that will regress will have done so by this time. Those with classic findings of endometrioma or mature cystic teratoma may be resected postpartum or during cesarean for obstetrical indications. Importantly, in any instance in which cancer is strongly suspected, the American College of Obstetricians and Gynecologists (2011) recommends consultation with a gynecologic oncologist.

Pregnancy-Related Ovarian Tumors

A group of adnexal masses result directly from the stimulating effects of various pregnancy hormones on ovarian stroma. These include pregnancy luteoma, hyperreactio luteinalis, and ovarian hyperstimulation syndrome.

Pregnancy Luteoma. These are rare, benign, ovarian neoplasms that are thought to arise from luteinized stromal cells and that classically cause elevated testosterone levels (Irving, 2011). Up to 25 percent of affected women will be virilized, and of these affected women, approximately half of their female fetuses will have some degree of virilization. Fortunately, most mothers and their fetuses are unaffected by the hyperandrogenemia because the placenta rapidly converts
androgens to estrogens (Kaňová, 2011).

In some cases, an adnexal mass along with maternal virilization will prompt sonography and measurement of testosterone and CA125 levels. Luteomas range in size from microscopic to greater than 20 cm. They appear as solid tumors, may be multiple or bilateral, and may be complex because of hemorrhagic areas (Choi, 2000). Concerns for malignancy may be further investigated by MR imaging (Kao, 2005; Tannus, 2009).

Total testosterone levels are increased, but with the caveat that levels in normal pregnancy can be substantially elevated (Appendix, p. 1291). Levels of CA125 antigen tumor marker are normal with a pregnancy luteoma, and significantly elevated levels indicate another cause. Differential diagnoses are primary ovarian cancer or metastatic disease and include granulosa cell tumors, thecomas, Sertoli-Leydig cell tumors, Leydig cell tumors, stromal hyperthecosis, and hyperreactio luteinalis.

Generally, luteomas do not require surgical intervention unless there is torsion, rupture, or hemorrhage (Masarie, 2010). These tumors spontaneously regress during the first few months postpartum, and androgen levels drop precipitously during the first 2 weeks following delivery (Wang, 2005). Lactation may be delayed a week or so by hyperandrogenemia (Clement, 1993; Dahl, 2008). Recurrence in subsequent pregnancies is rare.

**Hyperreactio Luteinalis.** In this condition, one or both ovaries develop multiple large thecalutein cysts, typically after the first trimester. Cysts are caused by luteinization of the follicular theca interna layer, and most are in response to stimulation by exceptionally high hCG levels (Russell, 2009). For this reason, they are more common with gestational trophoblastic disease, twins, fetal hydrops, and other conditions with increased placental mass. Similar to luteoma, maternal virilization develops in approximately a third of women, but there have been no reports of fetal virilization (Kaňová, 2011).

These ovarian tumors appear sonographically to have a “spoke wheel” pattern (Fig. 20-3, p. 399). If the diagnosis is confident, and unless complicated by torsion or hemorrhage, surgical intervention is not required. These masses resolve after delivery.

**Ovarian Hyperstimulation Syndrome.** This rare event is typified by multiple ovarian follicular cysts accompanied by increased capillary permeability. It most often is a complication of ovulation-induction therapy for infertility, although it rarely may develop in an otherwise normal pregnancy. Its etiopathogenesis is thought to involve hCG stimulation of vascular endothelial growth factor (VEGF) expression in granulosa-lutein cells (Soares, 2008). This causes increased vascular permeability that can lead to hypovolemia with ascites, pleural or pericardial effusion, acute kidney injury, and hypercoagulability. There is a clinical spectrum with symptoms that may include abdominal distention, rapid weight gain, dyspnea, and progressive hypovolemia. Serious complications are renal dysfunction, adult respiratory distress syndrome, ovarian rupture with hemorrhage, and thromboembolism.

Although most cases of ovarian hyperstimulation are associated with in vitro fertilization, increasing hCG levels from pregnancy can worsen the syndrome (Chen, 2012). Detailed guidelines for management have been outlined by the American Society for Reproductive Medicine (2008). Treatment is primarily supportive with attention to maintaining vascular volume and thromboprophylaxis.

**Ovarian Cancer**

Malignancies of the ovary are most common in older women and are the leading cause of death...
all women from genital-tract cancers (American Cancer Society, 2012). That said, the incidence of ovarian malignancy during pregnancy ranges from 1 in 20,000 to 50,000 births (Palmer, 2009; Eibye, 2013; Smith, 2003). Fortunately, 75 percent of these found in pregnancy are early-stage malignancies with a 5-year survival rate between 70 and 90 percent (Brewer, 2011). The types of malignancy are also markedly different in pregnant women compared with those in older women. In pregnant women, these are, in decreasing order of frequency, germ cell and sex cord-stromal tumors, low malignant potential tumors, and last, epithelial tumors (Morice, 2012).

Pregnancy apparently does not alter the prognosis of most ovarian malignancies. Management is similar to that for nonpregnant women, with the usual proviso that it may be modified depending on gestational age. Thus, if frozen section histopathological analysis verifies malignancy, then surgical staging is done with careful inspection of all accessible peritoneal and visceral surfaces (Giuntoli, 2006; Yazigi, 1988). Peritoneal washings are taken for cytology; biopsies are taken from the diaphragmatic surface and peritoneum; omentectomy is done; and biopsies are taken from pelvic and infrarenal paraaortic lymph nodes. Depending on the uterine size, some of these components, especially lymphadenectomy, may not be technically feasible.

If there is advanced disease, bilateral adnexectomy and omentectomy will decrease most tumor burden. In early pregnancy, hysterectomy and aggressive surgical debulking procedures may be elected. In other cases, minimal debulking as described is done and the operation terminated. In some cases of aggressive or large-volume disease, chemotherapy can be given during pregnancy while awaiting pulmonary maturation. As discussed on page 1227, monitoring maternal CA125 serum levels during chemotherapy is not accurate in pregnancy (Aslam, 2000; Morice, 2012).

**Adnexal Cysts**

Paratubal and paroovarian cysts are either distended remnants of the paramesonephric ducts or are mesothelial inclusion cysts. Although most are ≤ 3 cm, they occasionally attain worrisome dimensions (Genadry, 1977). Their reported incidence is influenced by size, but one autopsy series in nonpregnant women cited this to be 5 percent (Dorum, 2005). The most common paramesonephric cyst is the hydatid of Morgagni, which is pedunculated and typically dangles from one of the fimbria. These cysts infrequently cause complications and are most commonly identified at the time of cesarean delivery or puerperal sterilization, at which time they can simply be drained or excised. Neoplastic paraovarian cysts are rare, histologically resemble tumors of ovarian origin, and rarely are of borderline potential or frankly malignant (Honore, 1980; Korbin, 1998).

**Vulva and Vagina**

**Preinvasive Disease**

In young women, vulvar intraepithelial neoplasia (VIN) and vaginal intraepithelial neoplasia (VAIN) are seen more often than invasive disease and are commonly associated with HPV infection. As with cervical neoplasia, these premalignant conditions are treated after the puerperium.

**Squamous Cell Carcinoma**

Cancer of the vulva or vagina is generally a malignancy of older women, and thus, these are rarely associated with pregnancy. Even so, any suspicious lesions should be biopsied. Treatment is individualized according to the clinical stage and depth of invasion. In a review of 23 cases,
investigators concluded that radical surgery for stage I disease was feasible during pregnancy—including in the last trimester (Heller, 2000). We and others question the necessity of resection in late pregnancy in that definitive therapy can often be delayed because of vulvar cancer’s typical slow progression (Anderson, 2001). It appears that vaginal delivery is not contraindicated if vulvar and inguinal incisions are well healed.

Vulvar sarcoma, vulvar melanoma, and vaginal malignancies are rare in pregnancy and are the subjects of case reports (Alexander, 2004; Kuller, 1990; Matsuo, 2009).

**BREAST CARCINOMA**

The incidence of breast cancer is age dependent, however, because of its overall high frequency in women, it is relatively common in young women. Recall from Figure 63-1 that breast malignancies are the most frequent cancer found in pregnant women. And, as more women choose to delay childbearing, the frequency of associated breast cancer is certain to increase (Amant, 2012a). As an example, postponed childbearing was considered partially responsible for the increase in pregnancy-associated breast cancer in Sweden from 16 to 37 percent during the 40-year period from 1963 to 2002 (Andersson, 2009). Similar findings have been reported from Denmark (Eibye, 2013).

**Risk Factors**

Some, but not all, studies suggest that women with a family history of breast cancer—especially those with *BRCA1* and *BRCA2* breast cancer gene mutations—are more likely to develop breast malignancy during pregnancy (Johannsson, 1998; Shen, 1999; Wohlfahrt, 2002). However, although there is a definitely increased long-term risk with *BRCA1* and *BRCA2* mutations, it may be that parity modifies this risk. Specifically, parous women older than 40 years with these mutations have a significantly lower cancer risk than nulliparas with these mutations (Andrieu, 2006; Antoniou, 2006). Women with *BRCA1* and *BRCA2* gene mutations who undergo induced abortion or those who breast feed do not have an increased risk of breast cancer (Beral, 2004; Friedman, 2006). Moreover, Jernström and associates (2004) found that breast feeding actually conveyed a protective effect against this cancer in those with *BRCA1* gene mutation, but not in those with *BRCA2* mutations. Of other congenital risks, it is controversial whether diethylstilbestrol exposure in utero is associated with an increased breast cancer risk (Hoover, 2011; Larson, 2006; Titus-Ernstoff, 2006).

**Diagnosis**

More than 90 percent of pregnant women with breast cancer have a palpable mass, and greater than 80 percent are self-reported (Brewer, 2011). There are usually slight delays in clinical assessment, diagnostic procedures, and treatment of pregnant women with breast tumors (Berry, 1999). This can partially be attributed to increased pregnancy-induced breast tissue that obscures masses.

Evaluation of pregnant women with a breast mass should not differ from that for nonpregnant women. Thus, any suspicious breast mass should be pursued to diagnosis. Pragmatically, a palpable discrete mass can be biopsied or excised. If imaging is desirable to distinguish between a
solid mass and a cystic lesion, then sonography has high sensitivity and specificity (Navrozoglou, 2008). Mammography is appropriate if indicated, and the fetal radiation risk is negligible with appropriate shielding. Fetal exposure is only 0.04 mGy for the typical mammogram study. But, because breast tissue is denser in pregnancy, mammography has a false-negative rate of 35 to 40 percent (Woo, 2003). If the decision to biopsy is uncertain, then MR imaging may be used (Amant, 2010). With such techniques, masses can usually be described as either solid or cystic.

Cystic breast lesions are simple, complicated, or complex (Berg, 2003). Simple cysts do not require special management or monitoring, but they may be aspirated if symptomatic. Complicated cysts show internal echoes during sonography, and they sometimes are indistinguishable from solid masses. These are typically aspirated, and if the sonographic abnormality does not resolve completely, a core-needle biopsy is usually performed. Complex cysts have septa or intracystic masses seen on sonographic evaluation. Because some forms of breast cancer may be complex cysts, excision is usually recommended.

For solid breast masses, evaluation is with the triple test, that is, clinical examination, imaging, and needle biopsy. If all three suggest a benign lesion or if all three suggest a breast cancer, the test is said to be concordant. A concordant benign triple test is > 99-percent accurate, and breast lumps in this category can be followed by clinical examination alone. Fortunately, most masses in pregnancy have these three reassuring features. To the contrary, however, if any of the three assessments is suggestive of malignancy, then the mass should be excised regardless of the other two findings.

**Management**

Once breast cancer is diagnosed, a limited search of the most common metastatic sites is completed. For most women, this includes a chest radiograph, liver sonography, and skeletal MR imaging (Amant, 2012a).

Treatment of breast cancer is by a multidisciplinary team that includes an obstetrician, surgeon, and medical oncologist. Desires for pregnancy continuation are addressed up front. Data indicate that pregnancy interruption does not influence the course or prognosis of breast cancer (Cardonick, 2010). With pregnancy continuation, treatment in general is similar to that for nonpregnant women. However, chemotherapy and surgery are delayed to the second trimester, and adjuvant radiotherapy is withheld until after delivery (Brewer, 2011).

Surgical treatment may be definitive. In the absence of metastatic disease, either a wide excision or a modified or total mastectomy—each with axillary node staging—can be performed (Rosenkranz, 2006; Woo, 2003). Staging by sentinel lymph node biopsy and lymphoscintigraphy with technetium-99m is safe. Although often administered concurrently with lymphoscintigraphy, isosulfan blue and methylene blue dyes are pregnancy class C drugs, and some recommend that they be avoided (Mondi, 2007; Spanheimer, 2009). Breast reconstruction, if desired, is typically delayed until after delivery (Viswanathan, 2011).

Chemotherapy is usually given with either positive- or negative-node breast cancers. In premenopausal women, survival is improved even if lymph nodes are cancer free. For node-positive disease, multiagent chemotherapy is begun if delivery is not anticipated within several weeks. Drug classes are alkylating agents, anthracyclines, antimetabolites, and taxanes (Lippman, 2012). Cyclophosphamide, doxorubicin, methotrexate, and 5-fluorouracil are currently in use (García-Manero, 2009). After the first trimester, methotrexate can be substituted for doxorubicin. If an anthracycline-based agent such as doxorubicin is used, pretherapy maternal echocardiography is performed because of associated cardiotoxicity (Brewer, 2011). In 22 pregnant women treated
with modified radical mastectomy that was followed by chemotherapy in most, Berry and colleagues (1999) reported minimal fetal risks. Moreover, Hahn and coworkers (2006) reported good short-term outcomes for the offspring of 57 women treated during pregnancy with multiagent chemotherapy for breast cancer.

Immunotherapy for breast cancers has become commonplace. Trastuzumab (Herceptin) is a monoclonal antibody to the HER2/neu receptor, which is found in approximately a third of invasive breast cancers (Hudis, 2007). The drug is used more commonly as adjunctive therapy for early disease in HER2/neu-positive tumors but is not recommended in pregnancy (Amant, 2010). This is because HER2/neu is strongly expressed in fetal renal epithelium, and trastuzumab has been linked with miscarriage, with fetal renal failure and related oligohydramnios, and with neonatal deaths from preterm birth (Azim, 2010). For these reasons, highly effective contraception is used during and for 6 months following trastuzumab treatment. For women who conceive after only brief exposure, fetal renal effects appear to be reversible, and short-term neonatal outcomes have been normal with no congenital anomalies reported (Azim, 2012).

Prognosis

The effects of pregnancy on the course of breast cancer and its prognosis are complex. There is no doubt that breast cancer is more aggressive in younger women, but whether it is more aggressive during pregnancy in these same women is debatable. Clinically, most studies indicate little difference in overall survival rates with pregnancy-associated breast cancer compared with similarly aged and staged nonpregnant women (Beadle, 2009). There have been other reports of worse overall survival rates with pregnancy-associated breast cancer (Rodriguez, 2008). These investigators did both conclude, however, that later disease stages are more prevalent in pregnant women.

Thus, it appears that because breast cancer is usually found at a more advanced stage in pregnant women, overall prognosis is diminished. In an earlier review, Jacob and Stringer (1990) reported that approximately 30 percent of pregnant women had stage I disease, 30 percent had stage II, and 40 percent had stages III or IV. In addition, the aggregate of studies published after 1990 indicate that up to 60 percent of pregnant women have concomitant axillary node involvement at diagnosis. And although, stage for stage, the 5-year survival rate is comparable in pregnant and nonpregnant women, the more advanced stages that are typical of pregnant women worsen their prognosis (King, 1985; Nugent, 1985; Zemlickis, 1992).

Pregnancy Following Breast Cancer

After breast cancer treatment, chemotherapy will render some women infertile, and options for childbearing are limited (Kim, 2011). For those who became pregnant, there appear to be no adverse effects on long-term maternal survival rates (Averette, 1999; Velentgas, 1999). Moreover, a metaanalysis of 10 studies found that for women with early breast cancer, pregnancy that occurs 10 months after diagnosis may, in fact, have a survival benefit (Valachis, 2010). There are also no data indicating that lactation adversely affects the course of previously diagnosed breast cancer. Also, lactation and breast feeding are possible after conservative surgery and radiation of the treated breast (Higgins, 1994).

Recommendations for subsequent pregnancies in women successfully treated for breast malignancy are based on several factors that include consideration for the recurrence risk. Simply because recurrences are more common soon after treatment, it seems reasonable to advise a delay
of 2 to 3 years for observation. Hormonal contraceptive methods are contraindicated, and a copper-containing intrauterine device is an excellent long-acting reversible method for many. Even with contraceptive failure, women who conceive do not appear to have diminished survival (Ives, 2006). It is reassuring that women who undertake pregnancy after breast cancer treatment overall have good outcomes (Langagergaard, 2006). Of particular concern is that women treated with tamoxifen are at risk for several months after its discontinuation for having an infant with congenital anomalies. This is because of its extremely long half-life, and thus delaying conception is recommended for at least 2 months after its completion (Braems, 2011).

**THYROID CANCER**

Various thyroid gland malignancies constitute the most common endocrine cancers. Because most of these originate within discrete nodules, their evaluation is important. This typically includes sonography and measurement of serum thyroid-stimulating hormone (TSH) and free thyroxine levels. Fine-needle aspiration is indicated for any suspicious nodule (Yazbeck, 2012).

With a diagnosis of thyroid malignancy, pregnancy termination is not necessary (Alves, 2011). Primary therapy is total thyroidectomy performed ideally during the second trimester. Postoperatively, replacement thyroxine is given to maintain serum TSH levels between 0.1 and 0.5 mIU/L (Abalovich, 2007). Most thyroid cancers are well differentiated and follow an indolent course. Thus, delayed surgical treatment does not usually alter outcome (Yazbeck, 2012). If surgical therapy is postponed until after pregnancy, thyroxine is given to suppress any growth stimulus of TSH on tumor cells (Pacini, 2012).

In some types of thyroid malignancies, primary or postoperative treatment is given with radioiodine. This is contraindicated in both pregnancy and lactation. Transplacental iodine-131 is avidly trapped by the fetal thyroid gland to cause hypothyroidism (Chap. 58, p. 1149). During lactation, the breast also concentrates a substantial amount of iodide. This may pose neonatal risk due to $^{131}$I-containing milk ingestion and maternal risk from significant breast irradiation. To limit maternal exposure, a delay of 3 months between lactation and ablation will more reliably ensure complete breast involution (Sisson, 2011). Last, pregnancy should be avoided for 6 months to 1 year in women with thyroid cancer who receive $^{131}$I doses. This time ensures thyroid function stability and confirms thyroid cancer remission (Abalovich, 2007).

**LYMPHOID CELL MALIGNANCIES**

Hematological malignancies comprise 10 to 20 percent of cancers in pregnancy (Cohen, 2011; Eibye, 2013; Smith, 2003). Some of these present as leukemia involving bone marrow and blood. Others are solid lymphomas, which may be of B- or T-cell origin.

**Hodgkin Disease**

This lymphoma is probably B-cell derived and is cytologically distinguished from other lymphomas by Reed–Sternberg cells. It is the most common malignant lymphoma in women of childbearing age. In a population-based review of approximately 4 million pregnancies, Smith and associates (2003) reported that Hodgkin lymphoma complicated only 1 in 34,000 live births. Our
experiences are similar during the past 40 years at Parkland Hospital with nearly 500,000 births.

In more than 70 percent of Hodgkin disease cases, there is painless enlargement of lymph nodes above the diaphragm—the axillary, cervical, or submandibular chains. Approximately one third of patients have symptoms including fever, night sweats, malaise, weight loss, and pruritus. Diagnosis is by histological examination of involved nodes (Longo, 2012).

**Staging and Treatment**

The Ann Arbor staging system, shown in Table 63-2, is used for Hodgkin and other lymphomas. Recent studies have used risk categories—high, low, and very low—however, these are not succinctly defined (Armitage, 2010). Pregnancy limits the use of some radiographic studies for staging, but at minimum, chest radiography, abdominal imaging with sonography or MR imaging, and bone marrow biopsy are completed (Williams, 2001). MR imaging is excellent for evaluating thoracic and abdominal paraaortic lymph nodes (Fig. 63-7) (Brenner, 2012).

Substage A = no symptoms; substage B = fever, sweats, or weight loss; substage E = extralymphatic involvement excluding liver and bone marrow.
The current trend for nonpregnant individuals is to administer chemotherapy for all stages of Hodgkin disease. In pregnancy, for early-stage disease in the first trimester, options include observation until after 12 weeks, single-agent vinblastine until the second trimester, pregnancy termination followed by multiagent chemotherapy, or radiotherapy alone for isolated neck or axillary sites (El-Hemaidi, 2012; Rizack, 2009).

For advanced-stage disease, chemotherapy is recommended regardless of gestational age. Before 20 weeks, therapeutic abortion is a consideration, but if termination is unacceptable, then treatment with vinblastine followed by multiagent therapy in the second trimester can be used (Pereg, 2007). For most advanced-stage disease after the first trimester, cycles of doxorubicin, bleomycin, vinblastine, and dacarbadine (ABVD) are given, and radiotherapy can be added postpartum (Cohen, 2011). In general, postponement of therapy until fetal maturity is achieved seems justifiable only when the diagnosis is made late in pregnancy (Shulman, 2008). Importantly, in our experiences, pregnant women with Hodgkin disease—even after they are “cured”—are inordinately susceptible to infection and sepsis. Active antineoplastic therapy increases this vulnerability.

**Prognosis**

The overall prognosis with Hodgkin lymphoma is good, and survival rates exceed 70 percent. Pregnancy does not adversely affect the course or survival rate of women with this lymphoma (Brenner, 2012; Pavlidis, 2002). Moreover, adverse perinatal outcomes do not appear to be increased (Langagergaard, 2008). Finally, neither chemotherapy after the first trimester nor mediastinal and neck irradiation had reported adverse fetal effects (Jacobs, 1981).
The long-term prognosis for women with Hodgkin disease is encouraging. Horning and coworkers (1981) reported that half of women resumed normal menses after chemotherapy and that there were no birth defects in 24 neonates subsequently born to these women. Long-term complications of lymphoma treatment include secondary leukemia in those treated with chemotherapy, secondary breast cancer in those treated with radiotherapy, and myocardial damage and infarction, pulmonary fibrosis, hypothyroidism, and marrow suppression (Longo, 2012).

Non-Hodgkin Lymphomas

Although usually B-cell tumors, non-Hodgkin can also be T-cell or natural killer (NK)-cell neoplasms. Their biology, classification, and treatment are complex (Longo, 2012; O’Gara, 2009). For example, they are associated with viral infections, and indeed, their incidence has risen sharply at least partly because 5 to 10 percent of HIV-infected persons develop lymphoma. Other associated viruses include Epstein-Barr virus, hepatitis C virus, and human herpes virus 8. Some of these lymphomas are quite aggressive, and survival varies with the type of cell line involved.

Non-Hodgkin lymphomas are uncommon during pregnancy, and only approximately 100 cases have been reported (Brenner, 2012). They are staged according to the Ann Arbor system shown in Table 63-2. If diagnosed in the first trimester, pregnancy termination followed by multiagent chemotherapy is recommended for all but indolent or very early disease. These less aggressive forms may either be observed or be temporized with focal supradiaphragmatic radiotherapy, with full treatment after entering the second trimester. If one of these lymphomas is diagnosed after the first trimester, chemotherapy and immunotherapy with rituximab (Rituxan) are given (Cohen, 2011; Rizack, 2009). In a report describing follow-up at 6 to 29 years in 55 individuals whose mothers were given chemotherapy during pregnancy, there were no congenital, neurological, or psychological abnormalities (Avilés, 2001). Furthermore, these exposed persons had no cancers, including leukemia.

Burkitt lymphoma is an aggressive B-cell tumor associated with Epstein-Barr virus infection. Prognosis is poor, and treatment is given with multiagent chemotherapy. In a review of 19 women whose pregnancies were complicated by this lymphoma, 17 died within a year of diagnosis (Barnes, 1998).

Leukemias

In general, these malignancies arise either from lymphoid tissues—lymphoblastic or lymphocytic leukemias, or from bone marrow—myeloid leukemias. They can be acute or chronic. Although adult leukemias are more prevalent after age 40, they still are among the most common malignancies of young women. Leukemia was diagnosed in 1 in 40,000 pregnancies reported to the California Cancer Registry (Smith, 2003). In a review of 350 reports of pregnancy complicated by leukemia, of 72 cases reported from 1975 until 1988, 44 had acute myelogenous leukemia; 20 had acute lymphocytic leukemia; and eight had one of the chronic leukemias (Caligiuri, 1989). The last are uncommon in young women, and chronic hairy-cell leukemia has been reported in only six pregnancies (Stiles, 1998).

Acute leukemias almost always cause marked peripheral blood count abnormalities, and frequently there is an elevated white blood cell count with readily recognizable circulating blast cells. The diagnosis is made from bone marrow biopsy.

Currently, with contemporary therapy, remission during pregnancy is common, compared with almost 100-percent mortality before 1970. The goal of remission is aggressively pursued with
multiagent chemotherapy. There is no evidence that pregnancy termination further improves the prognosis, however, abortion is a consideration in early pregnancy to avoid potential chemotherapy teratogenesis. One example is treatment of acute promyelocytic leukemia with all-trans-retinoic acid, also known as tretinoin (Carradice, 2002; Celo, 1994). This is a potent teratogen that causes retinoic acid syndrome (Chap. 12, p. 251). In other cases, pregnancy termination before viability may simplify management of the acutely ill woman.

Other than these caveats, treatment of pregnant women with leukemia is similar to that for nonpregnant women. After induction chemotherapy, postremission maintenance therapy is mandatory to prevent a relapse, which is usually then treated with stem-cell transplantation (Wetzler, 2012). If allogeneic stem-cell transplantation is indicated, early delivery is considered. With some chronic leukemias, it may be possible to delay therapy until after delivery (Fey, 2008). As with lymphoma, infection and hemorrhage are significant complications that should be anticipated in women with active disease. Puerperal infection is particularly problematic.

There are few contemporaneous studies of leukemia treated during pregnancy. In an earlier review of 58 cases, Reynoso and colleagues (1987) reported that 75 percent were diagnosed after the first trimester. Half were acute myelogenous leukemia, which had a remission rate of 75 percent with chemotherapy. Only 40 percent of these pregnancies resulted in liveborn infants. Preterm delivery and stillbirth rates were also reported to be increased (Caligiuri, 1989).

