Augmentation refers to enhancement of spontaneous contractions that are considered inadequate because of failed cervical dilation and fetal descent. In the United States, the incidence of labor induction more than doubled from 9.5 percent in 1991 to 23.2 percent in 2011 (Martin, 2013). The incidence is variable between practices. At Parkland Hospital approximately 35 percent of labors are induced or augmented. By comparison, at the University of Alabama at Birmingham Hospital labor is induced in approximately 20 percent of women, and another 35 percent are given oxytocin for augmentation—a total of 55 percent. This chapter includes an overview of indications for labor induction and augmentation and a description of various techniques to effect preinduction cervical ripening.
Indications

Induction is indicated when the benefits to either mother or fetus outweigh those of pregnancy continuation. The more common indications include membrane rupture without labor, gestational hypertension, oligohydramnios, nonreassuring fetal status, postterm pregnancy, and various maternal medical conditions such as chronic hypertension and diabetes (American College of Obstetricians and Gynecologists, 2013b).

Contraindications

Methods to induce or augment labor are contraindicated by most conditions that preclude spontaneous labor or delivery. The few maternal contraindications are related to prior uterine incision type, contracted or distorted pelvic anatomy, abnormally implanted placetas, and uncommon conditions such as active genital herpes infection or cervical cancer. Fetal factors include appreciable macrosomia, severe hydrocephalus, malpresentation, or nonreassuring fetal status.

Techniques

Oxytocin has been used for decades to induce or augment labor. Other effective methods include prostaglandins, such as misoprostol and dinoprostone, and mechanical methods that encompass stripping of membranes, artificial rupture of membranes, extraamnionic saline infusion, transcervical balloons, and hygroscopic cervical dilators. Importantly, and as recommended in Guidelines for Perinatal Care, each obstetrical department should have its own written protocols that describe administration of these methods for labor induction and augmentation (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012).

Risks

Maternal complications associated with labor induction consist of cesarean delivery, chorioamnionitis, uterine scar rupture, and postpartum hemorrhage from uterine atony.

Cesarean Delivery Rate

This is especially increased in nulliparas undergoing induction (Luthy, 2004; Yeast, 1999). Indeed, several investigators have reported a two- to threefold increased risk (Hoffman, 2003; Maslow, 2000; Smith, 2003). Moreover, these rates are inversely related with cervical favorability at induction, that is, the Bishop score (Vahratian, 2005; Vrouenraets, 2005). The increased risk for cesarean delivery with labor induction does not appear to be lowered with preinduction cervical ripening in the nullipara with an unfavorable cervix (Mercer, 2005). In fact, the cesarean delivery rate following elective induction was significantly increased even in women with a Bishop score of 7 or greater compared with that in those with spontaneous labor (Hamar, 2001). Station and position of the fetal vertex may also affect success rates. For example, in nulliparas at > 41 weeks’ gestation and with an unengaged vertex, the cesarean delivery rate was increased 12-fold compared with that in women with an engaged fetal vertex (Shin, 2004).

The premise that elective labor induction increases the risk of cesarean delivery has been questioned (Macones, 2009). Many studies have compared women undergoing labor induction to those laboring spontaneously. However, using women undergoing expectant management,
Osmundson and colleagues (2010, 2011) reported similar cesarean delivery rates in more than 4000 women undergoing elective induction between 39 and nearly 41 weeks with or without a favorable cervix. Currently, this subject remains unresolved.

Chorioamnionitis

Amniotomy is often selected to augment labor (p. 531). Women whose labor is managed with amniotomy have an increased incidence of chorioamnionitis compared with those in spontaneous labor (American College of Obstetricians and Gynecologists, 2013a).

Rupture of a Prior Uterine Incision

Uterine rupture during labor in women with a history of prior uterine surgery can be catastrophic (Chap. 31, p. 613). Some of these risks were quantified by Lydon-Rochelle and associates (2001), who reported that the uterine rupture risk is increased threefold for women in spontaneous labor with a uterine scar. With oxytocin labor induction without prostaglandins, the risk was fivefold increased, and with prostaglandins, it was strikingly increased 15.6-fold. The Maternal-Fetal Medicine Units Network also reported a threefold increased risk of uterine scar rupture with oxytocin, and this was even higher when prostaglandins were also used (Landon, 2004). The American College of Obstetricians and Gynecologists (2013d) recommends against the use of misoprostol for preinduction cervical ripening or labor induction in women with a prior uterine scar (Chap. 31, p. 615).

Uterine Atony

Postpartum hemorrhage from uterine atony is more common in women undergoing induction or augmentation. And, atony with intractable hemorrhage, especially during cesarean delivery, is a frequent indication for peripartum hysterectomy (Shellhaas, 2009). In a study from Parkland Hospital, labor induction was associated with 17 percent of 553 emergency peripartum hysterectomies (Hernandez, 2013). In the United States, Bateman and coworkers (2012) reported that the postpartum hysterectomy rate increased 15 percent between 1994 and 2007. This was largely attributable to increased rates of atony associated with more medical labor inductions and more primary and repeat cesarean deliveries. Finally, elective induction was associated with more than a threefold increased rate of hysterectomy in the analysis by Bailit and colleagues (2010).

Elective Labor Induction

There can be no doubt that elective induction for convenience has become more prevalent. In the United States between 1991 and 2006, rates of early term labor induction increased significantly for all race and ethnicity groups (Murthy, 2011). This was highest for non-Hispanic white women in 2006. In this group, the rate was 20.5 percent if there was either diabetes or hypertension and was 9 percent for women without these indications. Clark and coworkers (2009) reported data from 14,955 deliveries at 37 weeks or greater. They noted that 32 percent were elective deliveries, and 19 percent were elective labor inductions.

The American College of Obstetricians and Gynecologists (2013b) does not endorse this widespread practice. Occasional exceptions might include logistical and other reasons such as a risk of rapid labor, a woman who lives a long distance from the hospital, or psychosocial indications. We are also of the opinion that routine elective induction at term is not justified because of the increased risks for adverse maternal outcomes. Elective delivery before 39
completed weeks is also associated with significant and appreciable adverse neonatal morbidity (Chiossi, 2013; Clark, 2009; Tita, 2009). If elective induction is considered at term, inherent risks must be discussed, informed consent obtained, and guidelines followed as promulgated by the American College of Obstetricians and Gynecologists (2013b), which are detailed in Chapter 31 (p. 610).

Guidelines to discourage elective inductions have been described by Fisch (2009) and Oshiro (2013) and their associates. Both groups reported significant decreases in elective delivery rates following guideline initiation. Tanne (2013) surveyed more than 800 United States hospitals and reported that efforts to reduce early term deliveries are succeeding.

Factors Affecting Successful Induction

Several factors increase or decrease the ability of labor induction to achieve vaginal delivery. Favorable factors include multiparity, body mass index (BMI) < 30, favorable cervix, and birthweight < 3500 g (Peregrine, 2006; Pevzner, 2009). For both nulliparas and multiparas, Kominiarek and colleagues (2011) found that labor duration to reach the active phase and to complete dilatation was adversely affected by a higher BMI.