MALIGNANT MELANOMA

These malignant tumors most frequently originate in the skin from a preexisting nevus and its pigment-producing melanocytes. Melanomas should be suspected in pigmented lesions with changes in contour, surface elevation, discoloration, itching, bleeding, or ulceration, which should prompt biopsy. They are most common in light-skinned whites and develop relatively frequently in women of childbearing age. They sometimes are first diagnosed during pregnancy, and the reported incidence ranges widely from 0.03 to 2.8 per 1000 live births (Eibye, 2013; Smith, 2003; Wong, 1990). This is likely because many are treated on an outpatient basis, and thus they are not entered into a tumor registry. As noted on page 1221, malignant melanoma is one of the tumors that is known to metastasize to the placenta and fetus. Placental evaluation for metastasis should be performed after delivery.

Staging and Treatment

Staging is clinical as follows: stage I is a melanoma with no palpable lymph nodes; in stage II lymph nodes are palpable; and in stage III, there are distant metastases. For patients with stage I tumor thickness is the single most important predictor of survival. The Clark classification includes five levels of involvement by depth into the epidermis, dermis, and subcutaneous fat. The Breslow scale measures tumor thickness and size, in addition to depth of invasion.

Primary surgical treatment for melanoma is determined by the stage and includes wide local resection, sometimes with extensive regional lymph node dissection. Schwartz and associates (2003) recommend sentinel lymph node mapping and biopsy using $^{99m}$Tc-sulfur colloid, which has a calculated fetal dose of 0.014 mSv or 0.014 mGy. Routine regional node dissection reportedly improves survival in nonpregnant patients with microscopic metastases (Cascinelli, 1998). For pregnant patients, an algorithm has been proposed that begins with resection of the primary tumor.
under local anesthesia and postpones sentinel lymph node biopsy until after delivery (Broer, 2012). Although prophylactic chemotherapy or immunotherapy is usually avoided during pregnancy, it may be given if indicated by tumor stage and maternal prognosis. In most cases of distant metastatic melanoma, treatment is at best palliative. At this time, the role of estrogen receptor-β in melanoma progression is under investigation, and it may be a target for therapeutic intervention (de Giorgi, 2011).

**Prognosis**

Stage-for-stage, survival is equivalent between pregnant and nonpregnant women. Therapeutic abortion does not appear to improve survival. Clinical stage is the strongest determinant of survival, and women with deep cutaneous invasion or regional node involvement have the worst prognosis (Dipaola, 1997; Kjems, 1993; Lens, 2008). Approximately 60 percent of recurrences will manifest within 2 years, and 90 percent by 5 years. Thus, most recommend that pregnancy be avoided for 3 to 5 years after surgical resection. Interim contraception can include combination oral contraceptives, as they do not appear to have adverse effects (Gandini, 2011). Related, subsequent pregnancies in women with localized melanoma do not appear to adversely affect cancer survival rates (Driscoll, 2009).

**GASTROINTESTINAL TRACT CANCER**

**Colorectal Cancer**

Malignancies of the colon and rectum are the third most frequent in women of all age groups in the United States (American Cancer Society, 2012). Even so, colorectal tumors seldom complicate pregnancy because they are uncommon before age 40. Smith and colleagues (2003) reported an approximate incidence of 1 per 150,000 deliveries in the California Cancer Registry. It was about 1 per 35,000 births in the Danish Registry (Eibye, 2013). The majority—80 percent—of colorectal carcinomas in pregnant women arise from the rectum. In one review, there were only 41 reported cases in pregnancy with cancer above the peritoneal reflection (Chan, 1999).

The most frequent symptoms of colorectal cancer are abdominal pain, distention, nausea and vomiting, constipation, and rectal bleeding. The diagnosis may be delayed because many of these symptoms are common in pregnancy. Certainly, if symptoms suggestive of colon disease persist, digital rectal examination, stool tests for occult blood, and flexible sigmoidoscopy or colonoscopy should be done.

Treatment of colon cancer in pregnant women follows the same general guidelines as for nonpregnant women. Without evidence of metastatic disease, surgical resection is preferred, but most pregnant women have advanced lesions (Walsh, 1998). During the first half of pregnancy, hysterectomy is not necessary to perform colon or rectal resection, and thus, therapeutic abortion is not mandated. During later pregnancy, therapy may be delayed until fetal maturation, however, hemorrhage, obstruction, or perforation may force surgical intervention (Minter, 2005). Vaginal delivery is usually avoided because lower rectal lesions may cause dystocia, or delivery may cause tumor hemorrhage.

There is no evidence that pregnancy influences the course of colorectal cancer, and the prognosis appears to be similar to that for identical stages in nonpregnant patients (Dahling, 2009). Carcinoembryonic antigen (CEA) is a tumor marker for colon cancer, and although it may be
elevated during normal pregnancy, baseline values may be useful to monitor disease (Minter, 2005).

### Other Gastrointestinal Neoplasms

Gastric cancer is rarely associated with pregnancy, and most reported cases are from Japan. Hirabayashi and associates (1987) reviewed outcomes in 60 pregnant women during a 70-year period from 1916 to 1985. Delayed diagnosis during pregnancy is common, and the prognosis is consistently poor (Lee, 2009). It is axiomatic that persistent unexplained upper gastrointestinal symptoms should be evaluated by endoscopy.

With Zollinger–Ellison syndrome, tumors typically found in the duodenum or pancreas secrete excess gastrin. This leads to increased stomach acid production and gastric ulceration. Most tumors are slow growing, and thus, the primary goal in pregnancy is control of acid secretion. Some advise surgical resection before pregnancy (Stewart, 1997). In pregnant women with metastatic disease or in those with previously undiagnosed tumors, antacids and antisecretory treatment with histamine H₂-receptor antagonists or proton-pump inhibitors usually controls acid secretion.

### MISCELLANEOUS TUMORS

Various other neoplasms have been reported in pregnancy and are usually the subject of case reports. Examples include carcinoid tumors, which are usually of gastrointestinal origin (Durkin, 1983). Both pancreatic and hepatocellular cancer are rare during pregnancy (Kakoza, 2009; Marinoni, 2006; Papoutsis, 2012; Perera, 2011). Bladerston and coworkers (1998) described a massive intrahepatic cholangiocarcinoma masquerading as HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome. Gastrointestinal cancers during pregnancy are often discovered because of ovarian metastases—Krukenberg tumors—which have a bleak prognosis (Glišić, 2006). Central nervous system benign and malignant neoplasms had a reported frequency of 1 in 10,000 to 28,000 (Eibye, 2013; Smith, 2003). Bladder and urachal duct carcinoma have been rarely reported coincident with pregnancy (McNally, 2013; Yeaton-Massey, 2013). Finally, bone and vaginal tumors have been described (ElNaggar, 2012; Kathiresan, 2011).

TRAVEL PRECAUTIONS DURING PREGNANCY

BIOTERRORISM

Infections have historically been a major cause of maternal and fetal morbidity and mortality worldwide, and they remain so in the 21st century. The unique maternal-fetal vascular connection in some cases serves to protect the fetus from infectious agents, whereas in other instances it provides a conduit for their transmission to the fetus. Maternal serological status, gestational age at the time infection is acquired, the mode of acquisition, and the immunological status of both the mother and her fetus all influence disease outcome.

MATERNAL AND FETAL IMMUNOLOGY

Pregnancy-Induced Immunological Changes

Even after intensive study, many of the maternal immunological adaptations to pregnancy are not well elucidated. It is known that pregnancy is associated with an increase in CD4-positive T cells secreting Th2-type cytokines—for example interleukins 4, 5, 10, and 13. Th1-type cytokine production—for example, interferon gamma and interleukin 2—appears to be somewhat suppressed, leading to a Th2 bias in pregnancy. This bias affects the ability to rapidly eliminate certain intracellular pathogens during pregnancy, although the clinical implications of this suppression are unknown (Jamieson, 2006a; Raghupathy, 2001; Svensson-Arvelund, 2014). Importantly, the Th2 humoral immune response remains intact.
Fetal and Newborn Immunology

The active immunological capacity of the fetus and neonate is compromised compared with that of older children and adults. That said, fetal cell-mediated and humoral immunity begin to develop by 9 to 15 weeks’ gestation (Warner, 2010). The primary fetal response to infection is immunoglobulin M (IgM). Passive immunity is provided by IgG transferred across the placenta. By 16 weeks, this transfer begins to increase rapidly, and by 26 weeks, fetal concentrations are equivalent to those of the mother. After birth, breast feeding is protective against some infections, although this protection begins to decline at 2 months of age. Current World Health Organization (2013) recommendations are to exclusively breast feed for the first 6 months of life with partial breast feeding until 2 years of age.

Vertical transmission refers to passage from the mother to her fetus of an infectious agent through the placenta, during labor or delivery, or by breast feeding. Thus, preterm rupture of membranes, prolonged labor, and obstetrical manipulations may increase the risk of neonatal infection. Those occurring less than 72 hours after delivery are usually caused by bacteria acquired in utero or during delivery, whereas infections after that time most likely were acquired afterward. Table 64-1 details specific infections by mode and timing of acquisition.

HIV = human immunodeficiency virus; HPV = human papillomavirus; HSV = herpes simplex virus.

Neonatal infection, especially in its early stages, may be difficult to diagnose because neonates
often fail to express classic clinical signs. If the fetus was infected in utero, there may be depression and acidosis at birth for no apparent reason. The neonate may suck poorly, vomit, or show abdominal distention. Respiratory insufficiency may develop, which may present similarly to idiopathic respiratory distress syndrome. The neonate may be lethargic or jittery. The response to sepsis may be hypothermia rather than hyperthermia, and the total leukocyte and neutrophil counts may be depressed.

VIRAL INFECTIONS

Varicella-Zoster Virus

Several viruses that infect the mother can also cause devastating fetal infections. Varicella-zoster virus (VZV) is a double-stranded DNA herpes virus acquired predominately during childhood, and 95 percent of adults have serological evidence of immunity (Plourd, 2005). The incidence of adult varicella infections declined by 74 percent after the introduction of varicella vaccination, probably secondary to herd immunity (Marin, 2008). This has resulted in a decrease in maternal and fetal varicella infections (Khandaker, 2011). Primary infection—varicella or chicken pox—is transmitted by direct contact with an infected individual, although respiratory transmission has been reported. The incubation period is 10 to 21 days, and a nonimmune woman has a 60- to 95-percent risk of becoming infected after exposure (Whitley, 2012). She is then contagious from 1 day before the onset of the rash until the lesions are crusted over.

Maternal Infection

Primary varicella infection presents with a 1- to 2-day flu-like prodrome, which is followed by pruritic vesicular lesions that crust over in 3 to 7 days. Infection tends to be more severe in adults, and a quarter of varicella deaths are within the 5 percent of nonimmune adults (Centers for Disease Control and Prevention, 2007).

Mortality is predominately due to varicella pneumonia, which is thought to be more severe during adulthood and particularly in pregnancy. Between 5 and 20 percent of infected pregnant women developed pneumonitis (Centers for Disease Control and Prevention, 2007; Harger, 2002) Risk factors for VZV pneumonia include smoking and having more than 100 cutaneous lesions. Maternal mortality rates with pneumonia have decreased to 1 to 2 percent (Chandra, 1998). Symptoms of pneumonia usually appear 3 to 5 days into the course of illness. It is characterized by fever, tachypnea, dry cough, dyspnea, and pleuritic pain. Nodular infiltrates are similar to other viral pneumonias (Chap. 51, p. 1018). Although resolution of pneumonitis parallels that of skin lesions, fever and compromised pulmonary function may persist for weeks.

If primary varicella infection is reactivated years later, it causes herpes zoster or shingles (Whitley, 2012). This presents as a unilateral dermatomal vesicular eruption associated with severe pain. Zoster does not appear to be more frequent or severe in pregnant women. Enders and associates (1994) reviewed 366 cases during pregnancy and found little evidence that zoster causes congenital malformations. Zoster is contagious if blisters are broken, although less so than primary varicella infection.

Fetal and Neonatal Infection

In women with chicken pox during the first half of pregnancy, the fetus may develop congenital
varicella syndrome. Some features include chorioretinitis, microphthalmia, cerebral cortical atrophy, growth restriction, hydronephrosis, limb hypoplasia, and cicatricial skin lesions as shown in Figure 64-1 (Auriti, 2009). Enders and coworkers (1994) evaluated 1373 pregnant women with varicella infection. When maternal infection developed before 13 weeks, only two of 472 pregnancies—0.4 percent—had neonates with congenital varicella. The highest risk was between 13 and 20 weeks, during which time seven of 351 exposed fetuses—2 percent—had evidence of congenital varicella. After 20 weeks’ gestation, the researchers found no clinical evidence of congenital infection. Thus, congenital infections, particularly after 20 weeks, are uncommon. Subsequent sporadic reports have described central nervous system abnormalities and skin lesions in fetuses who developed congenital varicella in weeks 21 to 28 of gestation (Lamont, 2011b; Marin, 2007).

![FIGURE 64-1 Atrophy of the lower extremity with bony defects and scarring in a fetus infected during the first trimester by varicella. (From Paryani, 1986, with permission.)](image)

If the fetus or neonate is exposed to active infection just before or during delivery, and therefore before maternal antibody has been formed, then there is a serious threat to newborns. Attack rates range from 25 to 50 percent, and mortality rates approach 30 percent. In some instances, neonates develop disseminated visceral and central nervous system disease, which is commonly fatal. For this reason, varicella-zoster immune globulin should be administered to neonates born to mothers who have clinical evidence of varicella 5 days before and up to 2 days after delivery.

**Diagnosis**

Maternal varicella infection is usually diagnosed clinically. The virus may also be isolated by scraping the vesicle base during primary infection and performing a Tzanck smear, tissue culture, or direct fluorescent antibody testing. Also, available nucleic acid amplification tests (NAATs) are very sensitive. Congenital varicella may be diagnosed using NAAT analysis of amnionic fluid.
although a positive result does not correlate well with the development of congenital infection (Mendelson, 2006). A detailed anatomical sonographic evaluation performed at least 5 weeks after maternal infection may disclose abnormalities, but the sensitivity is low (Mandelbrot, 2012).

Management

Maternal Viral Exposure. There are several aspects of maternal varicella virus exposure and infection in pregnancy that affect management. Because most adults are VZV seropositive, exposed pregnant women with a negative history for chicken pox should undergo VZV serologic testing. At least 70 percent of these women will be seropositive, and thus immune. Exposed pregnant women who are susceptible should be given VariZIG, a recently approved varicella zoster immune globulin. Although best given within 96 hours of exposure, its use is approved for up to 10 days to prevent or attenuate varicella infection (Centers for Disease Control and Prevention, 2012a, 2013h).

Maternal Infection. Any patient diagnosed with primary varicella infection should be isolated from pregnant women. Because pneumonia often presents with few symptoms, a chest radiograph is recommended by many. Most women require only supportive care, but those who require intravenous (IV) fluids and especially those with pneumonia are hospitalized. Intravenous acyclovir therapy is given to women requiring hospitalization—500 mg/m$^2$ or 10 to 15 mg/kg every 8 hours.

Vaccination. An attenuated live-virus vaccine—Varivax—was approved in 1995. Two doses, given 4 to 8 weeks apart, are recommended for adolescents and adults with no history of varicella. This results in 98-percent seroconversion (Centers for Disease Control and Prevention, 2007). Importantly, vaccine-induced immunity diminishes over time, and the breakthrough infection rate approximates 5 percent at 10 years (Chaves, 2007). The vaccine is not recommended for pregnant women or for those who may become pregnant within a month following each vaccine dose. That said, a registry of 981 vaccine-exposed pregnancies reports no cases of congenital varicella syndrome or other congenital associated malformations (Wilson, 2008). The attenuated vaccine virus is not secreted in breast milk. Thus, postpartum vaccination should not be delayed because of breast feeding (American College of Obstetricians and Gynecologists, 2013a; Bohlke, 2003).

Influenza

These respiratory infections are caused by members of the family Orthomyxoviridae. Influenza A and B form one genus of these RNA viruses, and both cause epidemic human disease. Influenza A viruses are subclassified further by hemagglutinin (H) and neuraminidase (N) surface antigens. Influenza outbreaks occur annually, and the most recent epidemic was in 2013–2014 caused by an influenza A/H$\text{1}$N$\text{1}$ strain.

Maternal and Fetal Infection

Maternal influenza is characterized by fever, dry cough, and systemic symptoms. Infection usually is not life-threatening in otherwise healthy adults, but pregnant women appear to be more susceptible to serious complications, particularly pulmonary involvement (Cox, 2006; Neuzil, 1998; Rasmussen, 2012). In early 2003, widespread influenza A infection affected pregnant women. At Parkland Hospital, more than 100 women were hospitalized for this infection, and 12
percent had pulmonary infiltrates seen radiographically (Rogers, 2010).

There is no firm evidence that influenza A virus causes congenital malformations (Irving, 2000; Saxén, 1990). Conversely, Lynberg and colleagues (1994) reported increased neural-tube defects in neonates born to women with influenza early in pregnancy, but this was possibly associated with hyperthermia (Chap. 12, p. 284). Viremia is infrequent, and transplacental passage is rare (Rasmussen, 2012). Stillbirth, preterm delivery, and first-trimester abortion have all been reported, usually correlated to severity of maternal infection (Centers for Disease Control and Prevention, 2011; Pierce, 2011; Yates, 2010).

Influenza may be detected in nasopharyngeal swabs using viral antigen rapid detection assays (Table 64-2). Reverse transcriptase–polymerase chain reaction (RT-PCR) is the more sensitive and specific test, although not commercially available in many hospitals (Dolin, 2012). In contrast, rapid influenza diagnostic tests (RIDTs) are least indicative, with sensitivities of 40 to 70 percent. In the Parkland Hospital emergency room, immunofluorescent antibody assays are used. Nasopharyngeal specimens are collected as early as possible after symptom onset to maximize influenza testing sensitivity. Importantly, decisions to administer antiviral medications for influenza treatment or chemoprophylaxis should be based on clinical symptoms and epidemiological factors. Moreover, the start of therapy should not be delayed pending testing results (Centers for Disease Control and Prevention, 2013f).

* Nasopharyngeal or throat swab.

RT-PCR = reverse transcription-polymerase chain reaction. Abbreviated from Centers for Disease Control and Prevention, 2013f.

**Management**

Two classes of antiviral medications are currently available. *Neuraminidase inhibitors* are highly effective for the treatment of early influenza A and B. These include *oseltamivir* (Tamiflu), which is taken orally for treatment and for chemoprophylaxis, and *zanamivir* (Relenza), which is inhaled for treatment. *Peramivir* is an investigational drug administered intravenously.

The *adamantanes* include amantadine and rimantadine, which were used for years for treatment and chemoprophylaxis of influenza A. In 2005, influenza A resistance to adamantane was reported to be > 90 percent in the United States, and thus, adamantane use is not currently recommended. It is possible that these drugs may again be effective for subsequently mutated strains.
There is limited experience with all five of these antiviral agents in pregnant women. They are Food and Drug Administration category C drugs, used when the potential benefits outweigh the risks. At Parkland Hospital, we recommend starting oseltamivir treatment within 48 hours of symptom onset—75 mg orally twice daily for 5 days. Prophylaxis with oseltamivir, 75 mg orally once daily for 10 days, is also recommended for significant exposures. Antibacterial medications should be added when a secondary bacterial pneumonia is suspected (Chap. 51, p. 1016).

Vaccination

Effective vaccines are formulated annually. Vaccination against influenza throughout the influenza season, but optimally in October or November, is recommended by the Centers for Disease Control and Prevention (CDC) (2013e) and the American College of Obstetricians and Gynecologists (2010) for all women who will be pregnant during the influenza season. This is especially important for those affected by chronic medical disorders such as diabetes, heart disease, asthma, or human immunodeficiency virus (HIV) infection (Jamieson, 2012). Inactivated vaccine prevents clinical illness in 70 to 90 percent of healthy adults. Importantly, there is no evidence of teratogenicity or other adverse maternal or fetal events (Conlin, 2013; Kharbanda, 2013; Munoz, 2012; Nordin, 2013; Sheffield, 2012). Moreover, several studies have found decreased rates of influenza in infants up to 6 months of age whose mothers were vaccinated during pregnancy (Steinhoff, 2012; Zaman, 2008). Immunogenicity of the trivalent inactivated seasonal influenza vaccine in pregnant women is similar to that in the nonpregnant individual (Sperling, 2012). A live attenuated influenza virus vaccine is available for intranasal use but is not recommended for pregnant women.

Mumps

This uncommon adult infection is caused by an RNA paramyxovirus. Because of childhood immunization, up to 90 percent of adults are seropositive (Rubin, 2012). The virus primarily infects the salivary glands, and hence its name—mumps—is derived from Latin, “to grimace.” Infection also may involve the gonads, meninges, pancreas, and other organs. It is transmitted by direct contact with respiratory secretions, saliva, or through fomites. Treatment is symptomatic, and mumps during pregnancy is no more severe than in nonpregnant adults.

Women who develop mumps in the first trimester may have an increased risk of spontaneous abortion. Infection in pregnancy is not associated with congenital malformations, and fetal infection is rare (McLean, 2013).

The live attenuated Jeryl-Lynn vaccine strain is part of the MMR vaccine—measles, mumps, and rubella—and is contraindicated in pregnancy according to the CDC (McLean, 2013). No malformations attributable to MMR vaccination in pregnancy have been reported, but pregnancy should be avoided for 30 days after mumps vaccination. The vaccine may be given to susceptible women postpartum, and breast feeding is not a contraindication.

Rubeola (Measles)

Measles is caused by a highly contagious RNA virus of the family Paramyxoviridae that only infects humans. Annual outbreaks occur in late winter and early spring, transmission is primarily by respiratory droplets, and the secondary attack rate among contacts exceeds 90 percent (Moss, 2012). Infection is characterized by fever, coryza, conjunctivitis, and cough. The characteristic erythematous maculopapular rash develops on the face and neck and then spreads to the back.
Koplik spots are small white lesions with surrounding erythema found within the oral cavity. Diagnosis is most commonly performed by serology, although RT-PCR tests are available. Treatment is supportive.

Pregnant women without evidence of measles immunity should be administered intravenous immune globulin (IVIG), 400 mg/kg within 6 days of a measles exposure (McLean, 2013). Active vaccination is not performed during pregnancy. However, susceptible women can be vaccinated routinely postpartum, and breast feeding is not contraindicated (Ohji, 2009).

The virus does not appear to be teratogenic (Siegel, 1973). However, an increased frequency of abortion, preterm delivery, and low-birthweight neonates is noted with maternal measles (American Academy of Pediatrics, 2006; Siegel, 1966). If a woman develops measles shortly before birth, there is considerable risk of serious infection developing in the neonate, especially in a preterm neonate.

Rubella—German Measles

This RNA togavirus typically causes infections of minor importance in the absence of pregnancy. Rubella infection in the first trimester, however, poses significant risk for abortion and severe congenital malformations. Transmission occurs via nasopharyngeal secretions, and the transmission rate is 80 percent to susceptible individuals. The peak incidence is late winter and spring.

Maternal rubella infection is usually a mild, febrile illness with a generalized maculopapular rash beginning on the face and spreading to the trunk and extremities. Other symptoms may include arthralgias or arthritis, head and neck lymphadenopathy, and conjunctivitis. The incubation period is 12 to 23 days. Viremia usually precedes clinical signs by about a week, and adults are infectious during viremia and through 5 to 7 days of the rash. Up to half of maternal infections are subclinical despite viremia that may cause devastating fetal infection (McLean, 2013; Zimmerman, 2012).

Diagnosis

Rubella may be isolated from the urine, blood, nasopharynx, and cerebrospinal fluid for up to 2 weeks after rash onset. The diagnosis is usually made, however, with serological analysis. Specific IgM antibody can be detected using enzyme-linked immunoassay from 4 to 5 days after onset of clinical disease, but it can persist for up to 6 weeks after appearance of the rash (Zimmerman, 2012). Importantly, rubella reinfection can give rise to transient low levels of IgM. Serum IgG antibody titers peak 1 to 2 weeks after rash onset. This rapid antibody response may complicate serodiagnosis unless samples are initially collected within a few days after the onset of the rash. If, for example, the first specimen was obtained 10 days after the rash, detection of IgG antibodies would fail to differentiate between very recent disease and preexisting immunity to rubella. IgG avidity testing is performed concomitant with the serological tests above. High-avidity IgG antibodies indicate an infection at least 2 months in the past.

Fetal Effects

Rubella is one of the most complete teratogens, and sequelae of fetal infection are worst during organogenesis (Adams Waldorf, 2013). Pregnant women with rubella infection and a rash during the first 12 weeks of gestation have a fetus with congenital infection in up to 90 percent of cases (Miller, 1982; Zimmerman, 2012). At 13 to 14 weeks’ gestation, this incidence was 54 percent,
and by the end of the second trimester, it was 25 percent. Defects are rare after 20 weeks (Miller, 1982). According to Reef and colleagues (2000), congenital rubella syndrome includes one or more of the following:

- Eye defects—cataracts and congenital glaucoma
- Congenital heart defects—patent ductus arteriosus and pulmonary artery stenosis
- Sensorineural deafness—the most common single defect
- Central nervous system defects—microcephaly, developmental delay, mental retardation, and meningoencephalitis
- Pigmentary retinopathy
- Neonatal purpura
- Hepatosplenomegaly and jaundice
- Radiolucent bone disease

Neonates born with congenital rubella may shed the virus for many months and thus be a threat to other infants and to susceptible adults who contact them.

The extended rubella syndrome, with progressive panencephalitis and type 1 diabetes, may not develop clinically until the second or third decade of life. As many as a third of neonates who are asymptomatic at birth may manifest such developmental injury (Webster, 1998).

Management and Prevention

There is no specific treatment for rubella. Droplet precautions for 7 days after the onset of the rash are recommended. Primary prevention relies on comprehensive vaccination programs (Coonrod, 2008). Although large epidemics of rubella have virtually disappeared in the United States because of immunization, up to 10 percent of women in the United States are susceptible (Zimmerman, 2012). Cluster outbreaks during the 1990s mainly involved persons born outside the United States, as congenital rubella is still common in developing nations (Banatvala, 2004; Reef, 2002).