In many cases, the uterus is simply poorly prepared for labor. One example is an “unripe cervix.” Indeed, investigators with the Consortium on Safe Labor reported that elective induction resulted in vaginal delivery in 97 percent of multiparas and 76 percent of nulliparas, but that induction was more often successful with a ripe cervix (Laughon, 2012a). The increased cesarean delivery risk associated with induction is likely also strongly influenced by the induction attempt duration, especially with an unfavorable cervix (Spong, 2012). Simon and Grobman (2005) concluded that a latent phase as long as 18 hours during induction allowed most of these women to achieve a vaginal delivery without a significantly increased risk of maternal or neonatal morbidity. Rouse and associates (2000) recommend a minimum of 12 hours of uterine stimulation with oxytocin after membrane rupture.

PREINDUCTION CERVICAL RIPENING

As noted, the condition of the cervix—described as cervical “ripeness” or “favorability”—is important to successful labor induction. That said, at least some estimates of favorability are highly subjective. In either case, there are pharmacological and mechanical methods that can enhance cervical favorability—also termed preinduction cervical ripening.

Some of the techniques described may have benefits when compared with oxytocin induction alone (Table 26-1). Some are also quite successful for initiating labor. That said, few data support the premise that any of these techniques results in a reduced cesarean delivery rate or in less maternal or neonatal morbidity compared with that in women in whom these methods are not used.

| TABLE 26-1. Some Commonly Used Regimens for Preinduction Cervical Ripening and/or Labor Induction |
Cervical “Favorability”

One quantifiable method used to predict labor induction outcomes is the score described by Bishop (1964) and presented in Table 26-2. As favorability or Bishop score decreases, the rate of induction to effect vaginal delivery also declines. A Bishop score of 9 conveys a high likelihood
for a successful induction. Put another way, most practitioners would consider that a woman whose cervix is 2-cm dilated, 80-percent effaced, soft, and midposition and with the fetal occiput at −1 station would have a successful labor induction. For research purposes, a Bishop score of 4 or less identifies an unfavorable cervix and may be an indication for cervical ripening.

From Bishop, 1964.

Laughon and coworkers (2011) attempted to simplify the Bishop score by performing a regression analysis on 5610 singleton, uncomplicated deliveries by nulliparas between 37\(^{0/7}\) and 41\(^{6/7}\) weeks. Only cervical dilation, station, and effacement were significantly associated with successful vaginal delivery. Thus, a simplified Bishop score, which incorporated only these three parameters, had a similar or improved positive- or negative- predictive value compared with that of the original Bishop score.

Transvaginal sonographic measurement of cervical length has been evaluated as a Bishop score alternative. Hatfield and associates (2007) performed a metaanalysis of 20 trials in which cervical length was used to predict successful induction. Because of study criteria heterogeneity—including the definition of “successful induction”—the authors concluded that the question remains unanswered. Both this study and the one by Uzun and colleagues (2013) found that sonographically determined cervical length was not superior to the Bishop score for predicting induction success.

Pharmacological Techniques

Unfortunately, women frequently have an indication for induction but also have an unfavorable cervix. Thus, considerable research has been directed toward techniques to “ripen” the cervix before uterine contraction stimulation. Importantly, more often than not, techniques used to improve cervical favorability also stimulate contractions and thereby aid subsequent labor induction or augmentation. Techniques most commonly used for preinduction cervical ripening and induction include several prostaglandin analogues.

Prostaglandin E\(_2\)

Dinoprostone is a synthetic analogue of prostaglandin E\(_2\). It is commercially available in three forms: a gel, a time-release vaginal insert, and a 10-mg suppository. The gel and time-release vaginal insert formulations are indicated only for cervical ripening before labor induction. However, the 10-mg suppository is indicated for pregnancy termination between 12 and 20 weeks and for evacuation of the uterus after fetal demise up to 28 weeks.
Local application of dinoprostone is commonly used for cervical ripening (American College of Obstetricians and Gynecologists, 2013b). Its gel form—Prepidil—is available in a 2.5-mL syringe for an intracervical application of 0.5 mg of dinoprostone. With the woman supine, the tip of a prefilled syringe is placed intracervically, and the gel is deposited just below the internal cervical os. After application, the woman remains reclined for at least 30 minutes. Doses may be repeated every 6 hours, with a maximum of three doses recommended in 24 hours.

A 10-mg dinoprostone vaginal insert—Cervidil—is also approved for cervical ripening. This is a thin, flat, rectangular polymeric wafer held within a small, white, mesh polyester sac (Fig. 26-1). The sac has a long attached tail to allow easy removal from the vagina. The insert provides slower release of medication—0.3 mg/hr—than the gel form. Cervidil is used as a single dose placed transversely in the posterior vaginal fornix. Lubricant should be used sparingly, if at all, because it can coat the device and hinder dinoprostone release. Following insertion, the woman should remain recumbent for at least 2 hours. The insert is removed after 12 hours or with labor onset and at least 30 minutes before the administration of oxytocin.

FIGURE 26-1 Cervidil vaginal insert contains 10 mg of dinoprostone designed to release approximately 0.3 mg/hr during a 10-hour period.

Most metaanalyses of dinoprostone efficacy report a reduced time to delivery within 24 hours. However, they do not consistently show a reduction in the cesarean delivery rate. Kelly and coworkers (2009) provided a Cochrane review of 63 trials and 10,441 women given vaginal prostaglandins or either placebo or no treatment. These investigators reported a higher vaginal delivery rate within 24 hours when prostaglandins were used. They also found that cesarean delivery rates were unchanged. Similar results were reported after another Cochrane review of intracervical dinoprostone gel by Boulvain and associates (2008). Compared with placebo or no treatment, a reduced risk of cesarean delivery was found only in a subgroup of women with an unfavorable cervix and intact membranes. Finally, the Foley catheter versus vaginal prostaglandin
E₂ gel for induction of labor at term (PROBAAT trials) were unblinded, randomized trials comparing these two options (Joziawak, 2011, 2013a, 2014). There was no difference in cesarean delivery rate, a finding consistent with accompanying metaanalyses.

**Side Effects.** Uterine tachysystole has been reported to follow vaginally administered prostaglandin E₂ in 1 to 5 percent of women (Hawkins, 2012). Although definitions of uterine activity vary among studies, most use the definition recommended by the American College of Obstetricians and Gynecologists (2013c):

1. **Uterine tachysystole** is defined as > 5 contractions in a 10-minute period. It should always be qualified by the presence or absence of fetal heart rate abnormalities.

2. **Uterine hypertonus, hyperstimulation, and hypercontractility are terms no longer defined, and their use is not recommended.**

Because uterine tachysystole associated with fetal compromise may develop when prostaglandins are used with preexisting spontaneous labor, such use is not recommended. If tachysystole follows the 10-mg insert, its removal by pulling on the tail of the surrounding net sac will usually reverse this effect. Irrigation to remove the gel preparation has not been shown to be helpful.

The manufacturers recommend caution when these preparations are used in women with ruptured membranes. Caution is also recommended when they are used in women with glaucoma or asthma. In a review of 189 women with asthma, however, dinoprostone was not associated with asthma worsening or exacerbation (Towers, 2004). Other contraindications listed by the manufacturers include a history of dinoprostone hypersensitivity, suspicion of fetal compromise or cephalopelvic disproportion, unexplained vaginal bleeding, women already receiving oxytocin, those with six or more previous term pregnancies, those with a contraindication to vaginal delivery, or women with a contraindication to oxytocin or who may be endangered by prolonged uterine contractions, for example, those with a history of cesarean delivery or uterine surgery.