To eradicate rubella and prevent congenital rubella syndrome completely, a comprehensive approach is recommended for immunizing the adult population (McLean, 2013). MMR vaccine should be offered to nonpregnant women of childbearing age who do not have evidence of immunity whenever they make contact with the health-care system. Vaccination of all susceptible hospital personnel who might be exposed to patients with rubella or who might have contact with pregnant women is important. Rubella vaccination should be avoided 1 month before or during pregnancy because the vaccine contains attenuated live virus. Although there is a small overall theoretical risk of up to 2.6 percent, there is no observed evidence that the vaccine induces malformations (Badilla, 2007; McLean, 2013). MMR vaccination is not an indication for pregnancy termination. Prenatal serological screening for rubella is indicated for all pregnant women. Women found to be nonimmune should be offered the MMR vaccine postpartum.

Despite native or vaccine-induced immunity, subclinical rubella maternal reinfection may develop during outbreaks. And although fetal infection can rarely occur, no adverse fetal effects have been described.

Respiratory Viruses

More than 200 antigenically distinct respiratory viruses cause the common cold, pharyngitis,
laryngitis, bronchitis, and pneumonia. Rhinovirus, coronavirus, and adenovirus are major causes of the common cold. The RNA-containing rhinovirus and coronavirus usually produce a trivial, self-limited illness characterized by rhinorrhea, sneezing, and congestion. The DNA-containing adenovirus is more likely to produce cough and lower respiratory tract involvement, including pneumonia.

Teratogenic effects of respiratory viruses are controversial. Women with a common cold had a four- to fivefold increased risk of fetal anencephaly in a 393-woman cohort in the Finnish Register of Congenital Malformations (Kurppa, 1991). In another population study, Shaw and coworkers (1998) analyzed California births from 1989 to 1991 and concluded that low attributable risks for neural-tube defects were associated with many illnesses in early pregnancy. Recently, amniotic fluid viral PCR studies were performed in 1191 women undergoing amniocentesis for fetal karyotyping. Viral PCR was positive in 6.5 percent, with adenovirus being the virus most frequently identified. There was an association with fetal-growth restriction, nonimmune hydrops, foot/hand abnormalities, and neural-tube defects (Adams, 2012).

Adenoviral infection is a known cause of childhood myocarditis. Towbin (1994) and Forsnes (1998) used PCR tests to identify and link adenovirus to fetal myocarditis and nonimmune hydrops.

**Hantaviruses**

These RNA viruses are members of the family Bunyaviridae. They are associated with a rodent reservoir, and transmission involves inhalation of virus excreted in rodent urine and feces. An outbreak in the Western United States occurred in 1993 due to Sin Nombre virus. The resulting Hantavirus pulmonary syndrome was characterized by severe adult respiratory distress syndrome with a case-fatality rate of 30 to 40 percent (Peters, 2012). Several outbreaks since then have occurred, the most recent in 2012.

Hantaviruses are a heterogenous group of viruses with low and variable rates of transplacental transmission. Howard and associates (1999) reported the syndrome to cause maternal death, fetal demise, and preterm birth. They found no evidence of vertical transmission of the Sin Nombre virus. However, vertical transmission occurred inconsistently in association with hemorrhagic fever and renal syndrome caused by another Hantavirus species, the Hantaan virus.

**Enteroviruses**

These viruses are a major subgroup of RNA picornaviruses that include poliovirus, coxsackievirus, and echovirus. They are trophic for intestinal epithelium but can also cause widespread maternal, fetal, and neonatal infections that may include the central nervous system, skin, heart, and lungs. Most maternal infections are subclinical yet can be fatal to the fetus-neonate (Goldenberg, 2003; Tassin, 2014). Hepatitis A is an enterovirus that is discussed in Chapter 55 (p. 1089).

**Coxsackievirus**

Infections with coxsackievirus group A and B are usually asymptomatic. Symptomatic infections—usually with group B—include aseptic meningitis, polio-like illness, hand foot and mouth disease, rashes, respiratory disease, pleuritis, pericarditis, and myocarditis. No treatment or vaccination is available (Cohen, 2012). Coxsackievirus may be transmitted by maternal secretions to the fetus at delivery in up to half of mothers who seroconverted during pregnancy (Modlin, 1988). Transplacental passage has also been reported (Ornoy, 2006).
Congenital malformations may be increased slightly in pregnant women who had serological evidence of coxsackievirus (Brown, 1972). Viremia can cause fetal hepatitis, skin lesions, myocarditis, and encephalomyelitis, all of which may be fatal. Koro’lkova and colleagues (1989) have also described cardiac anomalies. There is evidence of increased low-birth-weight, preterm, and small-for-gestational-age newborns (Chen, 2010). Finally, a rare association between maternal coxsackievirus infection and insulin-dependent diabetes in offspring has been reported (Dahlquist, 1996; Hyoti, 1995; Viskari, 2012).

**Poliovirus**

Most of these highly contagious but rare infections are subclinical or mild. The virus is trophic for the central nervous system, and it can cause paralytic poliomyelitis (Cohen, 2012). Siegel (1955) demonstrated that pregnant women not only were more susceptible to polio but also had a higher death rate. Perinatal transmission has been observed, especially when maternal infection developed in the third trimester (Bates, 1955). Inactivated subcutaneous polio vaccine is recommended for susceptible pregnant women who must travel to endemic areas or are placed in other high-risk situations. Live oral polio vaccine has been used for mass vaccination during pregnancy without harmful fetal effects (Harjulehto, 1989).

**Parvovirus**

Human parvovirus B19 causes *erythema infectiosum*, or *fifth disease*. The B19 virus is a small, single-stranded DNA virus that replicates in rapidly proliferating cells such as erythroblast precursors (Brown, 2012). This can lead to anemia, which is its primary fetal effect. Only individuals with the erythrocyte globoside membrane P antigen are susceptible. In women with severe hemolytic anemia—for example, sickle-cell disease—parvovirus infection may cause an aplastic crisis.

The main mode of parvovirus transmission is respiratory or hand-to-mouth contact, and the infection is common in spring months. The maternal infection rate is highest in women with school-aged children and in day-care workers but not usually in schoolteachers. Viremia develops 4 to 14 days after exposure. By adulthood, only 40 percent of women are susceptible. The annual seroconversion rate is 1 to 2 percent but is greater than 10 percent during epidemic periods (Brown, 2012). Secondary attack rates approach 50 percent.

**Maternal Infection**

In 20 to 30 percent of adults, infection is asymptomatic. Fever, headache, and flu-like symptoms may begin in the last few days of the viremic phase. Several days later, a bright red rash with erythoderma affects the face and gives a slapped-cheek appearance. The rash becomes lace-like and spreads to the trunk and extremities. Adults often have milder rashes and develop symmetrical polyarthritis that may persist several weeks. There is no evidence that parvovirus infection is altered by pregnancy (Valeur-Jensen, 1999). With recovery, there is production of IgM antibody 7 to 10 days postinfection, and this persists for 3 to 4 months. Several days after IgM is produced, IgG antibody is detectable and persists for life with natural immunity.

**Fetal Infection**

There is vertical transmission to the fetus in up to a third of maternal parvovirus infections (Bonvicini, 2011; de Jong, 2011; Lamont, 2011a). Fetal infection has been associated with
abortion, nonimmune hydrops, and stillbirth (Enders, 2010; Lassen, 2012; McClure, 2009). In a review of 1089 cases of maternal B19 infection from nine studies, Crane (2002) reported an overall fetal loss rate of 10 percent. It was 15 percent for infections before 20 weeks but was only 2.3 percent after 20 weeks. Its role in later unexplained stillbirths is unclear because most data are from retrospective cohorts with incomplete maternal and fetal histological evaluations (Norbeck, 2002; Skjölddebrand-Sparre, 2000; Tolfvenstam, 2001). Currently, there are no data to support evaluating asymptomatic mothers and stillborn fetuses for parvovirus infection.

Parvovirus is the most frequent infectious cause of nonimmune hydrops in autopsied fetuses (Rogers, 1999). That said, this complication develops only in approximately 1 percent of infected women and usually is caused by infection in the first half of gestation (Crane, 2002; Enders, 2004; Puccetti, 2012).

Yaegashi (2000) has extensively investigated the development and pathophysiology of parvovirus B19 fetal hydrops. At least 85 percent of cases of fetal infection developed within 10 weeks of maternal infection, and the mean interval was 6 to 7 weeks. More than 80 percent of hydrops cases were found in the second trimester, with a mean gestational age of 22 to 23 weeks. The critical period for maternal infection leading to fetal hydrops was estimated to be between 13 and 16 weeks—coincidental with the period in which fetal hepatic hemopoiesis is greatest.

**Diagnosis and Management**

An algorithm for diagnosis of maternal parvoviral infection is illustrated in Figure 64-2. Diagnosis is generally made by maternal serological testing for specific IgG and IgM antibodies (Bonvicini, 2011; Butchko, 2004; Enders, 2006). Viral DNA may be detectable by PCR in maternal serum during the prodrome and persist for months to years after infection. Fetal infection is diagnosed by detection of B19 viral DNA in amniotic fluid or IgM antibodies in fetal serum obtained by cordocentesis (de Jong, 2011; Weiffenbach, 2012). Fetal and maternal viral loads do not predict fetal morbidity and mortality (de Haan, 2007).
Exposure to parvovirus B19

Clinical disease:
- rash, pruritus, headache, fever, pharyngitis,
arthralgias, myalgias, joint swelling, nausea,
anorexia, transient aplastic crisis

Nonimmune hydrops fetalis

Maternal serological testing:
parvovirus B19 IgM and IgG

IgG (+) IgM (-)  
Prior infection

Immuine; no further evaluation

IgG (-) IgM (-)  
Repeat test in 2–4 weeks

Not infected; no further evaluation

IgG (+/-) IgM (+)  
Recent parvovirus B19 infection

Targeted ultrasound +/- MCA velocimetry every 2 weeks for 10 weeks after exposure or infection

Sonographic evidence of fetal infection: hydrops fetalis, hepatomegaly, splenomegaly, placentomegaly, elevated MCA peak systolic velocity

Yes  
Cordocentesis for
CBC, reticulocyte count, parvovirus B19 RNA (PCR); consider intrauterine transfusion

No  
No further evaluation; notify pediatric service at delivery
Most cases of parvovirus-associated hydrops develop in the first 10 weeks after infection (Enders, 2004). Thus, serial sonography every 2 weeks should be performed in women with recent infection (see Fig. 64-2). Middle cerebral artery (MCA) Doppler interrogation can also be used to predict fetal anemia (Chap. 10, p. 221). Elevated peak systolic velocity values in the fetal MCA accurately predict fetal anemia (Chauvet, 2011; Cosmi, 2002; Delle Chiaie, 2001). Fetal blood sampling is warranted with hydrops to assess the degree of fetal anemia. Fetal myocarditis may induce hydrops with less severe anemia.

Depending on gestational age, fetal transfusion for hydrops may improve outcome in some cases (Enders, 2004; Schild, 1999; von Kaisenberg, 2001). Mortality rates as high as 30 percent have been reported in hydropic fetuses without transfusions. With transfusion, 94 percent of hydrops cases resolve within 6 to 12 weeks, and the overall mortality rate is < 10 percent. Most fetuses require only one transfusion because hemopoiesis resumes as infection resolves. The technique for fetal transfusion is described in Chapter 14 (p. 300).

**Long-Term Prognosis**

Reports describing neurodevelopmental outcomes in fetuses transfused for B19 infection-induced anemia are conflicting. Nagel and colleagues (2007) reviewed 25 transfusions in 24 hydropic fetuses. There was abnormal neurodevelopment in five of 16 survivors—32 percent—at 6 months to 8 years. Outcomes were not related to severity of fetal anemia or acidemia, and these investigators hypothesized that the infection itself induced cerebral damage. De Jong (2012) described long-term neurodevelopmental outcomes in 28 children treated with intrauterine transfusion. At a median age of 5 years, 11 percent had neurodevelopmental impairment. Conversely, Dembinski (2003) followed 20 children for a mean of 52 months after transfusion. They found no significant neurodevelopmental delay despite severe fetal anemia.

**Prevention**

There is currently no approved vaccine for human parvovirus B19, and there is no evidence that antiviral treatment prevents maternal or fetal infection (Broliden, 2006). Decisions to avoid higher-risk work settings are complex and require assessment of exposure risks. Pregnant women should be counseled that risks for infection approximate 5 percent for casual, infrequent contact; 20 percent for intense, prolonged work exposure such as for teachers; and 50 percent for close, frequent interaction such as in the home. Workers at day-care centers and schools need not avoid infected children because infectivity is greatest before clinical illness. Finally, infected children do not require isolation.

**Cytomegalovirus**

This ubiquitous DNA herpes virus eventually infects most humans. Cytomegalovirus (CMV) is the most common perinatal infection in the developed world. Specifically, some evidence of fetal infection is found in 0.2 to 2.5 percent of all neonates (Kenneson, 2007). The virus is secreted into all body fluids, and person-to-person contact with viral-laden saliva, semen, urine, blood, and nasopharyngeal and cervical secretions can transmit infection. The fetus may become infected by transplacental viremia, or the neonate is infected at delivery or during breast feeding. Moreover,
acquisition continues to accrue. Day-care centers, for example, are a frequent source, and by 2 to 3 years of age, many children have infected one another and may transmit infection to their parents (Demmler, 1991; Pass, 1991). Revello and coworkers (2008) reported that amniocentesis in women whose blood is positive for CMV DNA does not result in iatrogenic fetal transmission.

Up to 85 percent of women from lower socioeconomic backgrounds are seropositive by the time of pregnancy, whereas only half of women in higher income groups are immune. Following primary CMV infection, and in a manner similar to other herpes virus infections, the virus becomes latent with periodic reactivation characterized by viral shedding. This occurs despite high serum levels of anti-CMV IgG antibody. These antibodies do not prevent maternal recurrence reactivation, or reinfection, nor do they totally mitigate fetal or neonatal infection.

Women who are seronegative before pregnancy but who develop primary CMV infection during pregnancy are at greatest risk to have an infected fetus. It is estimated that 25 percent of congenital CMV infections in the United States are from primary maternal infection (Wang, 2011). Because most CMV infections are clinically silent, they are detected by seroconversion, and this may be as high as 1 to 7 percent (Hyde, 2010).

### Maternal Infection

Pregnancy does not increase the risk or severity of maternal CMV infection. Most infections are asymptomatic, but 10 to 15 percent of infected adults have a mononucleosis-like syndrome characterized by fever, pharyngitis, lymphadenopathy, and polyarthritis. Immunocompromised women may develop myocarditis, pneumonitis, hepatitis, retinitis, gastroenteritis, or meningoencephalitis. Nigro and associates (2003) reported that most women in a cohort with primary infection had elevated serum aminotransferases or lymphocytosis. Reactivation disease usually is asymptomatic, although viral shedding is common.

Primary maternal CMV infection is transmitted to the fetus in approximately 40 percent of cases and can cause severe morbidity (Fowler, 1992; Liesnard, 2000). In contrast, recurrent maternal infection infects the fetus in only 0.15 to 1 percent of cases. A review of nine studies of CMV vertical transmission rates reported first-trimester transmission in 36 percent, second-trimester in 40 percent, and third-trimester in 65 percent (Picone, 2013). Naturally acquired immunity during pregnancy results in a 70-percent risk reduction of congenital CMV infection in future pregnancies (Fowler, 2003). However, as noted earlier, maternal immunity does not prevent recurrences, and maternal antibodies do not prevent fetal infection. Also, some seropositive women can be reinfected with a different viral strain that can cause fetal infection and symptomatic congenital disease (Ross, 2011).

### Fetal Infection

When a newborn has apparent sequelae of in utero-acquired CMV infection, it is referred to as **symptomatic CMV infection**. Congenital infection is a syndrome that may include growth restriction, microcephaly, intracranial calcifications, chorioretinitis, mental and motor retardation, sensorineural deficits, hepatosplenomegaly, jaundice, hemolytic anemia, and thrombocytopenic purpura (Fig. 64-3). The pathogenesis of these outcomes has been reviewed by Cheeran and colleagues (2009). Of the estimated 40,000 infected neonates born each year, only 5 to 10 percent demonstrate this syndrome (Fowler, 1992). Thus, most infected infants are asymptomatic at birth, but some develop late-onset sequelae. They may include hearing loss, neurological deficits, chorioretinitis, psychomotor retardation, and learning disabilities.
FIGURE 64-3 Sagittal (A) and coronal (B) cranial sonograms from a neonate with congenital cytomegalovirus infection. The arrows indicate periventricular calcifications.

Prenatal Diagnosis
Routine prenatal CMV serological screening is currently not recommended. Pregnant women should be tested for CMV if they present with a mononucleosis-like illness or if congenital infection is suspected based on abnormal sonographic findings. Primary infection is diagnosed using CMV-specific IgG testing of paired acute and convalescent sera. CMV IgM does not accurately reflect timing of seroconversion because IgM antibody levels may be elevated for more than a year (Stagno, 1985). Moreover, CMV IgM may be found with reactivation disease or reinfection with a new strain. Thus, specific CMV IgG avidity testing is valuable in confirming primary CMV infection (Fig. 64-4). High anti-CMV IgG avidity indicates primary maternal infection > 6 months before testing (Kanengisser-Pines, 2009). Finally, viral culture may be useful, although a minimum of 21 days is required before culture findings are considered negative.
FIGURE 64-4 Algorithm for evaluation of suspected maternal primary cytomegalovirus (CMV) infection in pregnancy. EIA = enzyme immunoassay; IgG = immunoglobulin G; IgM = immunoglobulin M.

Several fetal abnormalities associated with CMV infection may be seen with sonography, computed tomography, or magnetic resonance imaging. In some cases, they are found at the time of routine prenatal sonographic screening, but in others they are part of a specific evaluation in
women with CMV infection. Findings include microcephaly, ventriculomegaly, and cerebral calcifications; ascites, hepatomegaly, splenomegaly, and hyperechoic bowel; hydrops; and oligohydramnios (Malinger, 2003). Abnormal sonographic findings seen in combination with positive findings in fetal blood or amnionic fluid are predictive of an approximate 75-percent risk of symptomatic congenital infection (Enders, 2001).

CMV nucleic acid amplification testing of amnionic fluid is considered the gold standard for the diagnosis of fetal infection. Sensitivities range from 70 to 99 percent and depend on amniocentesis timing (Nigro, 2005; Revello, 2004). Sensitivity is highest when amniocentesis is performed at least 6 weeks after maternal infection and after 21 weeks (Azam, 2001; Guerra, 2000). A negative amnionic fluid PCR does not exclude fetal infection and may need to be repeated if suspicion for fetal infection is high.

Management and Prevention
The management of the immunocompetent pregnant woman with primary or recurrent CMV is limited to symptomatic treatment. If recent primary CMV infection is confirmed, amnionic fluid analysis should be offered. Counseling regarding fetal outcome depends on the gestation age during which primary infection is documented. Even with the high infection rate with primary infection in the first half of pregnancy, most fetuses develop normally. However, pregnancy termination may be an option for some.

Kimberlin (2003) showed that intravenous ganciclovir administered for 6 weeks to neonates with symptomatic central nervous system disease prevents hearing deterioration at 6 months and possibly later. Conversely, antiviral chemotherapy given antepartum does not avert in utero CMV transmission. Passive immunization with CMV-specific hyperimmune globulin lowers the risk of congenital CMV infection when given to pregnant women with primary disease (Nigro, 2005, 2012; Visentin, 2012). Further clinical trials are necessary before this becomes standard treatment (McCarthy, 2011).

There is no CMV vaccine. Prevention of congenital infection relies on avoiding maternal primary infection, especially in early pregnancy. Basic measures such as good hygiene and hand washing have been promoted, particularly for women with toddlers in day-care settings (Fowler, 2000). Although there may be sexual transmission from infected partners, there are no data on the efficacy of preventive strategies.

BACTERIAL INFECTIONS

Group A Streptococcus
Infections caused by *Streptococcus pyogenes* are important in pregnant women. It is the most frequent bacterial cause of acute pharyngitis and is associated with several systemic and cutaneous infections. *S pyogenes* produces numerous toxins and enzymes responsible for the local and systemic toxicity associated with this organism. Pyrogenic exotoxin-producing strains are usually associated with severe disease (Mason, 2012; Wessels, 2012). In most cases, streptococcal pharyngitis, scarlet fever, and erysipelas are not life threatening. Treatment, usually with penicillin, is similar in pregnant and nonpregnant women (Shulman, 2012).

In the United States, *Streptococcus pyogenes* infrequently causes puerperal infection. Still, it remains the most common cause of severe maternal postpartum infection and death worldwide, and
the incidence of these infections is increasing (Deutscher, 2011; Hamilton, 2013; Mason, 2012; Wessels, 2012). Puerperal infections are discussed in detail in Chapter 37 (p. 682). The early 1990s saw the rise of streptococcal toxic shock syndrome, manifested by hypotension, fever, and evidence of multiorgan failure with associated bacteremia. The case-fatality rate approximates 30 percent, and morbidity and mortality rates are improved with early recognition. Treatment includes clindamycin or penicillin therapy and often surgical debridement (Hamilton, 2013). No vaccine for group A streptococcus is commercially available.

**Group B Streptococcus**

*Streptococcus agalactiae* is a group B organism that can be found to colonize the gastrointestinal and genitourinary tract in 20 to 30 percent of pregnant women. Throughout pregnancy, group B Streptococcus (GBS) is isolated in a transient, intermittent, or chronic fashion. Although the organism is most likely always present in these same women, their isolation is not always homologous.

**Maternal and Perinatal Infection**

The spectrum of maternal and fetal GBS ranges from asymptomatic colonization to septicemia. *Streptococcus agalactiae* has been implicated in adverse pregnancy outcomes, including preterm labor, prematurely ruptured membranes, clinical and subclinical chorioamnionitis, and fetal infections. GBS can also cause maternal bacteriuria, pyelonephritis, osteomyelitis, postpartum mastitis, and puerperal infections. It remains the leading infectious cause of morbidity and mortality among infants in the United States (Centers for Disease Control and Prevention, 2010; Schrag, 2003; Wessels, 2012).

Neonatal sepsis has received the most attention due to its devastating consequences and available effective preventative measures. Infection < 7 days after birth is defined as *early-onset disease* and is seen in 0.24/1000 live births (Centers for Disease Control and Prevention, 2013a). Many investigators use a threshold of < 72 hours of life as most compatible with intrapartum acquisition of disease (Pulver, 2009; Wendel, 2002). We and others have also encountered several unexpected intrapartum stillbirths from GBS infections. Tudela and associates (2012) recently reported that newborns with early-onset GBS infection often had clinical evidence of fetal infection during labor or at delivery.

In many neonates, septicemia involves signs of serious illness that usually develop within 6 to 12 hours of birth. These include respiratory distress, apnea, and hypotension. At the outset, therefore, neonatal infection must be differentiated from respiratory distress syndrome caused by insufficient surfactant production of the preterm neonate (Chap. 34, p. 653). The mortality rate with early-onset disease has declined to approximately 4 percent, and preterm newborns are disparately affected.

*Late-onset disease* caused by GBS is noted in 0.32 per 1000 live births and usually manifests as meningitis 1 week to 3 months after birth (Centers for Disease Control and Prevention, 2013a). The mortality rate, although appreciable, is less for late-onset meningitis than for early-onset sepsis. Unfortunately, it is not uncommon for surviving infants of both early- and late-onset disease to exhibit devastating neurological sequelae.

**Prophylaxis for Perinatal Infections**

As GBS neonatal infections evolved beginning in the 1970s and before widespread intrapartum
chemoprophylaxis, rates of early-onset sepsis ranged from 2 to 3 per 1000 live births. In 2002, the Centers for Disease Control and Prevention, the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics revised guidelines for perinatal prevention of GBS disease. They recommended universal rectovaginal culture screening for GBS at 35 to 37 weeks’ gestation followed by intrapartum antibiotic prophylaxis for women identified to be carriers. Subsequent to implementation of these guidelines, the incidence of early-onset GBS neonatal sepsis has decreased to 0.24 cases per 1000 live births by 2012 (Centers for Disease Control and Prevention, 2013a). These guidelines were updated for early-onset GBS infection in 2010. They expanded laboratory identification criteria for GBS; updated algorithms for screening and intrapartum chemoprophylaxis for women with preterm prematurely ruptured membranes, preterm labor, or penicillin allergy; and described new dosing for penicillin G chemoprophylaxis.

Thus, during the past three decades, several strategies have been proposed to prevent perinatal acquisition of GBS infections (Ohlsson, 2013). These strategies have not been compared in randomized trials and are either culture-based or risk-based guidelines as subsequently discussed.

**Culture-Based Prevention.** The 2010 Centers for Disease Control and Prevention GBS Guidelines recommend a culture-based approach as shown in Figure 64-5. Such a protocol was also adopted by the American College of Obstetricians and Gynecologists (2013c). This approach is designed to identify women who should be given intrapartum antimicrobial prophylaxis. Women are screened for GBS colonization at 35 to 37 weeks’ gestation, and intrapartum antimicrobials are given to women with rectovaginal GBS-positive cultures. Selective enrichment broth followed by subculture improves detection. In addition, more rapid techniques such as DNA probes and nucleic acid amplification tests are being developed (Chan, 2006; Helali, 2012). A previous sibling with GBS invasive disease and identification of GBS bacteriuria in the current pregnancy are also considered indications for prophylaxis.
Vaginal and rectal GBS screening cultures at 35–37 weeks' gestation for ALL pregnant women (unless patient had GBS bacteriuria during the current pregnancy or a previous infant with invasive GBS disease)

Intrapartum prophylaxis indicated
- Previous infant with invasive GBS disease
- GBS bacteriuria during current pregnancy
- Positive GBS screening culture during current pregnancy (unless a planned cesarean delivery, in the absence of labor or amnionic membrane rupture, is performed)
- Unknown GBS status (culture not done, incomplete, or results unknown) and any of the following:
  - Delivery at < 37 weeks' gestation
  - Amnionic membrane rupture \(\geq 18\) hours
  - Intrapartum temperature \(\geq 100.4^\circ F (\geq 38.0^\circ C)\)
  - Intrapartum nucleic acid amplification test (NAAT) positive for GBS

Intrapartum prophylaxis not indicated
- Previous pregnancy with a positive GBS screening culture (unless a culture was also positive during the current pregnancy)
- Planned cesarean delivery performed in the absence of labor or membrane rupture (regardless of maternal GBS culture status)
- Negative vaginal and rectal GBS screening culture in late gestation during the current pregnancy, regardless of intrapartum risk factors
FIGURE 64-5 Indications for intrapartum prophylaxis to prevent perinatal group B streptococcal (GBS) disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures obtained at 35 to 37 weeks’ gestation. (From Centers for Disease Control and Prevention, 2010.)

**Risk-Based Prevention.** A risk-based approach is recommended for women in labor and whose GBS culture results are not known. This approach relies on risk factors associated with intrapartum GBS transmission. Intrapartum chemoprophylaxis is given to women who have any of the following: delivery < 37 weeks, ruptured membranes ≥ 18 hours, or intrapartum temperature ≥ 100.4°F (≥ 38.0°C). Women with GBS during the current pregnancy and women with a prior infant with invasive early-onset GBS disease are also given chemoprophylaxis.

At Parkland Hospital in 1995—and prior to consensus guidelines—we adopted the risk-based approach for intrapartum treatment of women at high risk. In addition, all term neonates who were not given intrapartum prophylaxis were treated in the delivery room with aqueous penicillin G, 50,000 to 60,000 units intramuscularly. Rates of early-onset GBS infection and sepsis and of non-GBS sepsis decreased to 0.4–0.66 per 1000 live births (Wendel, 2002). Non-GBS early-onset sepsis was identified in 0.24 per 1000 live births, and this was stable during the past two decades (Stafford, 2012). Thus, this approach has results similar to those reported by the Centers for Disease Control and Prevention (2010) for culture-based prevention.

**Intrapartum Antimicrobial Prophylaxis**

Prophylaxis administered 4 or more hours before delivery is highly effective (Fairlie, 2013). Regardless of screening method, penicillin remains the first-line agent for prophylaxis, and ampicillin is an acceptable alternative (Table 64-3). Women with a penicillin allergy and no history of anaphylaxis should be given cefazolin. Those at high risk for anaphylaxis should have antimicrobial susceptibility testing performed to exclude clindamycin resistance. Clindamycin-sensitive but erythromycin-resistant isolates should have a D-zone test performed to assess for inducible clindamycin resistance. If clindamycin resistance is confirmed, vancomycin should be administered. *Erythromycin is no longer used for penicillin-allergic patients.*

---

**TABLE 64-3. Regimens for Intrapartum Antimicrobial Prophylaxis for Perinatal GBS Disease**

---
Further recommendations for management of spontaneous preterm labor, threatened preterm delivery, or preterm prematurely ruptured membranes are shown in Figure 64-6. Women undergoing cesarean delivery before labor onset with intact membranes do not need intrapartum GBS chemoprophylaxis, regardless of GBS colonization status or gestational age.

This algorithm is not an exclusive course of management, and variations that incorporate individual circumstances or institutional preferences may be appropriate. IV = intravenous. (Adapted from Centers for Disease Control and Prevention, 2010.)

**Methicillin-Resistant *Staphylococcus Aureus***

*Staphylococcus aureus* is a pyogenic gram-positive organism and is considered the most virulent of the staphylococcal species. It primarily colonizes the nares, skin, genital tissues, and oropharynx. Approximately 20 percent of normal individuals are persistent carriers, 30 to 60 percent are intermittent carriers, and 20 to 50 percent are noncarriers (Gorwitz, 2008). Colonization is considered the greatest risk factor for infection (Sheffield, 2013). Methicillin-resistant *S aureus* (MRSA) colonizes only 2 percent of people but is a significant contributor to the health-care burden (Gorwitz, 2008). MRSA infections are associated with increased cost and higher mortality rates compared with those by methicillin-sensitive *S aureus* (MSSA) (Beigi 2009; Butterly, 2010; Kleven, 2007).
Community-associated MRSA (CA-MRSA) is diagnosed when identified in an outpatient setting or within 48 hours of hospitalization in a person without traditional risk factors. The latter include prior MRSA infection, hospitalization, dialysis or surgery within the past year, and indwelling catheters or devices. Hospital-associated MRSA (HA-MRSA) infections are nosocomial. Most cases of MRSA in pregnant women are CA-MRSA.

**MRSA and Pregnancy**

Anovaginal colonization with *S. aureus* is identified in 10 to 25 percent of obstetrical patients (Andrews, 2008; Creech, 2010; Top, 2010). MRSA has been isolated in 0.5 to 3.5 percent of these women. Skin and soft tissue infections are the most common presentation of MRSA in pregnant women (Fig. 64-7). Mastitis has been reported in up to a fourth of cases of MRSA complicating pregnancy (Laibl, 2005; Lee, 2010; Reddy, 2007). Perineal abscesses, wound infections at sites such as abdominal and episiotomy incisions, and chorioamnionitis are also associated with MRSA (Lareau, 2010; Pimentel, 2009; Rotas, 2007; Thurman, 2008). An increase in CA-MRSA infections has been reported in neonatal intensive care units and newborn nurseries. In these settings, infection is frequently associated with maternal and health-care worker MRSA skin infections and infected breast milk. Vertical transmission appears to be rare (Huang, 2009; Jimenez-Truque, 2012; Pinter, 2009).

**FIGURE 64-7** Typical presentation of a skin lesion caused by infection with community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA). Patients often present with what they describe as an infected spider bite.

**Management**

The Infectious Diseases Society of America has published guidelines for the treatment of MRSA infections (Liu, 2011). Uncomplicated superficial infections are managed by drainage and local wound care. The benefits of antibiotic treatment in this setting are unproven, and most studies have
not shown improved outcomes with the addition of MRSA-appropriate antibiotics (Forcade, 2012; Laibl, 2005). Severe superficial infections, especially those that fail to respond to local care or those in patients with medical comorbidities, should be treated with MRSA-appropriate antibiotics. Purulent cellulitis should be treated empirically for CA-MRSA until culture results are available.

Most CA-MRSA strains are sensitive to trimethoprim-sulfamethoxazole. If clindamycin treatment is considered, inducible resistance must be excluded by a D-zone test for erythromycin-resistant, clindamycin-sensitive isolates. Rifampin rapidly develops resistance and should not be used for monotherapy. Linezolid, although effective against MRSA, is expensive, and there is little information regarding its use in pregnancy. Doxycycline, minocycline, and tetracycline, although effective for MRSA infections, should not be used in pregnancy. Vancomycin remains the first-line therapy for inpatient MRSA infections.

The control and prevention of HA-MRSA and CA-MRSA rely on appropriate hand hygiene an prevention of skin-to-skin contact or contact with wound dressings. Decolonization should be considered only in cases in which a patient develops recurrent superficial infections despite optimal hygiene measures or if ongoing transmission occurs among household or close contacts (Liu, 2011). Decolonization measures include nasal treatment with mupirocin, chlorhexidine gluconate baths, and oral rifampin therapy. Routine decolonization has not been shown to be effective in the obstetrical population. For women with culture-proven CA-MRSA infection during pregnancy, we add single-dose vancomycin to routine β-lactam perioperative prophylaxis for cesarean deliveries and fourth-degree perineal lacerations. Breast feeding in these women is not prohibited, but optimal hygiene and attention to minor skin breaks is encouraged.

### Vulvar Abscess

Labia majora infections, which begin as cellulitis, have the potential for significant expansion and abscess formation. Risk factors include diabetes, obesity, perineal shaving, and immunosuppression. For early cellulitis, sitz baths and oral antibiotics are reasonable treatment. If present, a small abscess can be incised and drained, wound cultures obtained, abscess cavity packed, and surrounding cellulitis treated with oral antibiotics. These infections are typically polymicrobial, and suitable broad-spectrum antimicrobials are given along with coverage for MRSA (Thurman, 2008). For severe infections, especially in immunosuppressed or pregnant patients, hospitalization and intravenous antimicrobial therapy are often warranted due to increased risks for necrotizing fasciitis. Large abscesses are best drained in the operating room with adequate analgesia or anesthesia.

Cysts of the Bartholin gland duct are usually unilateral, sterile, and need no treatment during pregnancy. If a cyst is sufficiently large to obstruct delivery, then needle aspiration is an appropriate temporary measure. With gland duct infection, a localized unilateral vulvar bulge, tenderness, and erythema are present. Treatment is given with broad-spectrum antimicrobials, and drainage is established. In addition to obtaining wound cultures, testing is done for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. For a small abscess, incision and placement of a Word catheter may be suitable. For larger abscesses with extensive cellulitis, drainage is best performed in the operating room. In these cases, the incised edges of the abscess cavity may be marsupialized.

Occasionally, abscesses of the periurethral glands develop. The largest of these, the Skene gland, may require drainage and broad-spectrum antimicrobial treatment if there is suppuration.
Listeriosis

*Listeria monocytogenes* is an uncommon but probably underdiagnosed cause of neonatal sepsis. This facultative intracellular gram-positive bacillus can be isolated from the feces of 1 to 5 percent of adults. Nearly all cases of listeriosis are thought to be food-borne (Silk, 2013). Outbreaks have been caused by raw vegetables, coleslaw, apple cider, melons, milk, fresh Mexican-style cheese, smoked fish, and processed foods, such as pâté, hummus, wiener, and sliced deli meats (Cartwright, 2013; Centers for Disease Control and Prevention, 2013i; Janakiraman, 2008; Varma, 2007; Voetsch, 2007).

Listerial infections are more common in the very old or young, pregnant women, and immunocompromised patients. The incidence of such infections appears to be increasing in several countries worldwide (Allenberger, 2010; Cartwright, 2013; Goulet, 2012). In 1651 cases reported in 2009 to 2011, the Centers for Disease Control and Prevention found that 14 percent were in pregnant women (Silk, 2013). And in a recent review, pregnant women had a significantly higher rate for listeriosis compared with nonpregnant reproductive-aged women (Pouillot, 2012). It is unclear why pregnant women still account for a significant number of these reported cases. One hypothesis is that pregnant women are susceptible because of decreased cell-mediated immunity (Baud, 2011; Jamieson, 2006b; Wing, 2002). Another is that placental trophoblasts are susceptible to invasion by *Listeria monocytogenes* (Le Monnier, 2007).

Maternal and Fetal Infection

Listeriosis during pregnancy may be asymptomatic or may cause a febrile illness that is confused with influenza, pyelonephritis, or meningitis (Centers for Disease Control and Prevention, 2013i; Mylonakis, 2002). The diagnosis usually is not apparent until blood cultures are reported as positive. Occult or clinical infection also may stimulate labor (Boucher, 1986). Discolored, brownish, or meconium-stained amniotic fluid is common with fetal infection, even preterm gestations.

In 2011, a listerial outbreak associated with cantaloupes resulted in 147 infected individuals (Centers for Disease Control and Prevention, 2012b). Seven of these infections were related to pregnancy—four in pregnant women and three in newborns. Maternal listeriosis causes fetal infection that characteristically produces disseminated granulomatous lesions with microabscesses (Topalovski, 1993). Chorioamnionitis is common with maternal infection, and placental lesions include multiple, well-demarcated macroabscesses. Early- and late-onset neonatal infections are similar to GBS sepsis. In a review of 222 cases by Mylonakis (2002), infection resulted in abortion or stillbirth in 20 percent, and neonatal sepsis developed in 68 percent of surviving newborns. Voetsch (2007) detailed similar findings. A stillbirth caused by listeriosis is shown in Figure 64-8.
Treatment with ampicillin plus gentamicin is usually recommended because of synergism against *Listeria* species. Trimethoprim-sulfamethoxazole can be given to penicillin-allergic women. Maternal treatment in most cases is also effective for fetal infection (Chan, 2013). No vaccine is available, and prevention is by washing raw vegetables and cooking all raw food (Goulet, 2012; Silk, 2012). Pregnant women should also avoid the implicated foods listed previously.
Salmonellosis

Infections from *Salmonella* species continue to be a major and increasing cause of food-borne illness (Peques, 2012). Six serotypes account for most cases in the United States, including *Salmonella* subtypes *typhimurium* and *enteritidis*. Non-typhoid *Salmonella* gastroenteritis is contracted through contaminated food. Symptoms including nonbloody diarrhea, abdominal pain, fever, chills, nausea, and vomiting begin 6 to 48 hours after exposure. Diagnosis is made by stool studies. Intravenous crystalloid is given for rehydration. Antimicrobials are not given in uncomplicated infections because they do not commonly shorten illness and may prolong the convalescent carrier state. If gastroenteritis is complicated by bacteremia, antimicrobials are given as discussed below. Rare case reports have linked *Salmonella* bacteremia with abortion (Coughlin, 2002).

Typhoid fever caused by *Salmonella typhi* remains a global health problem, although it is uncommon in the United States. Infection is spread by oral ingestion of contaminated food, water, or milk. In pregnant women, the disease is more likely to be encountered during epidemics or in those with HIV infection (Hedriana, 1995). In former years, antepartum typhoid fever resulted in abortion, preterm labor, and maternal or fetal death (Dildy, 1990).

Fluoroquinolones and third-generation cephalosporins are the preferred treatment. For enteric (typhoid) fever, antimicrobial susceptibility testing is important because of the development of drug-resistant strains (Peques, 2012). Typhoid vaccines appear to exert no harmful effects when administered to pregnant women and should be given in an epidemic or before travel to endemic areas.

Shigellosis

Bacillary dysentery caused by *Shigella* is a relatively common, highly contagious cause of inflammatory exudative diarrhea in adults. Shigellosis is more common in children attending day-care centers and is transmitted via the fecal-oral route. Clinical manifestations range from mild diarrhea to severe dysentery, bloody stools, abdominal cramping, tenesmus, fever, and systemic toxicity.

Although shigellosis may be self-limited, careful attention to treatment of dehydration is essential in severe cases. We have cared for pregnant women in whom secretory diarrhea exceeded 10 L/day! Antimicrobial therapy is imperative, and effective treatment during pregnancy includes fluoroquinolones, ceftriaxone, or azithromycin. Antimicrobial resistance is rapidly emerging, and antibiotic susceptibility testing can help guide appropriate therapy (Centers for Disease Control and Prevention, 2013c).

Hansen Disease

Also known as leprosy, this chronic infection is caused by *Mycobacterium leprae* and is rare in the United States (United States Department of Health and Human Services, 2011). Diagnosis is confirmed by PCR. Multidrug therapy with dapsone, rifampin, and clofazimine is recommended for treatment and is generally safe during pregnancy (Britton, 2004). Duncan (1980) reported an excessive incidence of low-birthweight newborns among infected women. The placenta is not involved, and neonatal infection apparently is acquired from skin-to-skin or droplet transmission (Böddinghaus, 2007; Duncan, 1984). Vertical transmission is common in untreated mothers (Moschella, 2004).
**Lyme Disease**

Caused by the spirochete *Borrelia burgdorferi*, Lyme disease is the most commonly reported vector-borne illness in the United States (Centers for Disease Control and Prevention, 2012c). Lyme borreliosis follows tick bites of the genus *Ixodes*. Early infection causes a distinctive local skin lesion, *erythema migrans*, which may be accompanied by a flu-like syndrome and regional adenopathy. If untreated, disseminated infection follows in days to weeks. Multisystem involvement is frequent, but skin lesions, arthralgia and myalgia, carditis, and meningitis predominate. If still untreated after several weeks to months, late or persistent infection manifests in perhaps half of patients. Native immunity is acquired, and the disease enters a chronic phase. Although some patients remain asymptomatic, others in the chronic phase develop various skin, joint, or neurological manifestations (Wormser, 2006). Although relapses were initially considered common, recent clinical and epidemiological evidence suggests that most cases of recurrent erythema migrans occurring after appropriate antimicrobial therapy are actually new infections (Nadelman, 2012).

Clinical diagnosis is important because serological and PCR testing has many pitfalls (Schoen, 2013). IgM and IgG serological testing is recommended in early infection and is followed by Western blotting for confirmation. Ideally, acute and convalescent serological evaluation is completed if possible. The false-positive and -negative rates are high, and more accurate tests are being developed (Radolf, 2012; Schoen, 2013; Steere, 2012).

**Treatment and Prevention**

Optimal treatment of Lyme disease was reviewed by Wormser (2006) for the Infectious Diseases Society of America. For early infection, treatment with doxycycline, amoxicillin, or cefuroxime is recommended for 14 days, although doxycycline is usually avoided in pregnancy. A 14- to 28-day course of IV ceftriaxone, cefotaxime, or penicillin G is given for complicated early infections that include meningitis, carditis, or disseminated infections. Chronic arthritis and post-Lyme disease syndrome are treated with prolonged oral or IV regimens, however, symptoms respond poorly to treatment (Steere, 2012).

No vaccine is commercially available. Avoiding areas with endemic Lyme disease and improving tick control in those areas is the most effective prevention. Self-examination with removal of unengorged ticks within 36 hours of attachment reduces infection risk (Hayes, 2003). For tick bites recognized within 72 hours, a single 200-mg oral dose of doxycycline may reduce infection development.

There are several reports of Lyme disease in pregnancy, although large series are lacking. Transplacental transmission has been confirmed, but no congenital effects of maternal borreliosis have been conclusively identified (Elliott, 2001; Maraspin, 2011; Walsh, 2006). Prompt treatment of maternal early infection should prevent most adverse pregnancy outcomes (Mylonas, 2011).

**Tuberculosis**

Diagnosis and management of tuberculosis during pregnancy is discussed in detail in Chapter 51 (p. 1019).

**PROTOZOAL INFECTIONS**
Toxoplasmosis

The obligate intracellular parasite *Toxoplasma gondii* has a life cycle with two distinct stages (Kim, 2012). The *feline* stage takes place in the cat—the definitive host—and its prey. Unsporulated oocysts are secreted in feces. In the *nonfeline* stage, tissue cysts containing bradyzoites or oocysts are ingested by the intermediate host, including humans. Gastric acid digests the cysts to release bradyzoites, which infect small-intestinal epithelium. Here, they are transformed into rapidly dividing tachyzoites, which can infect all cells within the host mammal. Humoral and cell-mediated immune defenses eliminate most of these, but tissue cysts develop. Their lifelong persistence is the chronic form of toxoplasmosis.

Human infection is acquired by eating raw or undercooked meat infected with tissue cysts or by contact with oocysts from cat feces in contaminated litter, soil, or water. Prior infection is confirmed by serological testing, and its prevalence depends on geographic locale and parasite genotype. In the United States, there is a 5 to 30 percent seroprevalence in persons aged 10 to 15 years, and this can exceed 60 percent after age 50 (Kim, 2012). Thus, a significant segment of pregnant women in this country are susceptible to infection. The incidence of prenatal infection resulting in birth of a newborn with congenital toxoplasmosis has been estimated to vary from 0.8 per 10,000 live births in the United States to 10 per 10,000 in France (Dubey, 2000). Between 400 and 4000 cases of congenital toxoplasmosis are diagnosed annually in the United States. Globally, it is estimated that a third of the population has been exposed to this parasite (Verma, 2012).

**Maternal and Fetal Infection**

Most acute maternal infections in Europe and North America are subclinical and are detected only by prenatal or newborn serological screening. In some cases, maternal symptoms may include fatigue, fever, headache, muscle pain, and sometimes a maculopapular rash and posterior cervical lymphadenopathy. In immunocompetent adults, initial infection confers immunity, and prepregnancy infection nearly eliminates any risk of vertical transmission. Infection in immunocompromised women, however, may be severe, and reactivation may cause encephalitis, retinochoroiditis, or mass lesions. Maternal infection is associated with a fourfold increased preterm delivery rate before 37 weeks (Freeman, 2005). Even so, growth restriction is not increased. Toxoplasmosis serotype NE-II is most commonly associated with preterm birth and severe neonatal infection (McLeod, 2012).

The incidence and severity of fetal toxoplasmosis infection depend on gestational age at the time of maternal infection. Risks for fetal infection increase with pregnancy duration (Fig. 64-9). A metaanalysis estimated the risk to be 15 percent at 13 weeks, 44 percent at 26 weeks, and 71 percent at 36 weeks (SYROCOT Study Group, 2007). Conversely, the severity of fetal infection is much greater in early pregnancy, and these fetuses are much more likely to have clinical findings of infection.
Importantly, most infected fetuses are born without obvious stigmata of toxoplasmosis. Clinically affected neonates usually have generalized disease expressed as low birthweight, hepatosplenomegaly, jaundice, and anemia. Some primarily have neurological disease with intracranial calcifications and with hydrocephaly or microcephaly. Many eventually develop chorioretinitis and exhibit learning disabilities. This classic triad—chorioretinitis, intracranial calcifications, and hydrocephalus—is often accompanied by convulsions. Infected neonates with clinical signs are at risk for long-term complications.

**Screening and Diagnosis**

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) do not recommend prenatal screening for toxoplasmosis in areas of low prevalence, including the United States. In areas of high toxoplasmosis prevalence—for example, France and Austria—routine screening has resulted in diminished congenital disease (Wallon, 2013). With IgG antibody confirmed before pregnancy, there is no risk for a congenitally infected fetus (Montoya, 2004). Screening should be performed in immunocompromised pregnant women, regardless of country of residence.

Pregnant women suspected of having toxoplasmosis should be tested. The parasite is rarely detected in tissue or body fluids. Anti-toxoplasma IgG develops within 2 to 3 weeks after infection, peaks at 1 to 2 months, and usually persists for life—sometimes in high titers. Although IgM antibodies appear by 10 days after infection and usually become negative within 3 to 4 months, they may remain detectable for years. Thus, IgM antibodies should not be used alone to diagnose acute toxoplasmosis. IgA and IgE antibodies are also useful in diagnosing acute infection. Best results are obtained with the Toxoplasma Serologic Profile performed at the Palo Alto Medical Foundation Research Institute (www.toxolab@pamf.org). Toxoplasma IgG avidity
increases with time. Thus, if a high-avidity IgG result is found, infection in the preceding 3 to 5 months is excluded. Multiple commercial avidity tests are now available that provide a 100-percent positive-predictive value of high avidity confirming latent infection (Villard, 2013). PCR testing has a high sensitivity and specificity.

Prenatal diagnosis of toxoplasmosis is performed using DNA amplification techniques and sonographic evaluation. PCR of amniotic fluid or fetal blood has improved sensitivity compared with standard isolation techniques (Sterkers, 2012). The sensitivity varies with gestational age, and it is lowest at < 18 weeks (Montoya, 2008). Sonographic evidence of intracranial calcifications, hydrocephaly, liver calcifications, ascites, placental thickening, hyperechoic bowel, and growth restriction has been used prenatally to help confirm diagnosis.

Management
No randomized clinical trials have been performed to assess the benefit and efficacy of treatment to decrease the risk for congenital infection. A systematic review of data from 1438 treated pregnancies found weak evidence for early treatment to reduce congenital toxoplasmosis risks (SYROCOT Study Group, 2007). Treatment has been associated with a reduction in rates of serious neurological sequelae and neonatal demise (Cortina-Borja, 2010).

Prenatal treatment is based on two regimens—spiramycin alone or a pyrimethamine–sulfonamide combination with folinic acid. These two regimens have also been used consecutively (Hotop, 2012). Little evidence supports the use of a specific regimen. That said, most experts will use spiramycin in women with acute infection early in pregnancy. Pyrimethamine–sulfadiazine with folinic acid is selected for maternal infection after 18 weeks or if fetal infection is suspected.

Prevention
There is no vaccine for toxoplasmosis, so avoidance of infection is necessary if congenital infection is to be prevented. Efforts include: (1) cooking meat to safe temperatures; (2) peeling or thoroughly washing fruits and vegetables; (3) cleaning all food preparation surfaces and utensils that have contacted raw meat, poultry, seafood, or unwashed fruits and vegetables; (4) wearing gloves when changing cat litter, or else delegating this duty; and (5) avoiding feeding cats raw or undercooked meat and keeping cats indoors. Although these preventive steps are recommended, there are no data to support their effectiveness (Di Mario, 2009). Vaccine development is actively being pursued (Verma, 2012).

Malaria
Malaria remains a global health crisis. In 2010, there were an estimated 219 million cases and 655,000 deaths, mainly in sub-Saharan Africa (Chico, 2012; World Health Organization, 2011). Malaria has been effectively eradicated in Europe and in most of North America, and worldwide mortality rates have fallen more than 25 percent. In the United States, most cases of malaria are imported—some in returning military personnel (Centers for Disease Control and Prevention 2013j). Transmitted by infected *Anopheles* mosquitoes, five species of *Plasmodium* cause human disease—*falciparum, vivax, ovale, malariae*, and *knowlesi* (White, 2012).

Maternal and Fetal Infection
Clinical findings are fever, chills, and flu-like symptoms including headaches, myalgia, and malaise, which may occur at intervals. Symptoms are less severe with recurrences. Malaria may
be associated with anemia and jaundice, and *falciparum* infections may cause kidney failure, coma, and death. That said, many otherwise healthy but infected adults in endemic areas are asymptomatic. Pregnant women, although often asymptomatic, are said to be more likely to develop traditional symptoms (Desai, 2007).

Malarial infections during pregnancy—whether symptomatic or asymptomatic—are associated with increased rates of perinatal morbidity and mortality (Menéndez, 2007; Nosten, 2007; Rogerson, 2007). Adverse outcomes include stillbirth, preterm birth, low birthweight, and maternal anemia. The latter two are documented most frequently (Machado Filho, 2014; McClure, 2013). Maternal infection is associated with 14 percent of low-birthweight newborns worldwide (Eisele, 2012). These adverse perinatal outcomes correlate with high levels of placental parasitemia (Rogerson, 2007). The latter occurs when parasitized erythrocytes, monocytes, and macrophages accumulate in the vascular areas of the placenta (Fig. 64-10). Infections with *P. falciparum* are the worst, and early infection increases the risk for abortion (Desai, 2007). The incidence of malaria increases significantly in the latter two trimesters and postpartum (Diagne, 2000). Overall, congenital malaria occurs in < 5 percent of neonates born to infected mothers.
FIGURE 64-10 Photomicrograph of placental malaria. **A.** Multiple infected red blood cells (*long black arrow*) are seen in the intervillous space of this placenta. Multiple villi cut in cross section are shown, and three are highlighted (*short arrows*). **B.** Increased magnification of image (A). Multiple infected erythrocytes are seen, and two are identified (*arrows*).