**Administration.** Prostaglandin E₂ preparations should only be administered in or near the delivery suite. Moreover, uterine activity and fetal heart rate should be monitored (American College of Obstetricians and Gynecologists, 2013b). These guidelines stem from the risk of uterine tachysystole. When contractions begin, they are usually apparent in the first hour and show peak activity in the first 4 hours. According to manufacturer guidelines, oxytocin induction that follows prostaglandin use for cervical ripening should be delayed for 6 to 12 hours following prostaglandin E₂ gel administration or for at least 30 minutes after removal of the vaginal insert.

**Prostaglandin E₁**

Misoprostol—*Cytotec*—is a synthetic prostaglandin E₁ that is approved as a 100- or 200-μg tablet for peptic ulcer prevention. It has been used “off label” for preinduction cervical ripening and may be administered orally or vaginally. The tablets are stable at room temperature. Although widespread, the off-label use of misoprostol has been controversial (Wagner, 2005; Weeks, 2005). Specifically, G. D. Searle & Company (Cullen, 2000) notified physicians that misoprostol is not approved for labor induction or abortion. At the same time, however, the American College of Obstetricians and Gynecologists (2013b) reaffirmed its recommendation for use of the drug because of proven safety and efficacy. It currently is the preferred prostaglandin for cervical
Vaginal Administration. Numerous studies have reported equivalent or superior efficacy for cervical ripening or labor induction with vaginally administered misoprostol tablets compared with intracervical or intravaginal prostaglandin E\(_2\). A metaanalysis of 121 trials also confirmed these findings (Hofmeyr, 2010). Compared with oxytocin or with intravaginal or intracervical dinoprostone, misoprostol increased the vaginal delivery rate within 24 hours. Moreover, although the uterine tachysystole rate increased, this did not affect cesarean delivery rates. Compared with dinoprostone, misoprostol decreased the need for oxytocin induction, but it increased the frequency of meconium-stained amniotic fluid. Higher doses of misoprostol are associated with a decreased need for oxytocin but more uterine tachysystole with and without fetal heart rate changes. The American College of Obstetricians and Gynecologists (2013b) recommends the 25-μg vaginal dose—a fourth of a 100-μg tablet. The drug is evenly distributed among these quartered tablets.

Wing and colleagues (2013) recently described use of a vaginal polymer insert containing 200 μg of PGE\(_3\). They compared its efficacy with 10-mg dinoprostone inserts, and preliminary observations are favorable.

Oral Administration. Prostaglandin E\(_1\) tablets are also effective when given orally. Ho and coworkers (2010) performed a randomized controlled trial comparing titrated oral misoprostol with oxytocin. They found similar rates of vaginal delivery and side effects. In a metaanalysis of nine trials including nearly 3000 women, however, there were reported improvements in various outcomes with oral misoprostol (Kundodyiwa, 2009). In particular, there was a significantly lower cesarean delivery rate for the five trials comparing oral misoprostol with dinoprostone—relative risk 0.82. For the two trials comparing oral with vaginal misoprostol, oral misoprostol was associated with a lower rate of uterine tachysystole with fetal heart rate changes, but there were no significant differences with respect to rates of cesarean delivery or other outcomes.

Nitric Oxide Donors

Several findings have led to a search for clinical agents that stimulate nitric oxide (NO) production locally (Chanrachakul, 2000a). This is because nitric oxide is likely a mediator of cervical ripening (Chap. 21, p. 423). Also, cervical nitric oxide metabolite concentrations are increased at the beginning of uterine contractions. Last, cervical nitric oxide production is very low in postterm pregnancy (Väisänen-Tommiska, 2003, 2004).

Bullarbo and colleagues (2007) reviewed rationale and use of two nitric oxide donors, isosorbide mononitrate and glyceryl trinitrate. Isosorbide mononitrate induces cervical cyclooxygenase 2 (COX-2), and it also brings about cervical ultrastructure rearrangement similar to that seen with spontaneous cervical ripening (Ekerhovd, 2002, 2003). Despite this, clinical trials have not shown nitric oxide donors to be as effective as prostaglandin E\(_2\) for cervical ripening (Chanrachakul, 2000b; Osman, 2006). Moreover, the addition of isosorbide mononitrate to either dinoprostone or misoprostol did not enhance cervical ripening either in early or term pregnancy nor did it shorten time to vaginal delivery (Collingham, 2010; Ledingham, 2001; Wölfler, 2006). A metaanalysis of 10 trials including 1889 women concluded that nitric oxide donors do not appear to be useful for cervical ripening during labor induction (Kelly, 2011).

Mechanical Techniques
These include transcervical placement of a Foley catheter with or without extraamnionic saline infusion, hygroscopic cervical dilators, and membrane stripping. In a recent metaanalysis of 71 randomized trials including 9722 women, Jozwiak and associates (2012) reported that mechanical techniques reduced the risk of uterine tachysystole compared with prostaglandins, although cesarean delivery rates were unchanged. Trials comparing mechanical techniques with oxytocin found a lower rate of cesarean delivery with mechanical methods. Trials comparing mechanical techniques with dinoprostone found a higher rate of multiparous women undelivered at 24 hours with mechanical techniques. Another metaanalysis done to compare Foley catheter placement with intravaginal dinoprostone inserts also found similar rates of cesarean delivery and less frequent uterine tachysystole (Jozwiak, 2013a).

**Transcervical Catheter**

Generally, these techniques are only used when the cervix is unfavorable because the catheter tends to come out as the cervix opens. In most cases, a Foley catheter is placed through the internal cervical os, and downward tension is created by taping the catheter to the thigh (Mei-Dan, 2014). A modification of this—extraamnionic saline infusion (EASI)—consists of a constant saline infusion through the catheter into the space between the internal os and placental membranes (Fig. 26-2). Karjane and coworkers (2006) reported that chorioamnionitis was significantly less frequent when infusion was done compared with no infusion—6 versus 16 percent. A systematic review and metaanalysis of 30 trials found that Foley catheter induction alone compared with prostaglandins resulted in higher infection rates unless saline was infused (Heinemann, 2008).
Most studies of transcervical catheters do not show a reduction in the cesarean delivery rate compared with prostaglandins. Cromi and colleagues (2012) compared a double-tipped Foley catheter and the dinoprostone vaginal insert. They found higher rates of delivery within 24 hours with the mechanical technique, but no differences in the cesarean delivery rates. The PROBAAT trials, in which cervical ripening with a Foley catheter was compared with vaginal dinoprostone gel, dinoprostone vaginal inserts, and vaginal misoprostol, reported similar outcomes between the mechanical technique and the prostaglandin agents. Also, fewer overall cases of cardiotocographic changes were seen in the mechanical technique group (Jozwiak, 2011, 2013a, 2014; Wang, 2014).

Hygroscopic Cervical Dilators

Cervical dilatation can be accomplished using hygroscopic osmotic cervical dilators, as described for early pregnancy termination (Chap. 18, p. 365). These mechanical dilators have been successfully used for more than 40 years when inserted before pregnancy termination. They have also been used for cervical ripening before labor induction. Intuitive concerns of ascending infection have not been verified. Thus, their use appears to be safe, although anaphylaxis has rarely followed laminaria insertion (Lichtenberg, 2004). Dilators are attractive because of their low cost. However, placement generally requires a speculum and positioning of the woman on an examination table, which can be cumbersome and uncomfortable. A handful of studies performed in the 1990s compared hygroscopic cervical dilators and prostaglandins. There were few benefits of this mechanical technique other than cost.