**Diagnosis**
Identification of parasites by microscopical evaluation of a thick and thin blood smear remains the gold standard for diagnosis. In women with low parasite densities, however, the sensitivity of microscopy is poor. Malaria-specific antigens are now being used for rapid diagnostic testing. Not only is their sensitivity still an issue in pregnancy, but these tests are not routinely available (Fowkes, 2012; Kashif, 2013; White, 2012).
Management

The most frequently used antimalarial drugs are not contraindicated in pregnancy. The World Health Organization recommends all infected patients living in or traveling from endemic areas be treated with an artemisinin-based regimen for uncomplicated falciparum malaria. Little is known about these regimens in pregnancy (Mutabinqwa, 2013). The Centers for Disease Control and Prevention (2013g) recommends using atovaquone-proguanil or artemether-lumefantrine only if other treatment options are not available or tolerated.

The Centers for Disease Control and Prevention (2013g) recommends that pregnant women diagnosed with uncomplicated malaria caused by \textit{P. vivax}, \textit{P. malariae}, \textit{P. ovale}, and chloroquine-sensitive \textit{P. falciparum} should be treated with chloroquine or hydroxychloroquine. For women infected with chloroquine-resistant \textit{P. falciparum}, mefloquine or quinine sulfate with clindamycin should be used. Chloroquine-resistant \textit{P. vivax} should be treated with mefloquine. Chloroquine-sensitive \textit{P. vivax} or \textit{P. ovale} should be treated with chloroquine throughout pregnancy and then primaquine postpartum. Treatment regimens for uncomplicated and severe malarial infections in pregnancy are detailed at: \url{www.cdc.gov/malaria/diagnosis_treatment/clinicians3.html}. The CDC also maintains a malaria hotline for treatment recommendations (770-488-7788).

The World Health Organization (2011) allows for the use of intermittent preventative therapy during pregnancy. This consists of at least two treatment doses of sulfadoxine-pyrimethamine in the second and third trimesters. The rationale is that each dose will clear placental asymptomatic infections and provide up to 6 weeks of posttreatment prophylaxis. This ideally will decrease the rate of low-birthweight newborns in endemic areas (Harrington, 2013). A recent metaanalysis supported the use of at least three doses of intermittent preventative therapy to improve birthweight and decrease placental and maternal malarial infection at delivery (Kayentao, 2013).

Resistance to all the antimalarial drugs has been reported, including the recently added artemisinin. The World Health Organization recommends routine monitoring of antimalarial drug resistance and tailoring medication regimens.

Prevention and Chemoprophylaxis

Malaria control and prevention relies on chemoprophylaxis when traveling to or living in endemic areas. Vector control is also important. Insecticide-treated netting, pyrethroid insecticides, and \textit{N,N-diethyl-m-toluamide} (DEET)-based insect repellent decrease malarial rates in endemic areas. These are well tolerated in pregnancy (Menéndez, 2007). If travel is necessary, chemoprophylaxis is recommended.

Chloroquine and hydroxychloroquine prophylaxis is safe and well tolerated in pregnancy. It decreases placental infection from 20 percent to 4 percent in asymptomatic infected women in areas without chloroquine resistance (Cot, 1992). For travelers to areas with chloroquine-resistant \textit{P. falciparum}, mefloquine remains the only chemoprophylaxis recommended. Primaquine and doxycycline are contraindicated in pregnancy, and there are insufficient data on atovaquone-proguanil to recommend them at this time. Likewise, amodiaquine is used in Africa, but data are limited in pregnant women. The latest chemoprophylaxis regimens for pregnancy can be obtained from the Centers for Disease Control and PreventionTravelers’ Health website at: \url{http://www.cdc.gov/travel}. The Centers also publish \textit{Health Information for International Travel} (The Yellow Book) at: \url{www.cdc.gov/yellowbook}.

Amebiasis

Most persons infected with *Entamoeba histolytica* are asymptomatic. Amebic dysentery, however, may take a fulminant course during pregnancy, with fever, abdominal pain, and bloody stools. Prognosis is worse if complicated by a hepatic abscess. Diagnosis is made by identifying *E. histolytica* cysts or trophozoites within a stool sample. Therapy is similar to that for the nonpregnant woman, and metronidazole or tinidazole is the preferred drug for amebic colitis and invasive disease. Noninvasive infections may be treated with paromomycin (Stanley, 2012).

**MYCOTIC INFECTIONS**

Disseminated fungal infection—usually pneumonitis—during pregnancy is uncommon with coccidiomycosis, blastomycosis, cryptococcosis, or histoplasmosis. Their identification and management are considered in Chapter 51 (p. 1019).

**EMERGING INFECTIONS**

These are collectively defined as infectious diseases that have newly appeared or increased in incidence or geographic spread (Jamieson, 2006a,b; Theiler, 2008). At this time, emerging infections include West Nile virus, coronavirus, and several influenza A strains. They also include many bioterrorism agents.

### West Nile Virus

This mosquito-borne RNA flavivirus is a human neuropathogen. Since 1999, the reported numbers of human and animal infections have increased, and the geographical range of disease activity has expanded. The year 2012 was the second worst outbreak of total cases in the United States (Centers for Disease Control and Prevention, 2013b). West Nile viral infections are typically acquired through mosquito bites in late summer or perhaps through blood transfusion (Harrington, 2003). The incubation period is 2 to 14 days, and most persons have mild or no symptoms. Fewer than 1 percent of infected adults develop meningoencephalitis or acute flaccid paralysis (Granwehr, 2004). Presenting symptoms may include fever, mental status changes, muscle weakness, and coma (Chapa, 2003; Stewart, 2013).

Diagnosis of West Nile infection is based on clinical symptoms and the detection of viral IgG and IgM in serum and IgM in cerebrospinal fluid. There is no known effective antiviral treatment and management is supportive. The primary strategy for preventing exposure in pregnancy is the use of insect repellent containing DEET. This is considered safe for use around pregnant women (Koren, 2003). Avoiding outdoor activity and stagnant water and wearing protective clothing are also recommended.

Adverse effects of West Nile viremia on pregnancy are unclear. Animal data suggest that embryos are susceptible, and a case report of human fetal infection at 27 weeks described chorioretinitis and severe temporal and occipital lobe leukomalacia (Alpert, 2003; Julander, 2006). Of 77 maternal infections initially reported to the West Nile Virus Pregnancy Registry, there were four miscarriages, two elective abortions, and 72 live births, of which 6 percent were preterm (O’Leary, 2006). Three of these 72 newborns were shown to have West Nile infection, and it could not be established conclusively that infection was acquired congenitally. Of three
major malformations possibly associated with viral infection, none was definitively confirmed. Similar conclusions were reached by Pridjian and colleagues (2014), who analyzed data from the Centers for Disease Control and Prevention West Nile Virus Registry. Transmission of West Nile virus through breast feeding is rare (Hinckley, 2007).

Coronavirus Infections

Coronaviruses are single-stranded RNA viruses that are prevalent worldwide. They are associated with 10 to 35 percent of common colds, usually in the fall, winter, and early spring. In 2002, an especially virulent strain of coronavirus—severe acute respiratory syndrome (SARS–CoV)—was first noted in China. It rapidly spread throughout Asia, Europe, and North and South America. Transmission is through droplets or contact with infected secretions, fluids, and wastes. The incubation period is 2 to 16 days, and there appears to be a triphasic pattern to its clinical progression. The first week is characterized by prodromal symptoms of fever, myalgias, headache, and diarrhea. During the second week, patients may suffer recurrent fever, watery diarrhea, and a dry nonproductive cough with mild dyspnea. These are coincident with IgG seroconversion and a declining viral load. Progression at this stage is thought to be due to an overexuberant host immune response. The third, and at times, lethal phase—seen in about 20 percent of patients—is progression to SARS (Christian, 2004; Peiris, 2003a,b). Radiographic lung findings include ground-glass opacities and airspace consolidations that can rapidly progress within 1 to 2 days. The case-fatality rate approached 10 percent in the nonpregnant population and was as high as 25 percent in pregnant women (Lam, 2004; Wong, 2004). Although there have been no confirmed cases since 2004, the Centers for Disease Control and Prevention (2013d) now lists SARS-CoV as a “select agent” that has the potential to pose a severe threat to public health and safety. Another novel coronavirus infecting humans with a high case-fatality rate was detected in the Middle East in 2012 (MERS-CoV).

TRAVEL PRECAUTIONS DURING PREGNANCY

Pregnant travelers face obstetrical risks, general medical risks, and potentially hazardous destination risks. The International Society for Tropical Medicines has comprehensive information available at: http://www.istm.org. Also, the Centers for Disease Control and Prevention have extensive travel information regarding pregnancy and breast feeding at its websites listed on page 1257.

BIOTERRORISM

Bioterrorism involves the deliberate release of bacteria, viruses, or other infectious agents to cause illness or death. These natural agents are often altered to increase their infectivity or their resistance to medical therapy. Clinicians should be alert for significant increases in the number of persons with febrile illnesses accompanied by respiratory symptoms or with rashes not easily associated with common illnesses. Clinicians are urged to contact their state health department or the Centers for Disease Control and Prevention for contemporary information and recommendations. The American College of Obstetricians and Gynecologists (2013b) has recently
addressed disaster preparedness for obstetricians. It provides both general considerations and recommendations for hospital preparedness and obstetrics-specific recommendations.

---

**Smallpox**

The variola virus is considered a serious weapon because of high transmission and overall 30-percent case-fatality rate. The last case of smallpox in the United States was reported in 1949, and worldwide it was reported in Somalia in 1977. Transmission occurs with prolonged contact with infected persons, infected body fluids, or contaminated objects such as clothing. Smallpox presents with an acute-onset fever that is followed by a rash with firm, deep-seated vesicles or pustules. Nishiura (2006) and Suarez and Hankins (2002) have reviewed the severe perinatal and maternal morbidity and mortality caused by smallpox. The case-fatality rate of smallpox in pregnancy is 61 percent if the pregnant woman is unvaccinated. There is a significant increase in stillbirth, abortion, preterm labor and delivery, and neonatal demise in pregnancies complicated by smallpox infection.

Because the smallpox vaccine currently available is made with live vaccinia virus, pregnancy should be delayed for 4 weeks in recipients. It is generally not given to pregnant women because of the risk of fetal vaccinia, a rare but serious complication. Inadvertent smallpox vaccination during pregnancy has not, however, been associated with fetal malformations or preterm birth. Moreover, no cases of fetal vaccinia have been reported with second-generation smallpox vaccine exposure (Ryan, 2008a,b). The Smallpox Vaccine in Pregnancy Registry remains active, and vaccinated women are still being enrolled.

---

**Anthrax**

*Bacillus anthracis* is a gram-positive, spore-forming, aerobic bacterium. It can cause three main types of clinical anthrax: inhalational, cutaneous, and gastrointestinal (Holty, 2006; Swartz, 2001; Sweeney, 2011). The bioterrorist anthrax attacks of 2001 involved inhalational anthrax (Inglesby, 2002). Spores are inhaled and deposited in the alveoli. They are engulfed by macrophages and germinate in mediastinal lymph nodes. The incubation period is usually less than 1 week but may be as long as 2 months. Initial symptoms are nonspecific and include low-grade fever, nonproductive cough, malaise, and myalgias. Within 1 to 5 days of symptom onset, the second stage is heralded by the abrupt onset of severe respiratory distress and high fevers. Mediastinitis and hemorrhagic thoracic lymphadenitis are common, and there is a widened mediastinum on chest radiograph. Case-fatality rates with inhalational anthrax are high, even with aggressive antibiotic and supportive therapy (Dixon, 1999; Holty, 2006).

Anthrax affecting pregnant women and its treatment were recently reviewed by Meaney-Delman and coworkers (2012, 2013). They reported data on 20 pregnant and postpartum women. The overall mortality rate was 80 percent, with a 60-percent fetal or neonatal loss rate. Of note, most cases were published before the advent of antibiotics.

Regimens for postexposure anthrax prophylaxis are given for 2 months. The American College of Obstetricians and Gynecologists (2009) and the Centers for Disease Control and Prevention (Wright, 2010) recommend that asymptomatic pregnant and lactating women with documented exposure to *B anthracis* be given postexposure prophylaxis with ciprofloxacin, 500 mg orally twice daily for 60 days. Amoxicillin, 500 mg orally three times daily, can be substituted if the strain is proven sensitive. In the case of ciprofloxacin allergy and either penicillin allergy or resistance, doxycycline, 100 mg orally twice daily, is given for 60 days. Risks from anthrax far
outweigh any fetal risks from doxycycline (Meaney-Delman, 2013).

The anthrax vaccine (AVA) is an inactivated, cell-free product that requires five injections over 18 months. Vaccination is generally avoided in pregnancy because there are limited safety data. Reports of inadvertent vaccination of pregnant women with AVA have not found a significant increase in fetal malformations or miscarriage rates (Ryan, 2008c; Wiesen, 2002). Anthrax vaccine is an essential adjunct to postexposure antimicrobial prophylaxis, even in pregnancy (Wright, 2010).

### Other Bioterrorism Agents

Other category A bioterrorism agents include *Francisella tularensis*—tularemia, *Clostridium botulinum*—botulism, *Yersinia pestis*—plague, and viral hemorrhagic fevers—for example, Ebola, Marburg, Lassa, and Machupo. Multiple agents are also listed as category B and C. The guidelines for these biological agents are evolving and are detailed at the Centers for Disease Control and Prevention Bioterrorism website: [http://www.emergency.cdc.gov/agent/agentlist-category](http://www.emergency.cdc.gov/agent/agentlist-category).

Sexually transmitted infections or diseases are among the most common of all infectious diseases encountered during pregnancy. Because they may be injurious to both mother and fetus, they should be aggressively sought and treated. Importantly, education, screening, treatment, and prevention are essential components of prenatal care (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). Sexually transmitted infections (STIs) that affect pregnant women and potentially affect the fetus include syphilis, gonorrhea, trichomoniasis, and chlamydia, hepatitis B, human immunodeficiency virus (HIV), herpes simplex virus-1 and -2 (HSV-1, -2), and human papillomavirus (HPV) infections. Recommended therapy for most adhere to guidelines provided by the Centers for Disease Control and Prevention (CDC)(2010b). Treatment of most STIs is clearly associated with improved pregnancy outcome and prevention of perinatal mortality (Goldenberg, 2003, 2008; Ishaque, 2011; Koumans, 2012).

SYPHILIS

Despite the availability of adequate therapy for almost 70 years, syphilis remains a major issue for both mother and fetus. Syphilis rates reached an all-time low in 2000. But from 2001 through 2009 for the United States, there was a steady increase in primary and secondary syphilis rates, which then leveled in 2010 and 2011 (Centers for Disease Control and Prevention, 2013b). The primary
and secondary syphilis rate among women in 2012 was 0.9 case per 100,000 persons, which is a 9-percent decrease from 2010. Congenital syphilis rates also decreased in 2012, mirroring the decline in primary and secondary syphilis rates among women since 2008. However, syphilis remains a significant global health problem, with many countries reporting high numbers of new infections (Lukehart, 2012).

Pathogenesis and Transmission

The causative agent for syphilis is *Treponema pallidum*. Minute abrasions on the vaginal mucosa provide an entry portal for the spirochete, and cervical eversion, hyperemia, and friability increase the transmission risk. Spirochetes replicate and then disseminate through lymphatic channels within hours to days. The incubation period averages 3 weeks—3 to 90 days—depending on host factors and inoculum size. The early stages of syphilis include primary, secondary, and early latent syphilis. These are associated with the highest spirochete loads and transmission rates of up to 30 to 50 percent. In late-stage disease, transmission rates are much lower because of smaller inoculum sizes.

The fetus acquires syphilis by several routes. Spirochetes readily cross the placenta to cause congenital infection. Because of immune incompetence prior to midpregnancy, the fetus generally does not manifest the immunological inflammatory response characteristic of clinical disease before this time (Silverstein, 1962). Although transplacental transmission is the most common route, neonatal infection may follow after contact with spirochetes through lesions at delivery or across the placental membranes. Increased maternal syphilis rates have been linked to substance abuse, especially crack cocaine; inadequate prenatal care and screening; and treatment failures and reinfection (Johnson, 2007; Lago, 2004; Trepka, 2006; Warner, 2001; Wilson, 2007). A report from Maricopa County, Arizona, also cited minority race or ethnicity as a risk factor (Kirkcaldy, 2011).

Clinical Manifestations

Maternal syphilis can cause preterm labor, fetal death, fetal-growth restriction, and neonatal infection (Krakauer, 2012; Saloojee, 2004). Any stage of maternal syphilis may result in fetal infection, but risk is directly related to maternal spirochete load (Fiumara, 1952; Golden, 2003). Maternal syphilis is staged according to clinical features and disease duration:

1. **Primary syphilis** is diagnosed by the characteristic chancre, which develops at the inoculation site. It is usually painless, with a raised, red, firm border and a smooth base (Fig. 65-1). Nonsuppurative lymphadenopathy may develop. A chancre will usually resolve spontaneously in 2 to 8 weeks, even if untreated. Multiple lesions may be found, predominantly in HIV-1 co-infected women.

2. **Secondary syphilis** is diagnosed when the spirochete is disseminated and affects multiple organ systems. Manifestations develop 4 to 10 weeks after the chancre appears and include dermatological abnormalities in up to 90 percent of women. A diffuse macular rash, plantar and palmar targetlike lesions, patchy alopecia, and mucous patches may be seen (Figs. 65-2 and 65-3). Condylomata lata are flesh-colored papules and nodules found on the perineum and perianal area. They are teeming with spirochetes and are highly infectious. Most women with secondary syphilis will also express constitutional symptoms such as fever, malaise, anorexia, headache, myalgias, and arthralgias. Up to 40 percent will have cerebrospinal fluid abnormalities,
although only 1 to 2 percent will develop clinically apparent aseptic meningitis. Hepatitis, nephropathy, ocular changes, anterior uveitis, and periostitis may also develop.

3. *Latent syphilis* develops when primary or secondary syphilis is not treated. It is characterized by reactive serological testing, but resolved clinical manifestations. *Early latent syphilis* is latent disease acquired within the preceding 12 months. Disease diagnosed beyond 12 months is either *late latent syphilis* or *latent syphilis of unknown duration*.

4. *Tertiary* or *late syphilis* is a slowly progressive disease affecting any organ system but is rarely seen in reproductive-aged women.

**FIGURE 65-1** Primary syphilis. Photograph of a chancre with a raised, firm border and smooth, red base.
FIGURE 65-2 Target lesions on the palms of a pregnant woman with secondary syphilis.
As noted, congenital infection is uncommon before 18 weeks. Once fetal syphilis develops, however, it manifests as a continuum of involvement. Fetal hepatic abnormalities are followed by anemia and thrombocytopenia, then ascites and hydrops (Hollier, 2001). Stillbirth remains a major complication (Di Mario, 2007; Hawkes, 2011; Rac, 2014b). The newborn may have jaundice with petechiae or purpuric skin lesions, lymphadenopathy, rhinitis, pneumonia, myocarditis, nephrosis, or long-bone involvement.

With syphilitic infection, the placenta becomes large and pale (Fig. 65-4). Microscopically, villi lose their characteristic arborization and become thicker and clubbed (Kapur, 2004). Sheffield and colleagues (2002c) described such large villi in more than 60 percent of syphilitic placentas. Blood vessels markedly diminish in number, and in advanced cases, they almost entirely disappear as a result of endarteritis and stromal cell proliferation. Likely related, Lucas and coworkers (1991) demonstrated increased vascular resistance in uterine and umbilical arteries of infected pregnancies. In a study of 25 untreated women, Schwartz and associates (1995) reported that necrotizing funisitis was present in a third. Spirochetes were detected in almost 90 percent using silver and immunofluorescent staining.
FIGURE 65-4 Congenital syphilis. A. Fetogram of a stillborn infant infected with syphilis showing the “moth-eaten” appearance of the femurs (arrow). B. Enlarged hydropic placenta of a syphilis-infected neonate.

Diagnosis

The United States Preventive Services Task Force has reaffirmed its recommendation that clinicians screen all pregnant women for syphilis to treat and prevent congenital infection (Wolff, 2009). Testing is now required by law in all states and should be performed at the first prenatal visit. In populations in which the prevalence of syphilis is high, serological testing should be performed in the third trimester and again at delivery (Centers for Disease Control and Prevention, 2010b).

*Treponema pallidum* cannot be cultured from clinical specimens. Definitive diagnosis of early-stage lesions is made using dark-field examination and direct immunofluorescent antibody staining of lesion exudates (Centers for Disease Control and Prevention, 2010b). In asymptomatic patients or for screening purposes, serological testing is used. There are two types. The first type is nontreponemal testing that includes the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR). These tests are quantified and expressed as titers. Because titers reflect disease activity, they increase during early syphilis and often exceed levels of 1:32 in secondary syphilis. Following treatment of primary and secondary syphilis, serological testing at 3 to 6 months usually confirms a fourfold drop in VDRL or RPR titers (Rac, 2014a). Those with treatment failure or reinfection may lack this decline. Because VDRL titers do not correspond directly to RPR titers, consistent use of the same test for surveillance is recommended.

The other type of testing is treponemal-specific and includes the fluorescent treponemal-antibody absorption tests (FTA-ABS), the microhemagglutination assay for antibodies to T...
pallidum (MHA-TP), or the Treponema pallidum passive particle agglutination (TP-PA) test. These treponemal-specific tests generally remain positive throughout life.

Each of the serological tests has limitations including false-positive results. Traditionally, nontreponemal tests have been used for screening in the United States, and results are then confirmed by a specific treponemal test. Several laboratories have recently implemented a reverse screening algorithm, that is, screening with a treponemal test (Binnicker, 2012; Park, 2011). Both approaches are effective if appropriate screening, follow-up, and treatment are implemented. Patel and colleagues (2012) described missed opportunities for preventing and treating congenital syphilis in New York City. They found that 63 percent of mothers with newborns diagnosed with congenital syphilis had a missed opportunity for prevention. Most of these did not receive serological testing.

Rapid syphilis testing for “point of care” diagnosis is currently being developed and may be useful in settings with limited prenatal care (Centers for Disease Control and Prevention, 2010b; Greer, 2008). Treponemal immunochromatographic strip (ICS) tests and enzyme immunoassays (EIAs) are increasingly being used for screening and confirmatory testing (Henrich, 2011; Lukehart, 2012).

The prenatal diagnosis of congenital syphilis is difficult because an infected fetus often has a normal sonographic examination. Some findings, however, may be suggestive or even diagnostic—hydrops fetalis, ascites, hepatomegaly, placental thickening, elevated middle cerebral artery Doppler velocimetry measurements, and hydramnios all suggest infection (Rac, 2014b). Polymerase chain reaction (PCR) is specific for detection of T. pallidum in amnionic fluid, and treponemal DNA has been found in 40 percent of pregnancies infected before 20 weeks (Nathan, 1997; Wendel, 1991). Fetal syphilis has also been verified by amnionic fluid dark-field examination or rabbit infectivity testing in 64 percent of a cohort of women with untreated syphilis (Hollier, 2001). Although prenatal diagnosis can be made by funipuncture or amniocentesis, its clinical utility is not clear.

### Treatment

Syphilis therapy during pregnancy is given to eradicate maternal infection and to prevent or treat congenital syphilis. Parenteral penicillin G remains the preferred treatment for all stages of syphilis during pregnancy. Currently recommended treatment guidelines are shown in Table 65-1 and are the same as for nonpregnant adults. For pregnant women, authorities recommend that a second dose of benzathine penicillin G be given 1 week after the initial dose.

<table>
<thead>
<tr>
<th>TABLE 65-1. Recommended Treatment for Pregnant Women with Syphilis</th>
</tr>
</thead>
</table>
In retrospective analyses, benzathine penicillin G has been shown to be highly effective for early maternal infection. In a study of 340 pregnant women so treated, Alexander and associates (1999) reported six cases—1.8 percent—of congenital syphilis. Four of these six neonates were from a group of 75 women with secondary syphilis. The other two were identified in those delivered from a group of 102 women with early latent syphilis. Congenital syphilis was generally confined to neonates of women treated after 26 weeks and is likely related to the duration and severity of fetal infection. Sheffield and coworkers (2002b) reported that high maternal serological titers, preterm delivery, and delivery shortly after antepartum therapy are all risks for failure of maternal treatment to prevent neonatal infection. There are no proven alternatives to penicillin therapy during pregnancy. Erythromycin and azithromycin may be curative for the mother, but because of limited transplacental passage, these drugs do not prevent all congenital disease (Berman, 2004; Centers for Disease Control and Prevention, 2010b; Wendel, 1988; Zhou, 2007). In several countries, macrolide resistant strains of *T. pallidum* are now prevalent (Stamm, 2010). Cephalosporins may prove useful, but data are limited (Augenbraun, 1999, 2002; Zhou, 2007). Tetracyclines, including doxycycline, are effective for treatment of syphilis in the nonpregnant woman. These are generally not recommended during pregnancy, however, because of the risk of yellow-brown discoloration of fetal deciduous teeth (Chap. 12, p. 248).

**Penicillin Allergy**

Women with a history of penicillin allergy should have either an oral stepwise penicillin dose challenge or skin testing performed to confirm the risk of immunoglobulin E (IgE)-mediated anaphylaxis. If confirmed, penicillin desensitization is recommended, as shown in Table 65-2, and then followed by benzathine penicillin G treatment (Chisholm, 1997; Wendel, 1985).

From the Centers for Disease Control and Prevention, 2010b.
In most women with primary syphilis and approximately half with secondary infection, penicillin treatment causes a Jarisch-Herxheimer reaction. Uterine contractions frequently develop with this reaction and may be accompanied by decreased fetal movement and late fetal heart rate decelerations (Klein, 1990). In a study of 50 pregnant women who received benzathine penicillin for syphilis, Myles and colleagues (1998) reported a 40-percent incidence of a Jarisch-Herxheimer reaction. Of the 31 women monitored electronically, 42 percent developed regular uterine contractions with a median onset of 10 hours, and 39 percent developed variable decelerations with a median onset of 8 hours. All contractions resolved within 24 hours of therapy. Lucas and associates (1991) used Doppler velocimetry and demonstrated acutely increased vascular resistance during this time. Beta-lactam antibiotics for group B streptococcus intrapartum prophylaxis can also trigger this reaction in a woman with untreated syphilis (Rac, 2010).

All women with syphilis should be offered counseling and testing for HIV (Koumans, 2000). For women with concomitant HIV infection, the Centers for Disease Control and Prevention (2010b) recommend the same treatment as for HIV-negative persons. Clinical and serological

surveillance to detect treatment failures is also recommended at 3, 6, 9, 12, and 24 months in HIV-positive patients.