METHODS OF INDUCTION AND AUGMENTATION

Labor induction has primarily been effected with the use of amniotomy, prostaglandins, and oxytocin, alone or in combination. Because preinduction cervical ripening frequently eventuates in labor, studies to determine induction efficacy for some of these agents have produced sometimes confusing results. The use of prostaglandins for labor augmentation has generally been considered experimental.

Prostaglandin E₁

As discussed on page 527, both vaginal and oral misoprostol are used for either cervical ripening or labor induction. Hofmeyr and associates (2010) performed a Cochrane systematic review of agents for labor induction. They reported that vaginal misoprostol, followed by oxytocin if needed, compared with oxytocin alone resulted in fewer failures within 24 hours. As expected, prostaglandin use led to a higher incidence of uterine tachysystole, but cesarean delivery rates were similar.

It appears that 100 μg of oral or 25 μg of vaginal misoprostol are similar in efficacy compared with intravenous oxytocin for labor induction in women at or near term with either prematurely ruptured membranes or a favorable cervix (Lin, 2005; Lo, 2003). Misoprostol may be associated
with an increased rate of uterine tachysystole, particularly at higher doses. Also, induction with prostaglandin E\textsubscript{1} may prove ineffective and require subsequent induction or augmentation with oxytocin. Thus, although there are trade-offs regarding the risks, costs, and ease of administration of each drug, either is suitable for labor induction.

For labor augmentation, results of a randomized controlled trial showed oral misoprostol, 75 μg given at 4-hour intervals for a maximum of two doses, to be safe and effective (Bleich, 2011). The 75-μg dose was based on a previous dose-finding study (Villano, 2011). Although there was more uterine tachysystole among women with labor augmented with misoprostol, there were no significant differences in the frequency of nonreassuring fetal status or cesarean delivery.

### Oxytocin

As discussed, in most instances, preinduction cervical ripening and labor induction are simply a continuum. Thus, “ripening” will also stimulate labor. If not, induction or augmentation may be continued with solutions of oxytocin given by infusion pump. Synthetic oxytocin is one of the most frequently used medications in the United States. It was the first polypeptide hormone synthesized, an achievement for which the 1955 Nobel Prize in chemistry was awarded (du Vigneaud, 1953). Oxytocin may be used for labor induction or for augmentation. With oxytocin use, the American College of Obstetricians and Gynecologists (2013b) recommends fetal heart rate and contraction monitoring similar to that for any high-risk pregnancy. Contractions can be monitored either by palpation or by electronic means (Chap. 24, p. 497).

### Intravenous Oxytocin Administration

The goal of induction or augmentation is to effect uterine activity sufficient to produce cervical change and fetal descent, while avoiding development of a nonreassuring fetal status. In general, oxytocin should be discontinued if the number of contractions persists with a frequency of more than five in a 10-minute period or more than seven in a 15-minute period or with a persistent nonreassuring fetal heart rate pattern. Oxytocin discontinuation nearly always rapidly decreases contraction frequency. When oxytocin is stopped, its concentration in plasma rapidly falls because the half-life is approximately 3 to 5 minutes. Seitchik and coworkers (1984) found that the uterus contracts within 3 to 5 minutes of beginning an oxytocin infusion and that a plasma steady state is reached in 40 minutes. Response is highly variable and depends on preexisting uterine activity, cervical status, pregnancy duration, and individual biological differences. Caldeyro-Barcia and Poseiro (1960) reported that the uterine response to oxytocin increases from 20 to 30 weeks’ gestation and increases rapidly at term (Chap. 24, p. 498).

### Oxytocin Dosage.

A 1-mL ampule containing 10 units usually is diluted into 1000 mL of a crystalloid solution and administered by infusion pump. A typical infusate consists of 10 or 20 units, which is 10,000 or 20,000 mU or one or two 1-mL vials, mixed into 1000 mL of lactated Ringer solution. This mixture results in an oxytocin concentration of 10 or 20 mU/mL, respectively. To avoid bolus administration, the infusion should be inserted into the main intravenous line close to the venipuncture site.

Oxytocin is generally very successful when used to stimulate labor. A Cochrane metaanalysis of 12 trials involving 12,819 women comparing oxytocin with expectant management reported that fewer women—8 versus 54 percent—failed to deliver vaginally within 24 hours when oxytocin was used (Alfirevic, 2009). This metaanalysis studied different oxytocin dosing regimens. A smaller metaanalysis of four trials involving 660 women and comparing high-dose and low-dose
Oxytocin Regimens

As a result of numerous studies, several regimens for labor stimulation are now recommended by the American College of Obstetricians and Gynecologists (2013a). These and others are shown in Table 26-3. Initially, only variations of low-dose protocols were used in the United States. Then O’Driscoll and colleagues (1984) described their Dublin protocol for the active management of labor that called for oxytocin at a starting dosage of 6 mU/min and advanced in 6-mU/min increments. Subsequent comparative trials during the 1990s studied high-dose—4 to 6 mU/min—versus conventional low-dose—0.5 to 1.5 mU/min—regimens, both for labor induction and for augmentation.

**Note:**

- aWith uterine tachysystole and after oxytocin infusion is discontinued, it is restarted at the previous dose and increased at 3 mU/min incremental doses.
- bUterine tachysystole is more common with shorter intervals.

Data from Merrill, 1999; Satin, 1992, 1994; Xenakis, 1995.

From Parkland Hospital, Satin and associates (1992) evaluated an oxytocin regimen using an initial and incremental dosage of 6 mU/min compared with one using 1 mU/min. Increases at 20-minute intervals were provided as needed. Among 1112 women undergoing induction, the 6-mU/min regimen resulted in a shorter mean admission-to-delivery time, fewer failed inductions, and no cases of neonatal sepsis. Among 1676 women who had labor augmentation, those who received the 6-mU/min regimen had a shorter duration-to-delivery time, fewer forceps deliveries, fewer cesarean deliveries for dystocia, and decreased rates of intrapartum chorioamnionitis or neonatal sepsis. With this protocol, uterine tachysystole is managed by oxytocin discontinuation followed by resumption when indicated and at half the stopping dosage. Thereafter, the dosage is increased at 3 mU/min when appropriate, instead of the usual 6-mU/min increase used for women
without tachysystole. No adverse neonatal effects were observed. Xenakis and coworkers (1995) reported benefits using an incremental oxytocin regimen starting at 4 mU/min. In a comparative study of 1307 women by Merrill and Zlatnik (1999), 816 women were randomized for labor induction and 816 for augmentation with incremental oxytocin given at either 1.5 or 4.5 mU/min. Women randomized to the 4.5 mU/min dosage had significantly decreased mean durations of induction-to-second-stage labor and induction-to-delivery. Nulliparas randomized to the 4.5 mU/min dosage had a significantly lower cesarean delivery rate for dystocia compared with those given 1.5 mU/min dosage—5.9 versus 11.9 percent.

Thus, benefits favor higher-dose regimens of 4.5 to 6 mU/min compared with lower dosages of 0.5 to 1.5 mU/min. In 1990 at Parkland Hospital, routine use of the 6-mU/min oxytocin beginning and incremental dosage was incorporated and continues through today. In other labor units, a 2-mU/min beginning and incremental oxytocin regimen is preferred and administered. With either regimen, these dosages are employed for either labor induction or augmentation.

**Interval between Incremental Dosing**

Intervals to increase oxytocin doses vary from 15 to 40 minutes as shown in Table 26-3. Satin and colleagues (1994) addressed this aspect with a 6-mU/min regimen providing increases at either 20- or 40-minute intervals. Women assigned to the 20-minute interval regimen for labor augmentation had a significantly reduced cesarean delivery rate for dystocia compared with that for the 40-minute interval regimen—8 versus 12 percent. As perhaps expected, uterine tachysystole was significantly more frequent with the 20-minute escalation regimen.

Other investigators reported even more frequent incremental increases. Frigoletto (1995) and Xenakis (1995) and their coworkers gave oxytocin at 4 mU/min with increases as needed every 15 minutes. Merrill and Zlatnik (1999) started with 4.5 mU/min, with increases every 30 minutes. López-Zeno and associates (1992) began at 6 mU/min with increases every 15 minutes. Thus, there are several acceptable oxytocin protocols that at least appear dissimilar. But a comparison of protocols from two institutions indicates that this is not so:

1. The Parkland Hospital protocol calls for a starting dose of oxytocin at 6 mU/min and with 6-mU/min increases every 40 minutes, but it employs flexible dosing based on uterine tachysystole.
2. The University of Alabama at Birmingham Hospital protocol begins oxytocin at 2 mU/min and increases it as needed every 15 minutes to 4, 8, 12, 16, 20, 25, and 30 mU/min.

Thus, although the regimens at first appear disparate, if there is no uterine activity, either regimen is delivering 12 mU/min by 45 minutes into the infusion.

**Maximal Dosage**
The maximal effective dose of oxytocin to achieve adequate contractions in all women is different. Wen and colleagues (2001) studied 1151 consecutive nulliparas and found that the likelihood of progression to vaginal delivery decreased at and beyond an oxytocin dosage of 36 mU/min. Still, at a dosage of 72 mU/min, half of the nulliparas were delivered vaginally. Thus, if contractions are not adequate—less than 200 Montevideo units—and if the fetal status is reassuring and labor has arrested, an oxytocin infusion dose greater than 48 mU/min has no apparent risks.

**Risks versus Benefits**
Unless the uterus is scarred, uterine rupture associated with oxytocin infusion is rare, even in parous women (Chap. 41, p. 790). Flannelly and associates (1993) reported no uterine ruptures, with or without oxytocin, in 27,829 nulliparas. There were eight instances of overt uterine rupture during labor in 48,718 parous women. Only one of these was associated with oxytocin use.

Oxytocin has amino-acid homology similar to arginine vasopressin. Because of this, it has significant antidiuretic action, and when infused at doses of 20 mU/min or more, renal free water clearance decreases markedly. If aqueous fluids are infused in appreciable amounts along with oxytocin, water intoxication can lead to convulsions, coma, and even death. In general, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the flow rate of a more dilute solution. Consideration also should be given to use of crystalloids—either normal saline or lactated Ringer solution.

**Uterine Contraction Pressures**

Contraction forces in spontaneously laboring women range from 90 to 390 Montevideo units. As described in Chapter 24 (p. 498), the latter are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window. The pressures generated by each contraction are then summed. Caldeyro-Barcia (1950) and Seitchik (1984) with their coworkers found that the mean or median spontaneous uterine contraction pattern resulting in a progression to a vaginal delivery was between 140 and 150 Montevideo units.

In the management of active-phase arrest, and with no contraindication to intravenous oxytocin, decisions must be made with knowledge of the safe upper range of uterine activity. Hauth and colleagues (1986) described an effective and safe protocol for oxytocin augmentation for active-phase arrest. With it, more than 90 percent of women achieved an average of at least 200 to 225 Montevideo units. Hauth and associates (1991) later reported that nearly all women in whom active-phase arrest persisted despite oxytocin generated more than 200 Montevideo units. Importantly, despite no labor progression, there were no adverse maternal or perinatal effects in those undergoing cesarean delivery. There are no data regarding safety and efficacy of contraction patterns in women with a prior cesarean delivery, with twins, or with an overdistended uterus.

**Active-Phase Arrest**

First-stage arrest of labor is defined by the American College of Obstetricians and Gynecologists (2013a) as a completed latent phase along with contractions exceeding 200 Montevideo units for more than 2 hours without cervical change. Some investigators have attempted to define a more accurate duration for active-phase arrest (Spong, 2012). Arulkumaran and coworkers (1987) extended the 2-hour limit to 4 hours and reported a 1.3-percent cesarean delivery rate in women who continued to have adequate contractions and progressive cervical dilatation of at least 1 cm/hr. In women without progressive cervical dilatation who were allowed another 4 hours of labor, half required cesarean delivery.

Rouse and colleagues (1999) prospectively managed 542 women at term with active-phase arrest and no other complications. Their protocol was to achieve a sustained pattern of at least 200 Montevideo units for a minimum of 4 hours. This time frame was extended to 6 hours if activity of 200 Montevideo units or greater could not be sustained. Almost 92 percent of these women were delivered vaginally. As discussed in Chapter 23 (p. 459), these and other studies support the practice of allowing an active-phase arrest of 4 hours (Rouse, 2001; Solheim, 2009).

Zhang and coworkers (2002) analyzed labor duration from 4 cm to complete dilatation in 1329 nulliparas at term. They found that before dilatation of 7 cm was reached, lack of progress for
more than 2 hours was not uncommon in those who delivered vaginally. Alexander and associates (2002) reported that epidural analgesia prolonged active labor by 1 hour compared with duration of the active phase as defined by Friedman (1955). Consideration of these changes in the management of labor, especially in nulliparas, may safely reduce the cesarean delivery rate.

As data have accrued, investigators have increasingly questioned the thresholds for labor arrest disorders established by Friedman and others in the 1960s. In particular, investigators with the Consortium on Safe Labor reported that half of cases of dystocia after labor induction occurred before 6 cm of cervical dilation (Boyle, 2013; Zhang, 2010c). Even for women with spontaneous labor, these researchers found that active-phase labor was more likely to occur at 6 cm, and after slow progress between 4 and 6 cm (Zhang, 2010a). Additionally, they reported that a 2-hour threshold for diagnosing arrest disorders may be too brief when cervical dilation is < 6 cm (Zhang, 2010b). It was also shown that the duration of first-stage labor was more than 2 hours longer than had been reported using data from the Collaborative Perinatal Project (Laughon, 2012b).

### Amniotomy for Induction and Augmentation

A common indication for artificial rupture of the membranes—*surgical amniotomy*—includes the need for direct monitoring of the fetal heart rate or uterine contractions or both. During amniotomy, to minimize cord prolapse risk, dislodgement of the fetal head is avoided. For this, fundal or suprapubic pressure or both may be helpful. Some clinicians prefer to rupture membranes during a contraction. If the vertex is not well applied to the lower uterine segment, a gradual egress of amniotic fluid can sometimes be accomplished by several membrane punctures with a 26-gauge needle held with a ring forceps and with direct visualization using a vaginal speculum. In many of these, however, membranes tear and fluid is lost rapidly. Because of the risk of cord prolapse or rarely abruption, the fetal heart rate is assessed before and immediately after amniotomy.