**GONORRHEA**

Gonorrhea remains the second most commonly reported notifiable disease in the United States. The incidence of gonorrhea in the United States for 2012 was 107.5 cases per 100,000 persons, which is an increase of 4 percent since 2011 (Centers for Disease Control and Prevention, 2013b). The highest rates in women of any ethnicity were in the groups aged 20 to 24 years (578.5) and 15 to 19 years (521.2). Its prevalence in prenatal clinics in 2011 among women aged 15 to 24 years was 0.8 percent, although inner-city STI clinics have reported a prenatal prevalence of 5 to 10 percent (Berggren, 2011; Johnson, 2007). Risk factors include single marital status, adolescence, poverty, drug abuse, prostitution, other STIs, and lack of prenatal care (Berggren, 2011; Gorgos, 2011). Gonococcal infection is also a marker for concomitant chlamydial infection in up to 40 percent of infected women (Christmas, 1989; Miller, 2004). In most pregnant women, gonococcal infection is limited to the lower genital tract—the cervix, urethra, and periurethral and vestibular glands. Acute salpingitis is rare in pregnancy, but pregnant women account for a disproportionate number of disseminated gonococcal infections (Bleich, 2012; Ross, 1996; Yip, 1993).

Gonococcal infection may have deleterious effects in any trimester. There is an association between untreated gonococcal cervicitis and septic abortion as well as infection after voluntary abortion (Burkman, 1976). Preterm delivery, prematurely ruptured membranes, chorioamnionitis, and postpartum infection are reported to be more common in women infected with *Neisseria gonorrhoeae* (Alger, 1988; Johnson, 2011). Bleich and coworkers (2012) reviewed outcomes of 32 pregnant women admitted to Parkland Hospital for disseminated gonococcal infection. Although all the women promptly responded to appropriate antimicrobial therapy, one stillbirth was attributed to gonococcal sepsis.

**Screening and Treatment**

The U.S. Preventative Services Task Force recommends gonorrhea screening for all sexually active women, including pregnant women, if they are at increased risk (Meyers, 2008). Risk factors include age < 25 years, prior gonococcal infection, other STIs, prostitution, new or multiple sexual partners, drug use, and inconsistent condom use. For women who test positive, screening for syphilis, *Chlamydia trachomatis*, and HIV should precede treatment, if possible. If chlamydial testing is unavailable, presumptive therapy is given. Screening for gonorrhea in women is by culture or nucleic acid amplification tests (NAATs). Rapid tests for gonorrhea, although available, do not yet reach the sensitivity or specificity of culture or NAAT (Greer, 2008).

Gonorrhea treatment has evolved during the past decade due to the ability of *N gonorrhoeae* to rapidly develop antimicrobial resistance (Centers for Disease Control and Prevention, 2011b,c; Dionne-Odom, 2011; Ram, 2012; Unemo, 2011). Rapid development of fluoroquinolone resistance caused the CDC to remove that therapeutic class from its treatment guidelines in 2007. The Gonococcal Isolate Surveillance Project, a national sentinel surveillance system established to monitor trends in gonococcal antimicrobial resistance, has reported decreasing susceptibility to cephalosporins. This is the one remaining class of antimicrobial agents currently recommended for gonorrhea treatment (Bolan, 2012; Centers for Disease Control and Prevention, 2010b, 2012). This global public health threat has led the CDC in 2012 to change the gonorrhea treatment
recommendations.

Listed in Table 65-3 are the updated recommendations for treatment of uncomplicated gonococcal infection during pregnancy. The increased ceftriaxone dose of 250 mg should be given along with 1 gram of azithromycin. The latter provides another drug with a different mechanism of action against *N gonorrhoeae* and treats chlamydial co-infections. Cefixime tablets should be reserved for situations that preclude ceftriaxone treatment. If they are used, a test-of-cure should be performed 1 week after treatment. Azithromycin, 2 grams orally as a single dose, can be used in cephalosporin-allergic women. However, this treatment should be limited due to emerging macrolide resistance (Centers for Disease Control and Prevention, 2011c). Treatment is also recommended for sexual contacts. A test-of-cure is unnecessary if symptoms resolve, but because gonococcal reinfection is common, a second screening in late pregnancy should be considered for women treated earlier (Blatt, 2012).

---

**Disseminated Gonococcal Infections (DGI)**

Gonococcal bacteremia may cause disseminated infections that manifest as petechial or pustular skin lesions, arthralgias, septic arthritis, or tenosynovitis. For treatment, the Centers for Disease Control and Prevention (2010b) has recommended ceftriaxone, 1000 mg intramuscularly or intravenously (IV) every 24 hours. Treatment should be continued for 24 to 48 hours after improvement, and therapy is then changed to an oral agent to complete 1 week of therapy. Prompt recognition and antimicrobial treatment will usually result in favorable outcomes in pregnancy (Bleich, 2012). Meningitis and endocarditis rarely complicate pregnancy, but they may be fatal (Bataskov, 1991; Burgis, 2006; Ram, 2012). For gonococcal *endocarditis*, ceftriaxone 1000 to 2000 mg IV every 12 hours should be continued for at least 4 weeks, and for *meningitis*, 10 to 14 days (Centers for Disease Control and Prevention, 2010b).

---

**CHLAMYDIAL INFECTIONS**

*Chlamydia trachomatis* is an obligate intracellular bacterium that has several serotypes, including those that cause lymphogranuloma venereum. The most commonly encountered strains are those that attach only to columnar or transitional cell epithelium and cause cervical infection. It is the most commonly reported infectious disease in the United States, with 1.4 million cases reported in 2012. It is estimated, however, that there are approximately 2.8 million new cases annually, although most are undiagnosed (Centers for Disease Control and Prevention, 2008). In 2012, the incidence of chlamydial infection among women was 2.5 times greater than among men. Selective prenatal screening clinics in 2011 reported a median chlamydial infection rate of 7.7 percent.
Although most pregnant women have asymptomatic infection, a third have urethral syndrome, urethritis, or Bartholin gland infection (Peipert, 2003). Mucopurulent cervicitis may be due to chlamydial or gonococcal infection or both. It may also represent normal, hormonally stimulated endocervical glands with abundant mucus production. Other chlamydial infections not usually seen in pregnancy are endometritis, salpingitis, peritonitis, reactive arthritis, and Reiter syndrome.

The role of chlamydial infection in pregnancy complications remains controversial. A few studies have reported a direct association between *C. trachomatis* and miscarriage, whereas most show no correlation (Baud, 2011; Coste, 1991; Paukku, 1999; Sugiura-Ogasawara, 2005). It is disputed whether untreated cervical infection increases the risk of preterm delivery, preterm ruptured membranes, and perinatal mortality (Andrews, 2000, 2006; Baud, 2008; Blas, 2007; Silva, 2011). Johnson and colleagues (2011) reported a twofold risk for low-birthweight infants.

Chlamydial infection has not been associated with an increased risk of chorioamnionitis or with pelvic infection after cesarean delivery (Blanco, 1985; Gibbs, 1987). Conversely, delayed postpartum uterine infection has been described by Hoyme and associates (1986). The syndrome, which develops 2 to 3 weeks postpartum, is distinct from early postpartum metritis. It is characterized by vaginal bleeding or discharge, low-grade fever, lower abdominal pain, and uterine tenderness.

There is vertical transmission to 30 to 50 percent of neonates delivered vaginally from infected women. Perinatal transmission to newborns can cause pneumonia. Moreover, *C. trachomatis* is the most commonly identifiable infectious cause of ophthalmia neonatorum (Chap. 32, p. 631).

### Screening and Treatment

Prenatal screening for *C. trachomatis* is a complex issue, although there is little evidence for its effectiveness in asymptomatic women who are not in high-risk groups (Kohl, 2003; Meyers, 2007; Peipert, 2003). Identification and treatment of asymptomatic infected women may prevent neonatal infections, but evidence of adverse pregnancy outcome prevention is lacking. Currently, the U.S. Preventive Services Task Force (2007) and the CDC recommend prenatal screening at the first prenatal visit for women at increased risk for chlamydial infection, and again during the third trimester if high-risk behavior continues. In a systematic review of repeat chlamydial infection among women, Hosenfeld and coworkers (2009) reported a reinfection rate of 14 percent, and most recurred within the first 8 to 10 months. Interestingly, in another study, Sheffield and colleagues (2005) found that almost half of pregnant women with asymptomatic cervical chlamydia underwent spontaneous resolution of infection.

Diagnosis is made predominantly by culture or NAAT. Cultures are more expensive and less accurate than newer NAATs, including PCR (Greer, 2008). Roberts and associates (2011) evaluated nucleic acid amplification testing of urine compared with cervical secretions in more than 2000 pregnant women and found them to be equivalent.

Currently recommended treatment regimens for chlamydial infections are shown in Table 65-4. Azithromycin is first-line treatment and has been found to be safe and effective in pregnancy. The fluoroquinolones and doxycycline are avoided in pregnancy, as is erythromycin estolate because of drug-related hepatotoxicity. Repeat chlamydial testing 3 to 4 weeks after completion of therapy is recommended.

**Lymphogranuloma Venereum**

L1, L2, and L3 serovars of *C. trachomatis* cause *lymphogranuloma venereum (LGV)*. The primary genital infection is transient and seldom recognized. Inguinal adenitis may develop and at times lead to suppuration. It may be confused with chancroid. Ultimately, the lymphatics of the lower genital tract and perirectal tissues may be involved. Here, sclerosis and fibrosis can cause vulvar elephantiasis and severe rectal stricture. Fistula formation involving the rectum, perineum, and vulva also may evolve.

For treatment during pregnancy, erythromycin base, 500 mg orally four times daily, is given for 21 days (Centers for Disease Control and Prevention, 2010b). Although data regarding efficacy are scarce, some authorities recommend azithromycin, 1000 mg orally weekly for 3 weeks.

---

**HERPES SIMPLEX VIRUS**

Genital herpes simplex virus infection is one of the most common sexually transmitted diseases according to the Centers for Disease Control and Prevention (2010a,b). An estimated 50 million adolescents and adults are currently affected. In 2012, there were 228,000 initial office visits for genital herpes (Centers for Disease Control and Prevention, 2013b). Although most women are unaware of their infection, approximately one in six has serological evidence for HSV-2 infection. This incidence is as high as one in two for non-Hispanic black pregnant women (Corey, 2012). As most cases of HSV are transmitted by persons who are asymptomatic or unaware of their disease, herpes infections have become a major public health concern. It is estimated that 0.5 to 2 percent of pregnant women acquire HSV-1 or -2 during pregnancy (Brown, 1997).

---

**Pathogenesis and Transmission**

Two types of HSV have been distinguished based on immunological and clinical differences. Type
1 is responsible for most nongenital infections. However, more than half of new cases of genital herpes in adolescents and young adults are caused by HSV-1 infection. This is thought to be due to an increase in oral-genital sexual practices (Mertz, 2003; Pena, 2010; Roberts, 2003). Type 2 HSV is recovered almost exclusively from the genital tract and is usually transmitted by sexual contact. Most recurrences—greater than 90 percent—are secondary to HSV-2. There is a large amount of DNA sequence homology between the two viruses, and prior infection with one type attenuates a primary infection with the other type.

Neonatal transmission is by three routes: (1) intrauterine in 5 percent, (2) peripartum in 85 percent, or (3) postnatal in 10 percent (Kimberlin, 2004b). The fetus becomes infected by virus shed from the cervix or lower genital tract. It either invades the uterus following membrane rupture or is transmitted by contact with the fetus at delivery. The overall transmission rate is 1 in 3200 to 1 in 30,000 births depending on the population studied (Corey, 2012; Mahnert, 2007; Whitley, 2007). Neonatal herpes is caused by both HSV-1 and HSV-2, although HSV-2 infection predominates. Most infected infants are born to mothers with no reported history of HSV infection (Gardella, 2010).

The risk of neonatal infection correlates with the presence of HSV in the genital tract, the HSV type, invasive obstetrical procedures, and stage of maternal infection (Brown, 2005, 2007). Infants born to women who acquire genital HSV near the time of delivery have a 30- to 50-percent risk of infection. This is attributed to higher viral loads and the lack of transplacental protective antibodies (Brown, 1997; Brown, 2000). Women with recurrent HSV have less than a 1-percent risk of neonatal infection (Pasternak, 2010; Prober, 1987).

Clinical Manifestations

Once transmitted by genital-genital or oral-genital contact, HSV-1 or -2 replicates at the entry site. Following mucocutaneous infection, the virus moves retrograde along sensory nerves. It then remains latent in cranial nerves or dorsal spinal ganglia. HSV infections may be categorized into three groups:

1. **First episode primary infection** describes cases in which HSV-1 or -2 is isolated from genital secretions in the absence of HSV-1 or -2 antibodies. Only a third of newly acquired HSV-2 genital infections are symptomatic (Langenberg, 1999). The typical incubation period of 6 to 8 days (range 1 to 26 days) may be followed by a “classic presentation.” This is characterized by a papular eruption with itching or tingling, which then becomes painful and vesicular. Multiple vulvar and perineal lesions may coalesce, and inguinal adenopathy may be severe (Fig. 65-5). Transient systemic influenza-like symptoms are common and are presumably caused by viremia. Hepatitis, encephalitis, or pneumonia may develop, although disseminated disease is rare. Cervical involvement is common, but it may be inapparent clinically. Some cases are severe enough to require hospitalization. In 2 to 4 weeks, all signs and symptoms of infection disappear. Many women do not present with the typical lesions—instead, a pruritic or painful abraded area or knife-slit may be present. The incidence of asymptomatic primary infections may be as high as 80 percent (Centers for Disease Control and Prevention, 2010a,b).

2. **First episode nonprimary infection** is diagnosed when HSV is isolated in women who have only the other serum HSV-type antibody present. For example, HSV-2 is isolated from genital secretions in women already expressing serum HSV-1 antibodies. In general, these infections are characterized by fewer lesions, fewer systemic manifestations, less pain, and briefer duration of lesions and viral shedding. This is likely because of some immunity from cross-
reacting antibodies, for example, from childhood-acquired HSV-1 infection. In many cases, it may be impossible to differentiate clinically between the two types of first infection. Thus, serological confirmation may be beneficial.

3. Reactivation disease is characterized by isolation of HSV-1 or -2 from the genital tract in women with the same serotype antibodies. During the latency period, in which viral particles reside in nerve ganglia, reactivation is common and mediated through variable but poorly understood stimuli. Reactivation is termed recurrent infection and results in herpes-virus shedding. Most recurrent genital herpes is caused by type 2 virus (Centers for Disease Control and Prevention, 2010a,b; Corey, 2012). These lesions generally are fewer in number, are less tender, and shed virus for shorter periods—2 to 5 days—than those of primary infection. Typically, they recur at the same sites. Recurrences are most common in the first year after initial infection, and rates slowly decline over several years.

Asymptomatic viral shedding is defined by HSV as detected by culture or PCR in the absence of clinical findings. Most infected women shed virus intermittently, and most HSV transmission to a partner occurs during periods of asymptomatic viral shedding. Gardella and coworkers (2005) reported an HSV culture-positive rate of 0.5 percent and a PCR-positive rate of 2.7 percent in asymptomatic women presenting for delivery. More data are needed to determine the effect of asymptomatic shedding on neonatal transmission.

Most primary and first-episode infections in early pregnancy are probably not associated with an increased rate of spontaneous abortion or stillbirth (Eskild, 2002). In their review, Fagnant and
Monif (1989) found only 15 cases of congenital herpetic infection that were acquired during early pregnancy. Brown and Baker (1989) reported that late-pregnancy primary infection may be associated with preterm labor and fetal-growth restriction.

Newborn infection may manifest in a number of ways. Infection may be localized to the skin, eye, or mouth—SEM disease—in about 40 percent of cases. Central nervous system disease with encephalitis is seen in 30 percent of cases. Disseminated disease as shown in Figure 65-6 with involvement of multiple major organs is found in 32 percent. Localized infection is usually associated with a good outcome. Conversely, even with acyclovir treatment, disseminated infection has a mortality rate of nearly 30 percent (Corey, 2009; Kimberlin, 2004a,b, 2011). Importantly, serious developmental and central nervous system morbidity is seen in 20 to 50 percent of survivors with disseminated or cerebral infection.

![Cross-section showing necrotic brain tissue from a newborn who died from disseminated herpesvirus infection.](image)

**FIGURE 65-6** Cross-section showing necrotic brain tissue from a newborn who died from disseminated herpesvirus infection.

**Diagnosis**

According to the Centers for Disease Control and Prevention (2010a), clinical diagnosis of genital herpes is both insensitive and nonspecific and should be confirmed by laboratory testing. HSV tests available are either virological or type-specific serological tests.

Virological tests are performed on a specimen from a mucocutaneous lesion. Cell culture and PCR are the preferred tests. The sensitivity of HSV isolation is relatively low for viral culture as vesicular lesions ulcerate and then crust. Viral isolation results sometimes are not available for 1 to 2 weeks. PCR assays are more sensitive, the results generally are available in 1 to 2 days, and specimen handling is easier. The major limitation of PCR is cost and laboratory availability. The PCR assay is the preferred test for HSV detection in spinal fluid. Regardless of the test performed, HSV viral type should be differentiated because HSV type influences counseling and long-term
Several serological assay systems are available to detect antibody to HSV glycoproteins G1 and G2 (Anzivino, 2009; Centers for Disease Control and Prevention, 2010a). These proteins evoke type-specific antibody responses to HSV-1 and HSV-2 infection, respectively, and they reliably differentiate the two. This permits confirmation of clinical infection and identification of asymptomatic carriers. The Food and Drug Administration (FDA) has approved type-specific tests that are enzyme-linked immunosorbent assay (ELISA) or blot-style tests. Providers should request type-specific glycoprotein G-based assays when serology is being performed. Sensitivity approaches 90 to 100 percent and specificity 99 to 100 percent (Wald, 2002). IgG antibodies usually are detected 1 to 2 weeks after a primary infection. IgM antibody detection is not a useful test.

Point-of-care testing is being increasingly requested by practitioners to help guide management intrapartum or near delivery. There are type-specific serological tests available that use capillary blood or serum. Sensitivity varies from 80 to 98 percent with specificity ≥ 96 percent. False-positive and false-negative results may occur. Real-time quantitative PCR of genital tract secretions has recently been developed by Gardella and colleagues (2010). They reported sensitivity of 99.6 percent and specificity of 96.7 percent with a turnaround time of 2 hours. These features would prove valuable to guide clinical decision making at delivery.

Routine serological screening for herpes in pregnancy is not recommended by the American College of Obstetricians and Gynecologists (2012) due to cost and limited data on efficacy in reducing the incidence of neonatal herpes. Cost-decision analysis for prenatal type-specific antibody screening and suppressive therapy for partners has been found to be unacceptably expensive (Barnabas, 2002; Rouse, 2000; Thung, 2005). In contrast, it was found to be potentially cost-effective by Baker and associates (2004). Cleary and coworkers (2005) calculated that universal prenatal screening would reduce rates of perinatal death and severe sequelae from neonatal HSV. But they also found that it would require treatment of 3849 women to prevent one case of neonatal death or disease with severe sequelae. Universal screening would identify previously undiagnosed women who could then be counseled regarding safe practices and antepartum antiviral suppression, but a concrete benefit remains unproven.

Management

Antiviral therapy with acyclovir, famciclovir, or valacyclovir has been used for treatment of first-episode genital herpes in nonpregnant patients. Oral or parenteral preparations attenuate clinical infection and the viral shedding duration. Suppressive therapy has also been given to limit recurrent infections and to reduce heterosexual transmission (Corey, 2004, 2012). For intense discomfort, oral analgesics and topical anesthetics may provide some relief, and urinary retention is treated with an indwelling bladder catheter. Acyclovir appears to be safe for use in pregnant women (Briggs, 2011; Stone, 2004). The manufacturers of acyclovir and valacyclovir, in cooperation with the Centers for Disease Control and Prevention, maintained a registry of outcomes following exposure to these drugs during pregnancy through 1999. More than 700 neonates exposed during the first trimester were evaluated, and no increased adverse effects were found (Stone, 2004). At this time, there are insufficient data with famciclovir exposure, although a pregnancy registry is being maintained (1-888-669-6682).

Women with a primary outbreak during pregnancy may be given antiviral therapy to attenuate and decrease the duration of symptoms and viral shedding (Table 65.5). Women with HIV co-
infection may require a longer duration of treatment. Those with severe or disseminated HSV are given IV acyclovir, 5 to 10 mg/kg, every 8 hours for 2 to 7 days until clinically improved. This is followed by oral antiviral therapy to complete at least 10 days of total therapy (Centers for Disease Control and Prevention, 2010b). Recurrent HSV infections during pregnancy are treated for symptomatic relief only (see Table 65-5). Acyclovir resistance has been reported, predominantly with HSV-2 and in immunocompromised patients (Corey, 2012).

---

**Peripartum Shedding Prophylaxis**

Several studies have shown that acyclovir or valacyclovir suppression initiated at 36 weeks’ gestation will decrease the number of HSV outbreaks at term, thus decreasing the need for cesarean delivery (Hollier, 2008). Such suppressive therapy will also decrease viral shedding defined by both culture and PCR techniques (Scott, 2002; Sheffield, 2006; Watts, 2003). A systematic review of studies of acyclovir prophylaxis given from 36 weeks to delivery was reported by Sheffield and colleagues (2003). They found that delivery suppressive therapy was associated with significantly decreased rates of clinical HSV recurrence, cesarean deliveries for HSV recurrences, total HSV detection, and asymptomatic shedding. Subsequent studies using valacyclovir suppression have shown similar results (Andrews, 2006; Sheffield, 2006). Because of these studies, the American College of Obstetricians and Gynecologists (2012) recommends viral therapy at or beyond 36 weeks for women who have any recurrence during pregnancy. It is
unclear whether suppression is needed for women with outbreaks before but not during pregnancy. There have been several case reports of atypical neonatal herpes disease following maternal antiviral suppression. Thus, suppression does not prevent all cases of neonatal disease (Pinninti, 2012).

On presentation for delivery, a woman with a history of HSV should be questioned regarding prodromal symptoms such as vulvar burning or itching. A careful examination of the vulva, vagina, and cervix should be performed, and suspicious lesions should be cultured or PCR tested. Currently, there is no approved point-of-care test to guide management. Cesarean delivery is indicated for women with active genital lesions or prodromal symptoms (American College of Obstetricians and Gynecologists, 2012). Of note, 10 to 15 percent of neonates with HSV are born to women undergoing cesarean delivery. Cesarean delivery is not recommended for women with a history of HSV infection but no active genital disease at the time of delivery. Moreover, an active lesion in a nongenital area is not an indication for cesarean delivery. Instead, an occlusive dressing is placed, and vaginal delivery is allowed.

There is no evidence that external lesions cause ascending fetal infection with preterm ruptured membranes. Major and associates (2003) described expectant management of preterm premature membrane rupture in 29 women < 31 weeks. There were no cases of neonatal HSV, and the maximum infection risk was calculated to be 10 percent. Antiviral treatment use in this setting is reasonable, but of unproven efficacy. For women with a clinical recurrence at delivery, there is not an absolute duration of membrane rupture beyond which the fetus would not benefit from cesarean delivery (American College of Obstetricians and Gynecologists, 2013). Women with active HSV may breast feed if there are no active HSV breast lesions. Strict hand washing is advised. Valacyclovir and acyclovir may be used during breast feeding, as drug concentrations in breast milk are low. One study found the acyclovir concentration to be only 2 percent of that used for therapeutic dosing of the neonate (Sheffield, 2002a).

Other antiviral agents are under development. One is *pritelivir*, a viral helicase-primase complex that reduces HSV-2 shedding (Wald, 2014). Also, HSV-2 vaccine development is currently being aggressively pursued. Two glycoprotein D-based subunit vaccine trials have shown benefit in discordant couples by decreasing HSV-2 acquisition (Stanberry, 2002). Interestingly, a recent randomized controlled trial of a newer glycoprotein D-based HSV-2 vaccine showed it to be effective in women in preventing HSV-1, but not HSV-2, genital disease (Belshe, 2012). Further research is needed to better understand these challenging and contradictory results (Johnson, 2011).

**CHANCROID**

*Haemophilus ducreyi* can cause painful, nonindurated genital ulcers termed soft chancres that at times are accompanied by painful suppurative inguinal lymphadenopathy. Although common in some developing countries, it had become rare in the United States by the 1970s. There was an increase in the late 1980s, but only fifteen cases were reported in the United States in 2012. This marked decrease likely represents a true decline as well as diagnostic difficulties that led to underdiagnosis (Centers for Disease Control and Prevention, 2013b). Importantly, the ulcerative lesion is a high-risk cofactor for HIV transmission.

Diagnosis by culture is difficult because appropriate media are not widely available. Instead, clinical diagnosis is made when typical painful genital ulcer(s) are dark-field negative for spirochetes and herpes-virus test results are negative. No FDA-cleared PCR test is yet available
Recommended treatment in pregnancy is azithromycin, 1 g orally as a single dose; erythromycin base, 500 mg orally three times daily for 7 days; or ceftriaxone, 250 mg in a single intramuscular dose (Centers for Disease Control and Prevention, 2010b).

### HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) is one of the most common sexually transmitted infections, and more than 40 types infect the genital tract. Most reproductive-aged women become infected within a few years of becoming sexually active, although most infections are asymptomatic and transient. Oncogenic or high-risk HPV types 16 and 18 are associated with dysplasia and are discussed in Chapter 63 (p. 1222). Mucocutaneous external genital warts termed condyloma acuminata are usually caused by HPV types 6 and 11 but may also be caused by intermediate-and high-oncogenic-risk HPV.

The National Health and Nutrition Examination Survey (NHANES) 2003 to 2006 reported an overall HPV prevalence of 43 percent in females aged 14 to 59 years (Hariri, 2011). A 27-percent seroprevalence was also reported for subjects 18 through 25 years in the National Longitudinal Study of Adolescent Health (Manhart, 2006). Similar rates of HPV positivity have been reported for pregnant women (Aydin, 2010; Gajewska, 2005; Hernandez-Giron, 2005; Rama, 2010). Prevalence is highest in younger age groups.