### Elective Amniotomy

Membrane rupture with the intention of accelerating labor is often performed. In the investigations presented in Table 26-4, amniotomy at approximately 5-cm dilation accelerated spontaneous labor by 1 to 1½ hours. Importantly, neither the need for oxytocin stimulation nor the overall cesarean delivery rate was increased. Although mild and moderate cord compression patterns were increased following amniotomy, cesarean delivery rates for fetal distress were not increased. Most importantly, there were no adverse perinatal effects.

| TABLE 26-4. Randomized Clinical Trials of Elective Amniotomy in Early Spontaneous Labor at Term |
Amniotomy Induction

Artificial rupture of the membranes—sometimes called *surgical induction*—can be used to induce labor, and it always implies a commitment to delivery. The main disadvantage of amniotomy used alone for labor induction is the unpredictable and occasionally long interval until labor onset. That said, in a randomized trial, Bakos and Bäckström (1987) found that amniotomy alone or combined with oxytocin was superior to oxytocin alone. Mercer and colleagues (1995) randomized 209 women undergoing oxytocin induction to either early amniotomy at 1 to 2 cm or late amniotomy at 5 cm. Early amniotomy was associated with a significant 4-hour reduction in labor duration. With early amniotomy, however, there was an increased incidence of chorioamnionitis.

Amniotomy Augmentation

It is common practice to perform amniotomy when labor is abnormally slow. Rouse and associates (1994) found that amniotomy with oxytocin augmentation for arrested active-phase labor shortened the time to delivery by 44 minutes compared with that of oxytocin alone. Although amniotomy did not alter the delivery route, one drawback was that it significantly increased the incidence of chorioamnionitis. The American College of Obstetricians and Gynecologists (2013a) recommends the use of amniotomy to enhance progress in active labor, but cautions that this may increase the risks of infection and maternal fever.

Membrane Stripping for Labor Induction

Labor induction by membrane “stripping” is a frequent practice. Several studies have suggested that membrane stripping is safe and decreases the incidence of postterm pregnancy without consistently increasing the incidence of ruptured membranes, infection, or bleeding. Authors of a metaanalysis of 22 trials including 2797 women reported that membrane stripping reduced the number of women remaining undelivered after 41 weeks without increasing the infection risk. They concluded that eight women would need to undergo membrane stripping to avoid one labor induction. Downsides are discomfort and associated bleeding (Boulvain, 2005).
ACTIVE MANAGEMENT OF LABOR

This term describes a codified approach to the management of labor, which is discussed in detail in Chapter 22 (p. 452).

SECTION 8
DELIVERY
The natural culmination of second-stage labor is controlled vaginal delivery of a healthy neonate with minimal trauma to the mother. Vaginal delivery is the preferred route of delivery for most fetuses, although certain clinical settings may favor cesarean delivery. Spontaneous vaginal delivery is typical, however, maternal or fetal complications may warrant operative vaginal delivery as described in Chapter 29. Last, a malpresenting fetus or multifetal gestation in many cases may be delivered vaginally but requires special techniques. These are described in Chapters 28—Breech Delivery and 45—Multifetal Pregnancy.

**ROUTE OF DELIVERY**

In general, spontaneous vaginal vertex delivery poses the lowest risk of most maternal and fetal comorbidity. Compared with cesarean delivery, spontaneous vaginal delivery has lower associated rates of maternal infection, hemorrhage, anesthesia complications, and peripartum hysterectomy, among others. In contrast, for women undergoing spontaneous vaginal delivery
compared with cesarean delivery, pelvic floor disorders may be increased (Handa, 2011; Rortveit, 2003). Longitudinal studies, however, suggest that initial pelvic floor protection advantages gained from cesarean delivery are lost as women age (Dolan, 2010; Glazener, 2013; Rortveit, 2001). During their State-of-the-Science Conference, the National Institutes of Health panel (2006) summarized that stress urinary incontinence rates after elective cesarean delivery are lower than those following vaginal delivery. However, the duration of this protection is unclear, particularly in older and multiparous populations. This same conference considered the evidence implicating vaginal delivery in other pelvic floor disorders to be weak and not favoring either delivery route.

PREPARATION FOR DELIVERY

The end of second-stage labor is heralded as the perineum begins to distend, the overlying skin becomes stretched, and the fetal scalp is seen through the separating labia. Increased perineal pressure from the fetal head creates reflexive bearing-down efforts, which are encouraged when appropriate. At this time, preparations are made for delivery. Some considerations that arise during labor and which are also discussed in Chapter 22 (p. 451) are reiterated. For example, the bladder is palpated, and if it is distended, catheterization may be necessary. Continued attention is also given to fetal heart rate monitoring. As one example, a nuchal cord often tightens with descent and may lead to deepening variable decelerations. Antibiotic prophylaxis against infective endocarditis is not recommended for vaginal delivery in most women with cardiac conditions. Exceptions are in women with cyanotic heart disease or prosthetic valves or both. For these women, prophylaxis as outlined in Table 49-10 (p. 991) is indicated 30 to 60 minutes before the anticipated procedure (American College of Obstetricians and Gynecologists, 2011).

During second-stage labor, pushing positions may vary. But for delivery, dorsal lithotomy position is the most widely used and often the most satisfactory. For better exposure, leg holders or stirrups are used. Corton and associates (2012) found no increased rates of perineal lacerations with stirrup use compared to without their use. With positioning, legs are not separated too widely or placed one higher than the other. Within the leg holder, the popliteal region should rest comfortably in the proximal portion and the heel in the distal portion. The legs are not strapped into the stirrups, thereby allowing quick flexion of the thighs backward onto the abdomen should shoulder dystocia develop (p. 541). Legs may cramp during the second stage, in part, because of pressure by the fetal head on pelvic nerves. Cramping may be relieved by repositioning the affected leg or by brief massage.

Preparation for delivery includes vulvar and perineal cleansing. If desired, sterile drapes may be placed in such a way that only the immediate area around the vulva is exposed. In the past, scrubbing, gowning, gloving, and donning protective mask and eyewear was done to protect the laboring woman from infectious agents. Although these considerations remain valid, infectious disease exposure concerns today must also be extended to health-care providers.

OCCIPUT ANTERIOR POSITION

By the time of perineal distention, the position of the presenting occiput is usually known. In some cases, however, molding and caput formation have precluded accurate identification. At this time,
careful assessment is again performed as described in Chapter 22 (p. 438). In most cases, presentation is directly occiput anterior or is rotated slightly oblique. But, in perhaps 5 percent, persistent occiput posterior is identified. Rarely, the vertex will be presenting in the occiput transverse position when the head bulges the perineum.

### Delivery of the Head

With each contraction, the vulvovaginal opening is dilated by the fetal head to gradually form an ovoid and finally, an almost circular opening (Fig. 27-1). This encirclement of the largest head diameter by the vulvar ring is termed **crowning**. Unless an episiotomy has been made as described later, the perineum thins and especially in nulliparous women, may undergo spontaneous laceration. The anus becomes greatly stretched, and the anterior wall of the rectum may be easily seen through it.