#### External Genital Warts—Condyloma Acuminata

For unknown reasons, genital warts frequently increase in number and size during pregnancy. Acceleration of viral replication by the physiological changes of pregnancy might explain perineal lesion growth and progression of some to cervical neoplasm (Fife, 1999; Rando, 1989). These lesions may sometimes grow to fill the vagina or cover the perineum, thus making vaginal delivery or episiotomy difficult (Fig. 65-7). Because HPV infection may be subclinical and multifocal, most women with vulvar lesions also have cervical infection, and vice versa (Ault, 2003; Kroupis, 2011; Reichman, 2012).
Treatment

There may be an incomplete response to treatment during pregnancy, but lesions commonly improve or regress rapidly following delivery. Consequently, wart eradication during pregnancy is usually not necessary. Therapy is directed toward minimizing treatment toxicity to the mother and fetus and debulking symptomatic genital warts. There are several agents available, but pregnancy limits their use. There is no definitive evidence that any one of the subsequently discussed treatments is superior to another (Centers for Disease Control and Prevention, 2010b; Wiley, 2002).

*Trichloroacetic or bichloracetic acid,* 80- to 90-percent solution, applied topically once a week, is an effective regimen for external warts. Some prefer cryotherapy, laser ablation, or...
surgical excision (Arena, 2001; Centers for Disease Control and Prevention, 2010b). Agents not recommended in pregnancy because of concerns for maternal and fetal safety include podophyllin resin, podofilox 0.5-percent solution or gel, imiquimod 5-percent cream, interferon therapy, and sinecatechins.

### Neonatal Infection

Juvenile-onset recurrent respiratory papillomatosis is a rare, benign neoplasm of the larynx. It can cause hoarseness and respiratory distress in children and is often due to HPV types 6 or 11. In some cases, maternal genital HPV infection is associated with laryngeal papillomatosis, but studies differ in their findings of neonatal transmission rates. Although some have reported rates as high as 50 percent, it is likely that these findings are from maternal contamination or transient HPV infection (Campisi, 2010; Winer, 2004). A Danish population-based study indicated a neonatal transmission risk of 7 per 1000 infected women (Silverberg, 2003). Prolonged rupture of membranes was associated with a twofold increased risk, but risk was not associated with delivery mode. This low transmission risk has been confirmed in subsequent studies (Heim, 2007; Smith, 2004). Finally, long-term follow-up studies are consistent with a very low vertical transmission risk (Manns, 1999; Smith, 2004). The benefit of cesarean delivery to decrease transmission risk is unknown, and thus it is currently not recommended solely to prevent HPV transmission (Centers for Disease Control and Prevention, 2010b). HPV vaccination may decrease the rate over time (Hawkes, 2008; Kim, 2008).

### Immunization

Two HPV inactivated vaccines are currently licensed in the United States. These are a quadrivalent vaccine (Gardasil) containing HPV types 6, 11, 16, and 18 and a bivalent vaccine (Cervarix) containing HPV types 16 and 18. The vaccines are both a three-dose series and are licensed for females and males aged ≤ 26 years. They are effective for males (Giuliano, 2011). The vaccines are not recommended for pregnant women, however, inadvertent exposures do occur. Garland and coworkers (2009) analyzed data on these exposures from five Phase III clinical trials of Gardasil. They found no adverse pregnancy outcomes associated with the vaccine. Wacholder and associates (2010) pooled data from two multicenter Phase III trials and found no association between HPV vaccination and miscarriage risk. Postlicensure surveillance is ongoing using a manufacturer pregnancy registry (American College of Obstetricians and Gynecologists, 2010a). Women who are breast feeding may receive the vaccine. If a woman is found to be pregnant after starting the vaccination series, the remaining doses should be delayed until after delivery.

### VAGINITIS

Pregnant women commonly develop increased vaginal discharge, which in many instances is not pathological (Chap. 4, p. 50). The vaginal microbial flora provides protection against vaginal infection. Elucidation of the composition and function of the normal vaginal microflora is currently underway with the human microbiome project (Lamont, 2011).

### Bacterial Vaginosis
Not an infection in the ordinary sense, bacterial vaginosis (BV) is a maldistribution of normal vaginal flora. Numbers of lactobacilli are decreased, and overrepresented species are anaerobic bacteria that include *Gardnerella vaginalis*, *Mobiluncus*, and some *Bacteroides* species. As many as 30 percent of childbearing-aged women have bacterial vaginosis (Allsworth, 2007; Koumans, 2007; Simhan, 2008). Vitamin D deficiency has been identified as a risk factor for vaginosis in pregnancy. Moreover, douching, multiple partners, young age, smoking, and black race are associated with vaginosis in both pregnant and nonpregnant women (Bodnar, 2009; Desseauve, 2012; Hensel, 2011). In pregnancy, it is associated with preterm birth, early and late miscarriage, low birthweight, and increased neonatal morbidity (Goldenberg, 2008; Laxmi, 2012). Treatment is reserved for symptomatic women, who usually complain of a fishy-smelling discharge. Preferred treatment is metronidazole, 500 mg twice daily orally for 7 days; 250 mg three times daily orally for 7 days; or clindamycin 300 mg orally twice daily for 7 days (Centers for Disease Control and Prevention, 2010b). Unfortunately, although eradication is possible, treatment does not reduce preterm birth rates, and routine screening is not recommended (McDonald, 2007).

### Trichomoniasis

*Trichomonas vaginalis* can be identified during prenatal examination in up to 20 percent of women. Symptomatic vaginitis is much less prevalent, and it is characterized by foamy leukorrhea, pruritus, and irritation. Trichomonads are seen readily in fresh vaginal secretions as flagellated, pear-shaped, motile organisms that are somewhat larger than leukocytes.

Metronidazole, administered orally in a single 2-g dose, is effective in eradicating *T vaginalis* (Centers for Disease Control and Prevention, 2010b). It may be used at any gestational age—multiple studies have not shown an association between metronidazole use in any trimester of pregnancy and neonatal effects, including malformations (Briggs, 2011). Some studies have linked trichomonal infection with preterm birth, however, treatment has not decreased this risk (Gulmezoglu, 2011; Wendel, 2007). Thus, screening and treatment of asymptomatic women is not recommended during pregnancy.

### Candidiasis

*Candida albicans* or other *Candida* species can be identified by culture from the vagina during pregnancy in approximately 25 percent of women. Asymptomatic colonization requires no treatment. However, the organism may sometimes cause an extremely profuse, irritating discharge associated with a pruritic, tender, edematous vulva. Effective treatment is given with a number of azole creams that include 2-percent butoconazole, 1-percent clotrimazole, 2-percent miconazole, and 0.4- or 0.8-percent terconazole applied for 7 days (Centers for Disease Control and Prevention, 2010b). Topical treatment is recommended, but as described in Chapter 12 (p. 247), oral azoles are generally considered safe (Pitsouni, 2008). In some women, infection is likely to recur and require repeated treatment during pregnancy. In these cases, symptomatic infection usually subsides after pregnancy (Sobel, 2007).

### HUMAN IMMUNODEFICIENCY VIRUS

Acquired immunodeficiency syndrome (AIDS) was first described in 1981, and it is currently one of the worst global health pandemics in recorded history. Worldwide, it was estimated in 2012...
that there were 35.3 million infected persons with HIV/AIDS; 2.3 million new cases of HIV infection; and 1.6 million HIV-related deaths (UNAIDS, 2013). In the United States through 2011 the Centers for Disease Control and Prevention (2013a) estimated that there were more than 1.1 million infected individuals and more than 636,000 deaths (Centers for Disease Control and Prevention, 2013a). In 2010, women accounted for 20 percent of all HIV/AIDS cases among adults and adolescents, most of which resulted from heterosexual contact. Comparing 2008 with 2011, HIV incidence decreased in women, primarily black/African American women and women acquiring HIV through heterosexual contact.

The estimated number of perinatally acquired AIDS cases has decreased dramatically during the past two decades (Fig. 65-8). This is predominantly due to the implementation of prenatal HIV testing and antiviral therapy given to the pregnant woman and then to her neonate (De Cock, 2012). In addition, highly active antiretroviral therapy (HAART) has led to an increasing number of people living with chronic HIV infection and thus the associated comorbidities also affecting pregnancy (Fenton, 2007).

**FIGURE 65-8** Estimated number of perinatally acquired AIDS cases by year of diagnosis, 1985 to 2010, in the United States and dependent areas. (Data from the Centers for Disease Control and Prevention, 2011a.)

**Etiopathogenesis**

Causative agents of AIDS are RNA retroviruses termed **human immunodeficiency viruses**, HIV-1 and HIV-2. Most cases worldwide are caused by HIV-1 infection. Transmission is similar to
hepatitis B virus, and sexual intercourse is the major mode. The virus also is transmitted by blood or blood-contaminated products, and infected mothers may infect their fetuses perinatally or by their breast milk. The primary determinant of HIV-1 transmission is the plasma HIV-1 viral load.

The common denominator of clinical illness with AIDS is profound immunodeficiency that gives rise to various opportunistic infections and neoplasms. Sexual transmission occurs when mucosal dendritic cells bind to the HIV envelope glycoprotein gp120. These dendritic cells then present the viral particle to thymus-derived lymphocytes, that is, T lymphocytes. These lymphocytes are defined phenotypically by the cluster of differentiation 4 (CD4) glycoprotein surface antigens. The CD4 site serves as a receptor for the virus. Coreceptors are necessary for viral entry into the cell, and two chemokine receptors—CCR5 and CXCR4—are the most frequently identified (Fauci, 2012; Sheffield, 2007). The CCR5 coreceptor is found on the cell surface of CD4 positive (CD4+) cells in high progesterone states such as pregnancy, possibly aiding viral entry (Sheffield, 2009).

After initial infection, the level of viremia usually decreases to a set point, and patients with the highest viral burden at this time progress more rapidly to AIDS and death (Fauci, 2007, 2012). As shown in Figure 65-9, viral burden and neonatal infection incidence are directly related. Over time, the number of T cells drops insidiously and progressively, resulting eventually in profound immunosuppression. Although it is thought that pregnancy has minimal effects on CD4+ T-cell counts and HIV RNA levels, the latter are often higher 6 months postpartum than during pregnancy. Higher levels of inflammatory cytokines and a decrease in regulatory T cells in late pregnancy may contribute to maternal and fetal morbidity (Richardson, 2011).

![FIGURE 65-9](image)

**FIGURE 65-9** Incidence of perinatal human immunodeficiency virus (HIV) infection plotted against plasma HIV-1 RNA levels in 1542 neonates born to mothers in the Women and Infants Transmission Study. (Data from Cooper, 2002.)

### Clinical Manifestations

The incubation period from exposure to clinical disease is days to weeks, and the average is 3 to 6 weeks. Acute HIV infection is similar to many other viral syndromes and usually lasts less than 10
days. Common symptoms include fever and night sweats, fatigue, rash, headache, lymphadenopathy, pharyngitis, myalgias, arthralgias, nausea, vomiting, and diarrhea. After symptoms abate, the set point of chronic viremia is established. The progression from asymptomatic viremia to AIDS has a median time of approximately 10 years (Fauci, 2008). Route of infection, the pathogenicity of the infecting viral strain, the initial viral inoculum, and the immunological status of the host all affect the rapidity of progression.

Several clinical and laboratory manifestations will herald disease progression. Generalized lymphadenopathy, oral hairy leukoplakia, aphthous ulcers, and thrombocytopenia are common. A number of opportunistic infections associated with AIDS include esophageal or pulmonary candidiasis; persistent herpes simplex or zoster lesions; condyloma acuminata; pulmonary tuberculosis; cytomegaloviral pneumonia, retinitis, or gastrointestinal disease; molluscum contagiosum; \textit{Pneumocystis jiroveci} pneumonia; toxoplasmosis; and others. Neurological disease is common, and approximately half of patients have central nervous system symptoms. A CD4$^+$ count $< 200$/mm$^3$ is also considered definitive for the diagnosis of AIDS.

There are unique gynecological issues for women with HIV, such as menstrual abnormalities, contraceptive needs, and genital neoplasia, that are discussed in \textit{Williams Gynecology}, 2nd edition (Werner, 2012). Some of these as well as other STIs may persist into pregnancy (Cejtin, 2003; Stuart, 2005). Repeated pregnancy has no significant effect on the clinical or immunological course of viral infection (Minkoff, 2003).

### Prenatal HIV Screening

The Centers for Disease Control and Prevention (2006, 2010a), The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2011), and the United States Preventive Services Task Force (2012) recommend prenatal HIV screening using an \textit{opt-out approach}. This means that the woman is notified that HIV testing is included in a comprehensive set of antenatal tests, but that testing may be declined. Women are given information regarding HIV but are not required to sign a specific consent. Through the use of such \textit{opt-out} strategies, HIV testing rates have increased. Each provider should be aware of specific state laws concerning screening.

In areas in which the incidence of HIV or AIDS is 1 per 1000 person-years or greater, or if women at high risk for acquiring HIV during pregnancy, repeat testing in the third trimester is recommended (American College of Obstetricians and Gynecologists, 2011). High-risk factors include injection drug use, prostitution, a suspected or known HIV-infected sexual partner, multiple sexual partners, or a diagnosis of another sexually transmitted disease. Several states also recommend or require HIV testing at delivery.

Screening is performed using an enzyme-linked immunoassay with a sensitivity $> 99.5$ percent. A positive test is confirmed with either a Western blot or immunofluorescence assay (IFA), both of which have high specificity. According to the Centers for Disease Control and Prevention (2001), antibody can be detected in most patients within 1 month of infection, and thus, antibody serotesting may not exclude early infection. For acute primary HIV infection, identification of viral p24 core antigen or viral RNA or DNA is possible. False-positive confirmatory results are rare (Centers for Disease Control and Prevention, 2010b).

Women with limited prenatal care or with undocumented HIV status at delivery should have a “rapid” HIV test performed. These tests can detect HIV antibody in 60 minutes or less and have sensitivities and specificities comparable with those of conventional ELISAs (Chetty, 2012). A negative rapid test result does not need to be confirmed. However, in a woman exposed to HIV...
within the last 3 months, repeat testing is recommended. A positive rapid test result should be confirmed with a Western blot or IFA test. As shown in Table 65-6, peripartum and neonatal interventions to reduce perinatal transmission are based on the initial rapid testing results, and this can be discontinued if the confirmatory test is negative (American College of Obstetricians and Gynecologists, 2011; Centers for Disease Control and Prevention, 2010b). A detailed list of the rapid HIV tests currently available in the United States can be found at http://www.cdc.gov/hiv/topics/testing/resources/factsheets/rt-lab.htm (Centers for Disease Control and Prevention, 2007). The Mother-Infant Rapid Intervention at Delivery (MIRIAD multicenter study indicated that rapid HIV testing can be used to identify infected women so that peripartum antiretroviral prophylaxis can be administered to mother and infant (Bultery, 2004).

If the rapid HIV test result in labor and delivery is positive, the obstetrical provider should take the following steps:

1. Tell the woman she may have HIV infection and that her neonate also may be exposed
2. Explain that the rapid test result is preliminary and that false-positive results are possible
3. Assure the woman that a second test is being performed to confirm the positive rapid test result
4. To reduce the risk of transmission to the infant, immediate initiation of antiretroviral prophylaxis should be recommended without waiting for the results of the confirmatory test
5. Once the woman gives birth, discontinue maternal antiretroviral therapy pending receipt of confirmatory test results
6. Tell the women that she should postpone breast feeding until the confirmatory result is available because she should not breast feed if she is infected with HIV
7. Inform pediatric care providers (depending on state requirements) of positive maternal test results so that they may institute the appropriate neonatal prophylaxis

Summarized from American College of Obstetricians and Gynecologists, 2011.

### Maternal and Perinatal Transmission

Transplacental HIV transmission can occur early, and the virus has even been identified in specimens from elective abortion (Lewis, 1990). In most cases, however, mother-to-child transmission at the time of delivery is the most common cause of pediatric HIV infections. Between 15 and 40 percent of neonates born to non–breast-feeding, untreated, HIV-infected mothers are infected. Kourtis and colleagues (2001) have proposed a model for estimation of the temporal distribution of vertical transmission. They estimate that 20 percent of transmission occurs before 36 weeks’ gestation, 50 percent in the days before delivery, and 30 percent intrapartum. Transmission rates for breast feeding may be as high as 30 to 40 percent and are associated with systemic HIV viral burden (Kourtis, 2006, 2007a; Slyker, 2012). Vertical transmission is more common with preterm births, especially with prolonged membrane rupture. Analyzing data from the Perinatal AIDS Collaborative Transmission Study, Kuhn and coworkers (1999) reported a nearly fourfold increased risk with preterm delivery. Although an increased risk of perinatal transmission has been associated with membrane rupture in the past, recent analyses in the setting
of combination antiviral therapy have not found this to be a risk factor with an HIV viral load < 1000 copies/mL (Cotter, 2012).

In nonpregnant individuals, there is an association between concomitant STIs and horizontal HIV transmission. There is also evidence that vertical perinatal transmission may be increased with STIs (Schulte, 2001; Watts, 2012). Women with maternal HSV-2 antibody have a significant 50-percent increased risk of intrapartum HIV-1 maternal-to-child transmission (Cowan, 2008). They attributed up to 25 percent of vertical transmission to maternal HSV-2 co-infection. Elevated cytokine and chemokine levels in the placenta, reflecting inflammation, are associated with in utero transmission (Kumar, 2012). A recent Cochrane analysis, however, has failed to show that sexually transmitted infection control is an effective HIV prevention strategy (Ng, 2011).

Perinatal HIV transmission is most accurately correlated with maternal plasma HIV RNA burden (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012; Watts, 2002). As shown in Figure 65-9, cohort neonatal infection was 1 percent with < 400 copies/mL, and it was > 30 percent when maternal viral RNA levels were > 100,000 copies/mL. Transmission of HIV infection, however, has been observed at all HIV RNA levels, including those that were undetectable by current assays. This may be attributed to discordance between the viral load in plasma and that in the genital secretions. Because of these findings, the viral load should not be used to determine whether to initiate antiretroviral therapy in pregnancy.

### Preconceptional Counseling

Effective contraception should be discussed if pregnancy is undesired. Certain antiviral medications decrease hormonal contraception efficacy and are discussed in Chapter 38 (p. 708). Recommendations are also available at [http://AIDSinfo.nih.gov](http://AIDSinfo.nih.gov) and are updated frequently as new data become available. Counseling also includes education for decreasing high-risk sexual behaviors to prevent transmission and to decrease the acquisition of other sexually transmitted diseases. Currently used antiretroviral medications are reviewed to avoid those with high teratogenic potential should the woman become pregnant. A specific example is efavirenz, which has significant teratogenic effects on primate fetuses (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). Preference should also include those that decrease HIV RNA viral load effectively before pregnancy.

### Management During Pregnancy

These women need special attention and are seen in consultation by physicians with special interest in this field. At Parkland Hospital, the initial assessment of an HIV-infected pregnant woman includes:

- Standard prenatal laboratory surveys that include serum creatinine, hemogram, and bacteriuria screening (Chap. 9, p. 171)
- Plasma HIV RNA quantification—“viral load,” CD4+ T-lymphocyte count, and antiretroviral resistance testing
- Serum hepatic aminotransferase levels
- HSV-1 and -2, cytomegalovirus, toxoplasmosis, and hepatitis C serology screening
- Baseline chest radiograph
• Tuberculosis skin testing—purified protein derivative (PPD) or interferon-gamma release assay
• Evaluation of need for pneumococcal, hepatitis B, hepatitis A, Tdap, and influenza vaccines
• Sonographic evaluation to establish gestational age.

Antiretroviral Therapy

Treatment is recommended for all HIV-infected pregnant women. This may be a departure for those not receiving treatment when nonpregnant because they did not meet certain criteria. Treatment reduces the risk of perinatal transmission regardless of CD4⁺ T-cell count or HIV RNA level. Antiretroviral therapy is complicated, and pregnancy only adds to the complexity. In general, HAART is begun if the woman is not already receiving one of the regimens. Antiretroviral agents are grouped into several classes and used to design antiretroviral regimens (Table 65-7). The 2012 Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission classify each agent into five use categories: preferred, alternative, use in special circumstances, not recommended, and insufficient data to recommend use. The woman is counseled regarding risks and benefits of antiretroviral agents to make an informed decision as to her treatment regimen. Regardless of what regimen is begun, adherence is important because the risk of viral drug resistance is lessened.

*Insufficient data to recommend use.
pregnancy (Table 65-8). Women already taking HAART at pregnancy onset are encouraged to continue the regimen if there is adequate viral suppression. The neural-tube defect risk associated with efavirenz is restricted to the first 6 weeks of pregnancy. Thus, efavirenz can be continued if the woman presents after this time and if adequate virological suppression is documented. Until recently, addition of zidovudine to all regimens was recommended. Currently, however, in women with adequate viremia suppression with a regimen not containing zidovudine, continuation of the current regimen is appropriate. Zidovudine is given intravenously during labor and delivery to women with an HIV RNA viral load > 400 copies/mL or who have an unknown viral load near delivery (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012). A 2 mg/kg load is infused over 1 hour followed by zidovudine 1 mg/kg/hr until delivery.

| HIV-infected woman taking antiretroviral therapy who becomes pregnant | **Antiretroviral naïve**—fall into two categories. First, women who meet the criteria for antiretroviral therapy initiation in nonpregnant adults are given HAART regardless of trimester. Because of an increased risk of hepatotoxicity, nevirapine is reserved for women with a CD4⁺ cell count < 250 cells/mm³. In general, the starting HAART regimen is two nucleoside reverse transcriptase inhibitors (NRTIs) plus a non-nucleosid

Women who have never received antiretroviral therapy—*antiretroviral naïve*—fall into two categories. First, women who meet the criteria for antiretroviral therapy initiation in nonpregnant adults are given HAART regardless of trimester. Because of an increased risk of hepatotoxicity, *nevirapine* is reserved for women with a CD4⁺ cell count < 250 cells/mm³. In general, the starting HAART regimen is two nucleoside reverse transcriptase inhibitors (NRTIs) plus a non-nucleoside...
reverse transcriptase inhibitor (NNRTI) or protease inhibitor(s). At Parkland Hospital as of 2014, our standard regimen in treatment-naïve women is lopinavir/ritonavir—formulated as Kaletra—plus zidovudine/lamivudine—formulated as Combivir. The lopinavir/ritonavir regimen should be increased in the late second and third trimester. Atazanavir, another protease inhibitor, is also now listed as a preferred agent and can be used in place of lopinavir/ritonavir. If used, it is combined with low-dose ritonavir boosting.

The second category contains treatment-naïve HIV-infected pregnant women who do not meet nonpregnant adult indications for antiretroviral therapy. These women are counseled regarding the benefits of initiating therapy to prevent perinatal viral transmission. Because of potential teratogenic effects, women may delay therapy until the second trimester. That said, however, earlier initiation may be more effective in reducing perinatal transmission (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012; Read, 2012).

Women who have previously received antiretroviral therapy but are currently not taking medications should undergo HIV resistance testing because antiretroviral use increases their risk of drug resistance. Regimens may then be tailored based on prior medication use and response as well as current resistance patterns. The final group includes women who present in labor and who are taking no medications. These women are given intravenous zidovudine intrapartum (see Table 65-8). The National Perinatal HIV Hotline (1–888–448–8765) is a federally funded service that provides free consultation to providers.

**Laboratory Assessment**

CD4+ T-lymphocyte count, HIV RNA viral load measurement, complete blood count, and liver function tests are done 4 weeks after beginning or changing therapy to assess response and exclude toxicity. Thereafter, HIV RNA viral loads are measured monthly until RNA levels are undetectable. CD4 T-lymphocyte and HIV RNA levels can then be measured every trimester. If the HIV RNA viral load increases or does not decrease appropriately, then medication compliance and antiretroviral drug resistance are assessed. Poor adherence to therapy is a significant problem in pregnancy.

Although there was an association of early studies with glucose intolerance and protease inhibitor use, this has not been corroborated (Hitti, 2007; Tang, 2006). Standard serum glucose screening should be performed at 24 to 28 weeks unless indicated earlier. In addition, careful surveillance is important for interactions between antiretroviral drugs as well as therapies for opportunistic infection, hepatitis B and C, and tuberculosis (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012; Piscitelli, 2001).

**Complications of HIV Infection**

Management of some HIV complications may be altered by pregnancy. If the CD4+ T-cell count is < 200/mm³, primary prophylaxis for Pneumocystis jiroveci (formerly P carinii) pneumonia is recommended with sulfamethoxazole-trimethoprim or dapsone. Pneumonitis is treated with oral or IV sulfamethoxazole-trimethoprim or dapsone-trimethoprim. Other symptomatic opportunistic infections that may develop are from latent or newly acquired toxoplasmosis, herpes virus, mycobacteria, and candida. The National Institutes of Health, Centers for Disease Control and Prevention, and Infectious Diseases Society of America (2013) have published guidelines for prevention and treatment of opportunistic infections. Maternal HIV infection has also been associated with fetal-growth restriction, preeclampsia, and preterm membrane rupture (Ndirangu, 2012; Rollins, 2007; Suy, 2006).
**Perinatal Outcomes**

Even with treatment, the incidence of perinatal complications in HIV-infected women is increased, although the newer drug regimens may diminish these rates. Multiple studies reviewed in the 2012 Perinatal Treatment Guidelines address the association of antiretroviral medications with preterm delivery. Most of those have shown a small but significantly increased risk. Kourtis and colleagues (2007b) performed a metaanalysis of 14 European and U.S. studies and found an overall greater risk for preterm delivery. They did find, however, that women taking regimens that included a protease inhibitor had a small increased risk—1.3-fold—that was nevertheless significant. Antiretroviral medication use in the second half of pregnancy was shown by Lopez and associates (2012) to increase iatrogenic preterm birth but did not affect spontaneous preterm birth rates. This slightly increased frequency of preterm birth clearly is outweighed by the benefits of decreasing perinatal HIV transmission.

**Medication Toxicity**

At least two follow-up studies of children from the Pediatric AIDS Clinical Trial Group (PACTG) 076 Study found no adverse effects at 18 months and up to a mean of 5.6 years after zidovudine exposure (Culnane, 1999; Sperling, 1998). Prenatal exposure to HAART may increase the risk for neonatal neutropenia and anemia, although no long-term hematological or hepatic toxicities have been documented (Bae, 2008; Dryden-Peterson, 2011). Preliminary data also show a possible effect on infant mitochondrial DNA proliferation and/or expression with maternal antiretroviral drug treatment (Cote, 2008; Hernandez, 2012; Jitratkosol, 2012). For these reasons, long-term follow-up is recommended for all infants exposed in utero to antiviral medications.