![Delivery of the head. The occiput is being kept close to the symphysis by moderate pressure on the fetal chin at the tip of the maternal coccyx.](image)

**FIGURE 27-1** Delivery of the head. The occiput is being kept close to the symphysis by moderate pressure on the fetal chin at the tip of the maternal coccyx.

There once was considerable controversy concerning routine episiotomy use. It is now clear that episiotomy increases the risk of a tear into the external anal sphincter, the rectum, or both. Conversely, anterior tears involving the urethra and labia are more common in women in whom an episiotomy is avoided. Most, including us, advocate individualization and do not routinely perform episiotomy.

To limit spontaneous vaginal laceration, some perform intrapartum perineal massage to widen the introitus for head passage. With this, the perineum is grasped in the midline by both hands using
the thumb and opposing fingers. Outward and lateral stretch against the perineum is then repeatedly applied. Evidence for this technique is limited and mixed regarding efficacy for perineal protection when applied either antepartum or intrapartum (Geranmayeh, 2012; Mei-dan, 2008; Stamp, 2001).

When the head distends the vulva and perineum enough to open the vaginal introitus to a diameter of 5 cm or more, a gloved hand may be used to support the perineum (Fig. 27-2). The other hand is used to guide and control the fetal head to avoid expulsive delivery. Slow delivery of the head may decrease lacerations (Laine, 2008). Alternatively, if expulsive efforts are inadequate or expeditious delivery is needed, the modified Ritgen maneuver may be employed. With this, gloved fingers beneath a draped towel exert forward pressure on the fetal chin through the perineum just in front of the coccyx. Concurrently, the other hand presses superiorly against the occiput (Fig. 27-3). Originally described in 1855, the Ritgen maneuver allows controlled fetal head delivery (Cunningham, 2008). It also favors neck extension so that the head passes through the introitus and over the perineum with its smallest diameters. Comparing the Ritgen maneuver with simple perineal support in 1623 women, Jönsson and colleagues (2008) found a similar incidence of third- and fourth-degree tears—5.5 percent with the maneuver and 4.4 percent with simple support. Last, some espouse a “hands-poised” method, in which the attendant does not touch the perineum during delivery of the head (Mayerhofer, 2002; McCandlish, 1998). Compared with traditional perineal support, this expectant method does not appear to offer greater third-degree laceration protection (Aasheim, 2011).

FIGURE 27-2 Delivery of the head. The mouth appears over the perineum.
FIGURE 27-3 Modified Ritgen maneuver. Moderate upward pressure is applied to the fetal chin by the posterior hand covered with a sterile towel, while the suboccipital region of the fetal head is held against the symphysis.

Delivery of the Shoulders

Following delivery of the fetal head, a finger should be passed across the fetal neck to determine whether it is encircled by one or more umbilical cord loops (Fig. 27-4). A nuchal cord is found in approximately 25 percent of deliveries and ordinarily causes no harm. If an umbilical cord coil is felt, it should be slipped over the head if loose enough. If applied too tightly, the loop should be cut between two clamps. Such tight nuchal cords complicate approximately 6 percent of all deliveries but are not associated with worse neonatal outcome than those without a cord loop (Henry, 2013).
FIGURE 27-4 The umbilical cord, if identified around the neck, is readily slipped over the head.

Following its delivery, the fetal head falls posteriorly, bringing the face almost into contact with the maternal anus. The occiput promptly turns toward one of the maternal thighs, and the head assumes a transverse position (Fig. 27-5). This external rotation indicates that the bisacromial diameter, which is the transverse diameter of the thorax, has rotated into the anteroposterior diameter of the pelvis.
FIGURE 27-5 Delivery of the shoulders. A. Gentle downward traction to effect descent of the anterior shoulder. B. Delivery of the anterior shoulder completed. Gentle upward traction to deliver the posterior shoulder.

Most often, the shoulders appear at the vulva just after external rotation and are born spontaneously. If delayed, extraction aids controlled delivery. The sides of the head are grasped with two hands, and gentle downward traction is applied until the anterior shoulder appears under the pubic arch. Next, by an upward movement, the posterior shoulder is delivered. During delivery, abrupt or powerful force is avoided to avert brachial plexus injury.

The rest of the body almost always follows the shoulders without difficulty. With prolonged delay, however, its birth may be hastened by moderate traction on the head and moderate pressure
on the uterine fundus. Hooking the fingers in the axillae is avoided. This can injure upper extremity nerves and produce a transient or possibly permanent paralysis. Traction, furthermore, should be exerted only in the direction of the long axis of the neonate. If applied obliquely, it causes neck bending and excessive brachial plexus stretching. Immediately after delivery of the newborn, there is usually a gush of amniotic fluid, often blood-tinged but not grossly bloody.

Previously, immediate nasopharyngeal bulb suctioning of the newborn was routine to remove secretions. It was found, however, that suctioning of the nasopharynx may lead to neonatal bradycardia (Gungor, 2006). The American Heart Association neonatal resuscitation recommendations currently eschew most suctioning immediately following birth—even with meconium present. This includes bulb syringe aspiration. Suctioning should be reserved for neonates who have obvious obstruction to spontaneous breathing or who require positive-pressure ventilation (Kattwinkel, 2010). Similarly, if meconium is present and the newborn is depressed, then intubation and tracheal suctioning is recommended (American College of Obstetricians and Gynecologists, 2013b). These aspects are discussed in further detail in Chapter 33 (p. 638).

### Clamping the Cord

The umbilical cord is cut between two clamps placed 6 to 8 cm from the fetal abdomen, and later an umbilical cord clamp is applied 2 to 3 cm from its insertion into the fetal abdomen. A plastic clamp that is safe, efficient, and fairly inexpensive, such as the Double Grip Umbilical Clamp (Hollister), is used at Parkland Hospital.

For term neonates, the timing of umbilical cord clamping remains debatable. A delay in umbilical cord clamping for up to 60 seconds may increase total body iron stores, expand blood volume, and decrease anemia incidence in the neonate (Andersson, 2011; Yao, 1974). This may be particularly valuable in populations in which iron deficiency is prevalent (Abalos, 2009). Conversely, and as discussed in Chapter 33 (p. 643), higher hemoglobin concentration increases risks for hyperbilirubinemia and extended hospitalization for neonatal phototherapy (McDonald, 2008). Delayed cord clamping may also hinder timely and needed neonatal resuscitation. Fortunately, in general, delayed umbilical cord clamping compared with early clamping does not worsen Apgar scores, umbilical cord pH, or respiratory distress caused by polycythemia. Regarding maternal outcomes, rates of postpartum hemorrhage are similar between early and delayed clamping groups (Andersson, 2013). Fewer data are available regarding cord “milking,” in which the operator pushes blood through the cord toward the newborn. This maneuver appears safe and may be advantageous if rapid cord clamping is clinically indicated (Upadhyay, 2013).

For the preterm neonate, delayed cord clamping has several benefits. These include higher red cell volume, decreased need for blood transfusion, better circulatory stability, and lower rates of intraventricular hemorrhage and of necrotizing enterocolitis (Rabe, 2012; Raju, 2013; Sommers, 2012).