**Prenatal HIV Transmission**

Maternal HAART treatment along with intrapartum zidovudine prophylaxis has dramatically reduced the perinatal HIV transmission risk from approximately 25 percent to 2 percent or less. HAART during pregnancy was reported to be associated with a decreased incidence of placental villitis, which may partially account for the lower HIV transmission rate in treated women (Stewart, 2014a). Optimal management of labor is uncertain, but if labor is progressing with intact membranes, artificial rupture and invasive fetal monitoring are avoided. Labor augmentation is used when needed to shorten the interval to delivery to further decrease the transmission risk. Operative delivery with forceps or vacuum extractor is avoided if possible. Postpartum hemorrhage is managed with oxytocin and prostaglandin analogues. Methergine and other ergot alkaloids adversely interact with reverse transcriptase and protease inhibitors to cause severe vasoconstriction.

Cesarean delivery has been recommended to decrease HIV prenatal transmission. An earlier metaanalysis of 15 prospective cohort studies by the International Perinatal HIV Group (1999) included 8533 mother-neonate pairs. Vertical HIV transmission was shown to be reduced by about half when cesarean was compared with vaginal delivery. When antiretroviral therapy was given in the prenatal, intrapartum, and neonatal periods along with cesarean delivery, the likelihood of neonatal transmission was reduced by 87 percent compared with vaginal delivery and without antiretroviral therapy. The European Mode of Delivery Collaboration (1999) has reported similar findings.

Based on these observations, the American College of Obstetricians and Gynecologists (2010b) concluded that scheduled cesarean delivery should be discussed and recommended for HIV-infected women whose HIV-1 RNA load exceeds 1000 copies/mL. Scheduled delivery is recommended at 38 weeks’ gestation in these women. Although data are insufficient to estimate...
such benefits for women whose HIV RNA levels are < 1000 copies/mL, it is unlikely that scheduled cesarean delivery would confer additional risk reduction if the woman has been taking antiviral therapy (Jamieson, 2007; Read, 2005). If cesarean delivery is performed for obstetrical indications, it should be performed at 39 weeks with standard perioperative antimicrobials for prophylaxis. HIV-infected women undergoing a scheduled cesarean delivery should be given IV zidovudine as a loading dose followed by 2 more hours of continuous maintenance therapy—a total of 3 hours of infused zidovudine.

Breast Feeding

Vertical transmission is increased by breast feeding, and it generally is not recommended for HIV-positive women in the United States (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012; Read, 2003). The probability of HIV transmission per liter of breast milk ingested is estimated to be similar in magnitude to heterosexual transmission with unsafe sex in adults (Richardson, 2003). As with other exposures, risk is related to the maternal HIV RNA level, HIV disease status, breast health, and duration of breast feeding (De Cock, 2000; John-Stewart, 2004). Most transmission occurs in the first 6 months, and as many as two thirds of infections in breast-fed infants are from breast milk. In the Petra Study Team (2002) from Africa, the prophylactic benefits of short-course perinatal antiviral regimens were diminished considerably by 18 months of age due to breast feeding. The World Health Organization (2010) has recommended exclusive breast feeding the first 6 months of life for infants of women living in developing countries in which infectious diseases and malnutrition are the primary causes of infant deaths. Breast feeding can be continued for 12 months until a nutritionally adequate diet is available.

Postpartum Management

Many otherwise healthy women with normal CD4+ T-cell counts and low HIV RNA levels may discontinue treatment after delivery and be closely monitored according to adult guidelines. The exception is the woman who plans another pregnancy in the near future. Stewart and colleagues (2014b) showed that interpregnancy viral load suppression is associated with less vertical transmission in a subsequent pregnancy. Psychosocial support is essential during this time, especially while awaiting diagnostic testing for pediatric infection. Contraceptive needs are complex and also may entail condoms in discordantly infected couples. As discussed in Chapter 38 (p. 708), antiretroviral drugs may affect oral contraceptive hormone levels and possibly of injectable agents (Stuart, 2012). Intrauterine devices may be an acceptable choice in some women with normal immunocompetence and a low risk for STIs. The Centers for Disease Control and Prevention has recently revised the recommendations for the use of hormonal contraception among women at high risk for HIV infection or infected with HIV (Tepper, 2012). It reaffirmed prior recommendations that hormonal contraception use is safe for these women and that condom use should be encouraged regardless of contraceptive method.

<sup>a</sup>Unless otherwise specified, all normal reference values are from the seventeenth edition of *Harrison’s Principles of Internal Medicine* (37).

<sup>b</sup>Range includes references with and without iron supplementation.

<sup>c</sup>Reference values are from *Laboratory Reference Handbook*, Pathology Department, Parkland Hospital, 2005.

<sup>d</sup>Normal reference range is specific range for females.

<sup>e</sup>Reference values are from the 15th edition of *Harrison’s Principles of Internal Medicine* (12).

<sup>f</sup>Range is for premenopausal females and varies by menstrual cycle phase.

<sup>g</sup>Reference values are from Cerneca et al: Coagulation and fibrinolysis changes in normal pregnancy increased levels of procoagulants and reduced levels of inhibitors during pregnancy induce a hypercoagulable state, combined with a reactive fibrinolysis (15).

<sup>h</sup>Reference values are from Cerneca et al and Choi et al: Tissue plasminogen activator levels change with plasma fibrinogen concentrations during pregnancy (15, 16).

<sup>i</sup>Reference values are from Mannucci et al: Changes in health and disease of the metalloprotease that cleaves von Willebrand factor (44A).

<sup>j</sup>Reference values are from Bacq et al: Liver function tests in normal pregnancy: a prospective study of 102 pregnant women and 102 matched controls (5).

<sup>k</sup>Reference values are from Leiserowitz et al: Creatine kinase and its MB isoenzyme in the third trimester and the peripartum period (41).

<sup>l</sup>Reference values are from Dunlop: Serial changes in renal haemodynamics during normal human pregnancy (19). Appendix courtesy of Dr. Mina Abbassi-Ghanavati and Dr. Laura G. Greer.

</table>

Values are ranges or means ± SD.
Circ = circumference; d = diastolic; ESS = end-systolic wall stress; FS = fractional shortening; IVRT = isovolumic relaxation time; IVS<sub>d</sub> = interventricular septum-diastole; LV = left ventricle; LVEDD = left ventricular end-diastolic dimension; LVESD = left ventricular end-systolic dimension; PW = posterior wall; RWT = relative wall thickening; SW = septal wall; VCFC = rate-adjusted mean velocity of circumferential fiber thickening.

Data from Savu (62A) and Vitarelli (71A).

Antifungal agents, teratogenicity of, 247
Anti-Fy, 307
Antihistamine(s)
in dermatological disorders, 1217
in pemphigoid gestationis, 1216
and topical emollients, in pruritus, 1085

Antihypertensive(s)
for chronic hypertension, 1005–1007
for gestational hypertension, 761–763
and oral contraceptives, interactions, 708
in preeclampsia, 749

Antiinflammatory agent(s)
leflunomide, 247–248
nonsteroidal antiinflammatory drugs, 247
and oral contraceptives, interactions, 708
teratogenicity of, 247–248

Antiinflammatory component, of pregnancy, 56

Anti-Jk\(a\), 307

Antileukotrienes, for asthma, 1014

Antimicrobial drug(s)
- aminoglycosides, 248
- for asymptomatic bacteriuria in pregnancy, 1053
- before cesarean delivery, 590
- chloramphenicol, 248
- nitrofurantoin, 248
- pyelonephritis and, 1055
- sulfonamides, 248
- teratogenicity of, 248
- tetracyclines, 248

Antineoplastic agent(s)
- cyclophosphamide, 248
- methotrexate, 248–249
- tamoxifen, 249
- teratogenicity of, 248–249
- trastuzumab, 249

Antineutrophil cytoplasmic antibodies, 1149
Antinuclear antibodies, 1170
Antioxidants, in preeclampsia, 749

Antiphospholipid antibodies, 259, 1174
- and pregnancy, 1174
- and thromboembolism, 1033

Antiphospholipid antibody syndrome (APS), 259, 1173–1176
- clinical features, 1173, 1173
- diagnosis, 1174
- and fetal-growth restriction, 878–879
- against natural anticoagulants, 1174
- specific, 1173–1174

Antiphospholipid syndrome, 1033

Antipsychotics
- for mental disorders in pregnancy, 1208
- teratogenicity of, 250, 251

Antiretroviral drugs, classes of, 1280
Antiretroviral therapy, 1279
Anti-ribonucleoprotein, 1172

Antithrombin, 57, 1030
deficiency, 1030
heparin in, 1031
pregnancies outcomes in, 1030–1031
in pregnancy, 1030–1031
prevalence of, 1030
type I, 1030
type II, 1030
function of, 1030
Antithrombin III, functional
  in nonpregnant adult, 1288
  in uncomplicated pregnancy, 1288
Antithrombotic agents, in preeclampsia, 749
Antiviral agents
  recommendations for, 1281
  teratogenicity of, 249
Antiviral medications, 1274
Anxiety disorder(s), 1210
  in pregnancy, 1210
  treatment of, 1208, 1210
Aortic coarctation, 993–994
Aortic dissection, 992–993
Aortic insufficiency, 983
Aortic stenosis, 983
Aortic valvuloplasty, for critical aortic stenosis, 331
Apgar scoring system, 627–628, 627
  low, and neurological impairment, 639, 642
Aplastic anemia, 1106–1107
Apnea, in neonates, 625
Apolipoprotein A-I, normal laboratory values
  in nonpregnant adult, 1291
  in uncomplicated pregnancy, 1291
Apolipoprotein B, normal laboratory values
  in nonpregnant adult, 1291
  in uncomplicated pregnancy, 1291
Apolipoprotein H, 1173
Aponeuroses, 16
Appendiceal computed tomography, 1079
Appendicitis, 1078–1080
  computed tomography in, 1079
  diagnosis of, 1079
  incidence of, 1078–1079
laparoscopic surgery in pregnancy for, 1079
management of, 1079
MR imaging in, 1079, 1079f
postpartum, 1080
pregnancy outcomes, 1079–1080
sonography in, 1079

Aquaporins, 410
Aqueductal stenosis, 224f
Arachnoiditis, spinal (subarachnoid) block and, 512
Arcuate uterus (class VI), 41
Argatroban, for heparin-induced thrombocytopenia, 1040
Arginine vasopressin (AVP), 144
from fetal pituitary gland, 141
Arias-Stella reaction, 49
Aromatase deficiency of
and adult growth pattern, 110
fetal-placental, 110
Arrest disorder, 459
Arrest of descent
Arrest of dilatation, 446
Arrhythmia(s), 991–992
bradyarrhythmias, 991–992
cardiac, 481–482
medical therapy in, 321–323
bradyarrhythmias, 322–323
premature atrial contractions, 321
tachyarrhythmias, 321–322
prolonged QT-interval, 992
supraventricular tachycardias, 992
ventricular tachycardia, 992
Arrhythmogenic right ventricular dysplasia, 990
Arterial thromboembolism, rFVIIa use and, 817
Arteriovenous malformations (AVMs), 1194
bleeding from, 1194
in pregnancy, 1194
treatment of, 1194
Arteriovenous oxygen, maternal, 63
Asherman syndrome, 258–259
Ashkenazi Jewish descent
preconceptional counseling of, 161
recessive diseases in, 297
Tay-Sachs disease in, 296–297
Aspartate aminotransferase (AST)
- normal laboratory values
  - in nonpregnant adult, 1289
  - in uncomplicated pregnancy, 1289
Asphyxia neonatorum, 638
Aspiration, 519–520
  - fasting, 519–520
  - pathophysiology of, 520
  - treatment of, 520
Aspirin
  - low-dose
    - plus heparin in preeclampsia, 749
    - for preeclampsia prevention, 749, 749t
      - and oral contraceptives, interactions, 708t
    - in thrombocytosis, 1115
Assisted reproductive technology (ART), and monozygotic twinning, 892
Asthma, 1011–1015
  - acute, management of, 1015
  - chronic, management of, 1014–1015
  - clinical evaluation of, 1014
  - clinical stages of, 1012–1014, 1012f
  - environmental allergic stimulant and, 1012
  - fetal effects of drugs, 1014
  - fetal response to maternal hypoxemia, 1014
  - forced expiratory volume at 1 second in, 1014
  - and labor and delivery, 1015
  - pathophysiology of, 1012
  - pregnancy and, 1013–1014
  - effects of, 1013
  - outcomes of, 1013–1014
    - severity classification, 1012t
  - treatment of
    - antileukotrienes for, 1014
    - cromones for, 1014
    - inhaled β–agonists for, 1014–1015
    - inhaled corticosteroids for, 1014–1015
    - stepwise approach to, 1014f
    - theophylline for, 1015
Asymptomatic viral shedding, 1272
Asynclitism, 439, 441f
anterior, 439, 441f
posterior, 439, 441f

Atazanavir, 1280
Atelectasis, and puerperal fever, 682
Atopic eruption of pregnancy (AEP), 1216
Atosiban, for preterm labor, 853
Atrial flutter, 322f
Atrial isomerism, 209
Atrial natriuretic peptide (ANP), 422–423
  normal laboratory values
  in nonpregnant adult, 1291
  in uncomplicated pregnancy, 1291
    in phase 2 of parturition, 522–523
    in preeclampsia, 739
Atrial natriuretic peptide converting enzyme, 876
Atrial septostomy, for hypoplastic left heart, 331
Atrophy, of lower extremity, 1240f
Atypical glandular cells of undetermined significance (AGUS), 1221
Autism spectrum disorders, 643
Autoimmune adrenalitis, 1161
Autoimmune hemolysis, 1104–1105
Autoimmune hepatitis, 1092
Autologous transfusion, 817
Autonomic dysreflexia, 1198
Autoregulation, 814
Autosomal dominant inheritance, 270–271
  advanced paternal age and, 270–271
  codominant genes in, 270
  expressivity in, 270
  penetrance in, 270
Autosomal dominant polycystic kidney disease (ADPKD), 216
Autosomal monosomy, 265
Autosomal recessive inheritance, 271–272
  consanguinity and, 271–272
  in ethnic groups, 295f
  inborn errors of metabolism, 271
  in individuals of Eastern European Jewish Descent, 298f
  phenylketonuria and, 271
Autosomal recessive polycystic kidney disease (ARPKD), 216
autosomal trisomy, 351
Azathioprine
in colitis, 1076
in Crohn disease, 1077

Baby Friendly Hospital Initiative, 673–674

*Bacillus anthracis*, 1258
Backache, prenatal care and, 187–188
Back pain, epidural analgesia and, 514
Bacterial infections, 1248–1254
effect of, on fetal growth, 877
group A Streptococcus, 1248–1249
group B Streptococcus, 1249–1251
Hansen disease, 1254
listeriosis, 1253
Lyme disease, 1254
MRSA, 1251–1252
salmonellosis, 1253–1254
shigellosis, 1254
transfusion-related, 818
tuberculosis, 1254
vulvar abscess, 1252–1253

Bacterial pneumonia, 1016–1018
diagnosis of, 1016
management of, 1016–1017
pregnancy outcome with, 1017
prevention of, 1017–1018

Bacterial sepsis, parenteral nutrition and, 1070
Bacterial vaginosis, 842
and preterm labor, 842
prophylaxis against, in sexual assault victim, 952t

Bacteriuria, asymptomatic, 1053–1054, 1054t
diagnosis of, 1053
incidence of, 1053
prevalence of, 1053
significance of, 1053
treatment of, 1053–1054, 1053t

β–adrenergic agonist, for asthma, 1015
β–adrenergic receptor agonists, for preterm labor, 852
Bag-and-mask ventilation, 625, 627f
Bakri balloon, for paracervical hematoma, 790
Bakri Postpartum Balloon, 786
Balloon tamponade, 1094
for uterine atony treatment, 786–787
Banana sign, 202, 290f
Bariatric surgery, for obesity, 969–970
pregnancy and, 969
recommendations for, 969–970
restrictive malabsorptive procedures in, 969
restrictive procedures in, 969
Barker hypothesis, 178
Barrier methods, of contraception, 712–713
cervical cap, 712–713
diaphragm plus spermicide, 712–713
female condom, 712, 712f
male condom, 712
Bartholin glands, 20
Baseline fetal heart activity, 476–482
abrupt baseline spiking, 481, 481f
beat-to-beat variability, 478–481
bradycardia, 478
cardiac arrhythmias, 481–482
grades of, 480f
sinusoidal pattern, 482, 482f
tachycardia, 478
wandering baseline, 478
Basophils, normal laboratory values
in nonpregnant adult, 1287
in uncomplicated pregnancy, 1287
Battledore placenta, 122
Bayley Mental Development Index, 326
β-blockers, 1160
Beat-to-beat variability, 339, 473
Bed rest, in pregnancy, 851
Behavioral Risk Factor Surveillance System, 173
Behçet disease, 1180
Bell palsy, 1197–1198, 1197f
Benadryl, in dermatological disorders, 1217
Benign intracranial hypertension. See Idiopathic intracranial hypertension

principles of, 1219–1221
surgery, 1219

*Candida albicans*, 1276

*Candida* septicemia, parenteral nutrition and, 1070
Candida vulvovaginitis infection, 1133
CAOS. *See* Chronic abruption-oligohydramnios sequence
Caput succedaneum, 444, 471, 646–647
  formation of, 444f
  in recently delivered newborn, 444f

Carbamazepine
  in bipolar disorders, 1208t
  teratogenic effects of, 1190t

Carbetocin, 595
  for postpartum hemorrhage, 547

Carbohydrate metabolism, 53, 53f
Carbon monoxide poisoning, 1023–1024
  pregnancy and, 1023–1024
  treatment of, 1024

Carboprost
  for postpartum hemorrhage, 547
  for uterine atony treatment, 785

Carcinoembryonic antigen, for colon cancer, 1334
Carcinoma in situ (CIS), 1223
Cardiac anomalies, folic acid metabolism and, 245
Cardiac arrhythmia(s), 481–482
Cardiac defects, 275
Cardiac index, calculation of, 942t
Cardiac natriuretic peptides, 61
Cardiac output, 59–60, 59f
  calculation of, 942t
Cardiac rhabdomyoma(s), 211–212
Cardiac sounds, normal, 58
Cardinal ligaments, 28
Cardinal movements of labor, 439, 440f
Cardiomyopathy, 988–990, 1130–1131
  causes of, 988t, 990
  dilated, 988–990
hypertrophic, 988
peripartum, 988–990, 989f
primary, 988
restrictive, 990
secondary, 988

Cardiopulmonary parameters
  calculation of, 942t
  formulas for, 942, 942t

Cardiopulmonary resuscitation (CPR), 956–957
  and cesarean delivery, 956–957
  considerations for, in second half of pregnancy, 956

Cardiovascular system
  physiology of, 58–62
  cardiac natriuretic peptides, 61
  cardiac output, 59–60, 59f
  circulation and blood pressure, 60–61, 61f
  endothelins, 61
  heart, 58–59
    cardiac plasticity, 59
    normal cardiac sounds, 58
  hemodynamic function in late pregnancy, 60, 60t
  nitric oxide, 61–62
  prostaglandins, 61
  renin, angiotensin II, and plasma volume, 61
    in preeclampsia, 736–738
  blood volume, 737–738, 738f
  myocardial function, 736–737
  ventricular function, 737, 737f

Carpal tunnel syndrome, 1198
  differential diagnosis of, 1198
  in pregnancy, 1198
  symptoms of, 1198

Carpe diem. See Williams Obstetrics
Catastrophic antiphospholipid antibody syndrome, 1173
Catheter sepsis, parenteral nutrition and, 1070
Caudal regression sequence, 204
Cavum septum pellucidum (CSP), 198, 200
CCAM. See Congenital cystic adenomatoid malformation (CCAM)
CCAM-volume ratio (CVR), 323–324
C3 complement, normal laboratory values
  in nonpregnant adult, 1291
C4 complement, normal laboratory values
  in uncomplicated pregnancy, 1291
  in nonpregnant adult, 1291
  in uncomplicated pregnancy, 1291
CDE (Rh) blood group incompatibility, 307
CD4 T-lymphocyte, 1280
  in pneumocystis pneumonia, 1018–1019
Cefazolin, before cesarean delivery, 590
Celiac disease, and abortion, 352
Cell-free fetal DNA testing, 279, 279f
  in congenital adrenal hyperplasia, 323
  of Down syndrome, 291–292
  recommendations for, 292
Cell histogenesis, and amnion, 99
Cell salvage, 817
Cell signaling systems, for myometrial cell, 424
Cellular adhesion molecules (CAMs), 90
Central nervous system, imaging for, 1187
Cephalic index, 198
Cephalic pole, 434
Cephalic presentation, 433–434
  longitudinal lie, 434f
Cephalocele, 201–202
Cephalohematoma(s), 646–647
  and caput succedaneum, 646–647
Cephalopelvic disproportion (CPD), 446, 455
Cephalosporin
  for asymptomatic bacteriuria in pregnancy, 1053t
  before cesarean delivery, 590
Cerclage placement
  in cervical insufficiency, 361–363, 362f
  complications of, 363
  McDonald, 362f
  modified Shirodkar, 362f
  transabdominal cerclage, 363
  and preterm birth prevention, 844
Cerebral artery thrombosis, 1192
Cerebral blood flow, 743
Cerebral edema, 745
Cerebral palsy, 638–639, 640
  Apgar scores and, 642, 642t
ataxic, 639, 640
classification of, 640
disabilities and seizure disorders with, 643
electronic fetal monitoring and, 641
hemiparetic, 639
hemiplegic cerebral palsy, 639
and hypoxic-ischemic encephalopathy, 641
intrapartum hypoxia and, 641
magnesium sulfate for prevention of, 855
neuroimaging studies in, 642–643
placental vascular anastomoses in multifetal gestation and, 906
in postterm births, 863
in preterm infants, 657–658
incidence and epidemiology of, 658
intraventricular hemorrhage and, 658
ischemia and, 658
perinatal infection and, 658–659
prevention of, 659
type of, 658
prevalence and incidence of, 640–641
risk factors for, 641, 641t
spastic diplegia, 639
spastic quadriplegic, 639, 640
umbilical cord blood gas studies and, 642
Cerebral venous thrombosis, 1193
Cerebrospinal fluid (CSF), leakage of, 512
Cerebrovascular diseases, 1191–1194. See also Stroke
Certolizumab, in Crohn disease, 1077
Ceruloplasmin, normal laboratory values
in nonpregnant adult, 1289
in uncomplicated pregnancy, 1289
Cervical abnormalities, 40
Cervical anatomical and structural integrity, 409
Cervical cancer
invasive, 1223–1224
delivery and, 1224
prognosis with, 1223–1224
radical trachelectomy, pregnancy after, 1224
sagittal T-2 weighted MRI, 1224f

    uterine torsion, 43
Uterine growth, in multifetal gestation, 898–899
Uterine hypertrophy, 47
Uterine infection, 683–686
puerperal, 683–686. See also Metritis, puerperal

Uterine inversion
- hemorrhage with, 787–788
- incidence of, 787
- incomplete, 788f
- management of, 787–788, 788f
- progressive degrees of, 787, 787f
- recognition of, 787
- risk factors for, 787
- surgical intervention for, 788, 788f
- with uterus protruding from birth canal, 787, 787f

Uterine involution, 417

*Uterine leiomyomas*, 359

Uterine myocyte contraction, 418f
- regulation of, 417

Uterine myocyte relaxation, 418f
- cGMP and cAMP role in, 417
- regulation of, 417

Uterine natural killer (uNK) cells, 98

Uterine necrosis, B-Lynch sutures and, 819

Uterine packing, for uterine atony treatment, 786

Uterine quiescence, 408–409, 408f

Uterine relaxation, 418f

Uterine rupture
- blunt trauma and, 953
- causes of, 791, 792t
- cesarean delivery and, 791
- complete, 617
- decision-to-delivery time in, 617–618
- diagnosis of, 617, 617f
- and dystocia, 470
- hemorrhage with, 790–793
- hysterectomy *versus* repair for, 618
- incidence of, 791
- incomplete, 617
- management of, 792
- maternal deaths from, 617–618
- outcomes of, 792
- oxytocin induction and risk of, 616
- pathogenesis of, 791–792, 792f
- predisposing factors for, 791
primary, 790
risk of, after cesarean delivery, 609
secondary, 790
traumatic, 792–793
trial of labor and, 610–612, 611t, 617–618

Uterine souffle, 169
Uterine stimulation, 426–427
Uterine tachysystole, 527, 529
Uterine torsion, 43
Uteroovarian ligament, 30
Uteroplacental apoplexy, 797, 797f
Uteroplacental blood flow, 47–48
    regulation of, 47–48
Uteroplacental blood flow regulation, 47–48
Uterosacral ligaments, 28
Uterotonics, for postpartum blood loss, 547–548
Uterotonin degradation, accelerated, 423
Uterotonins, 410
Uterus, 408
    adenomyosis, 1226
    anatomy of, 25–26, 25f; 26f; 27f
cervix, 26, 26f
myometrium and endometrium, 26, 27f
    endometrial carcinoma, 1226
    endometriosis, 1226
    G-protein-linked angiotensin II receptors in, 427
    leiomyomas of, 1224–1226
cesarean delivery and, 1225f
fertility and, 1226
pregnancy and, 1225f
    complications of, 1225–1226
symptoms of, 1225
    physiology of, 46–48
myocyte arrangement, 47
uterine contractility, 47
uterine size, shape, and position, 47
uteroplacental blood flow, 47–48
    segments and rings development in, 413f
    size reduction, 416
during vaginal delivery, 413f
Uterus perforation, intrauterine devices and, 697
Vacuum cups, for operative vaginal delivery, 583, 583f, 583t

Vacuum extraction, 574, 583
  - indications for, 574
  - maternal morbidity with, 575–576
  - and pelvic floor disorders, 576
  - perinatal injuries with, 576
  - prerequisites for, 576, 576t
  - technique, 583–585, 584f
  - cup placement at flexion point, 583–584, 584f
  - traction, initiation of, 584, 584f
  - vacuum pressure conversions, 584, 584t
    - training for, 576–577
    - trial, 584–585
    - vacuum extractor design, 583, 583f, 583t

Vagina
  - abnormalities of, 39–40
  - longitudinal septa in, 39–40
  - obstetrical significance of, 39
  - transverse septum in, 40
    - anatomy of, 20–21, 20f
  - cul-de-sac, 21
  - glands, 21
  - length of, 21
  - vaginal lining, 21
  - vaginal lumen, 21