The American College of Obstetricians and Gynecologists (2012c) has concluded that there is insufficient evidence to support or refute benefits from delayed umbilical cord clamping for term neonates in resource-rich settings. For preterm newborns, however, evidence supports delaying umbilical cord clamping to 30 to 60 seconds after birth. This opinion is also endorsed by the American Academy of Pediatrics (2013). Our policy is to clamp the cord after assessing the need to clear the airway, all of which usually requires approximately 30 seconds. The newborn is not elevated above the introitus at vaginal delivery or much above the maternal abdominal wall at the time of cesarean delivery.
Approximately 2 to 10 percent of singleton term cephalic fetuses deliver in an occiput posterior (OP) position (Cheng, 2010). As shown in Figure 27-6, many fetuses delivering OP were occiput anterior (OA) in early labor and reflect malrotation during labor. Predisposing risks include epidural analgesia, nulliparity, greater fetal weight, and prior OP position delivery (Cheng, 2006a; Gardberg, 2004; Lieberman, 2005).

**Morbidity**

Women with a persistent OP position have higher associated rates of prolonged second-stage labor, cesarean delivery, and operative vaginal delivery. For women who deliver vaginally, rates of blood loss and of third- and fourth-degree laceration, so-called higher-order vaginal lacerations, are increased (Senécal, 2005).

Infants delivered from an OP position have many more complications than those born positioned OA. Cheng and coworkers (2006b) compared outcomes of 2591 women undergoing
delivery with a persistent OP position with those of 28,801 women whose newborns were
delivered OA. Virtually every possible delivery complication was found more frequently with
persistent OP position. Only 46 percent of these women delivered spontaneously, and the
remainder accounted for 9 percent of cesarean deliveries performed. These investigators also
found that an OP position at delivery was associated with increased adverse short-term neonatal
outcomes that included acidemic umbilical cord gases, birth trauma, Apgar scores < 7, and
intensive care nursery admission, among others. Similar results were reported by Ponkey (2003)
and Fitzpatrick (2001) and their associates.

Methods to prevent persistent OP position and its associated morbidity have been investigated.
First, digital examination for identification of fetal head position can be inaccurate, and
sonography can be used to increase accuracy (Dupuis, 2005; Souka, 2003; Zahalka, 2005). Such
information may provide an explanation for prolonged second-stage labor or may identify suitable
candidates for manual rotation. In contrast, varying maternal position either before or during labor
does not appear to lower rates of persistent OP position (Desbriere, 2013; Kariminia, 2004).

### Delivery of Persistent Occiput Posterior Position

Delivery of a fetus with an OP position may be completed by spontaneous or operative vaginal
delivery. First, if the pelvic outlet is roomy and the vaginal outlet and perineum are somewhat
relaxed from prior deliveries, rapid spontaneous OP delivery will often take place. Conversely, if
the vaginal outlet is resistant to stretch and the perineum is firm, second-stage labor may be
appreciably prolonged. During each expulsive effort, the head is driven against the perineum to a
much greater degree than when the head position is OA. This leads to greater rates of higher-order
perineal lacerations (Groutz, 2011; Melamed, 2013).

In some cases, spontaneous vaginal delivery from an OP position does not appear feasible or
expedited delivery is needed. Here, manual rotation with spontaneous delivery from an OA
position may be preferred. This technique is described fully in Chapter 29 (p. 580). Successful
rotation rates range from 47 to 90 percent. And, as would be expected, lower rates of cesarean
delivery, vaginal laceration, and maternal blood loss follow rotation to OA position and vaginal
delivery (Le Ray, 2005; Sen, 2013; Shaffer, 2006, 2011). Disadvantageously, manual rotation is
linked with higher cervical laceration rates. Thus, careful inspection of the cervix following
rotation is prudent.

For exigent delivery, forceps or vacuum device can be applied to a persistent OP position. This
is often performed in conjunction with an episiotomy. Also, if the head is engaged, the cervix fully
dilated, and the pelvis adequate, forceps rotation may be attempted. These circumstances most
likely prevail when expulsive efforts of the mother during the second stage are ineffective. Both
these operative vaginal techniques are detailed in Chapter 29 (p. 582).

Infrequently, protrusion of fetal scalp through the introitus is the consequence of marked
elongation of the fetal head from molding combined with formation of a large caput succedaneum.
In some cases, the head may not even be engaged—that is, the biparietal diameter may not have
passed through the pelvic inlet. In these, labor is characteristically long and descent of the head is
slow. Careful palpation above the symphysis may disclose the fetal head to be above the pelvic
inlet. Prompt cesarean delivery is appropriate.

At Parkland Hospital, spontaneous delivery or manual rotation is preferred for management of
persistent OP position. In other cases, either manual rotation to OA position followed by forceps
delivery or forceps delivery from the OP position is used. If neither can be completed with
relative ease, cesarean delivery is performed.
OCCIPUT TRANSVERSE POSITION

In the absence of a pelvic architecture abnormality or asynclitism, the occiput transverse position is usually transitory. Thus, unless contractions are hypotonic, the head usually spontaneously rotates to an OA position. If hypotonic uterine contractions are suspected and cephalopelvic disproportion is absent, then an oxytocin infusion can be used to stimulate labor.

If rotation ceases because of poor expulsive forces, vaginal delivery usually can be accomplished readily in a number of ways. The easiest is manual rotation of the occiput either anteriorly to OA or less commonly, posteriorly to OP. If either is successful, Le Ray and coworkers (2007) reported a 4-percent cesarean delivery rate compared with a 60-percent rate in women in whom manual rotation was not successful. Some recommend rotation with Kielland forceps for the persistent occiput transverse position as outlined in Chapter 29 (p. 582). These forceps are used to rotate the occiput to the anterior position, and delivery is accomplished with the same forceps or by substitution with either Simpson or Tucker–McLane forceps.

In some cases, there may be an underlying cause leading to the persistent occiput transverse position that is not easily overcome. For example, a platypelloid pelvis is flattened anteroposteriorly and an android pelvis is heart shaped. With these, there may be inadequate space for occipital rotation to either an OA or OP position (Fig. 2-20, p. 34). Because of these concerns, undue force should be avoided if forceps delivery is attempted.

SHOULDER DYSTOCIA

Following complete emergence of the fetal head during vaginal delivery, the remainder of the body may not rapidly follow. The anterior fetal shoulder can become wedged behind the symphysis pubis and fail to deliver using normally exerted downward traction and maternal pushing. Because the umbilical cord is compressed within the birth canal, such dystocia is an emergency. Several maneuvers, in addition to downward traction on the fetal head, may be performed to free the shoulder. This requires a team approach, in which effective communication and leadership are critical.

Consensus regarding a specific definition of shoulder dystocia is lacking. Some investigators focus on whether maneuvers to free the shoulder are needed, whereas others use the head-to-body delivery time interval as defining (Beall, 1998). Spong and coworkers (1995) reported that the mean head-to-body delivery time in normal births was 24 seconds compared with 79 seconds in those with shoulder dystocia. These investigators proposed that a head-to-body delivery time > 60 seconds be used to define shoulder dystocia. Currently, however, the diagnosis continues to rely on the clinical perception that the normal downward traction needed for fetal shoulder delivery is ineffective.

Because of these differing definitions, the incidence of shoulder dystocia varies. Current reports cite an incidence between 0.6 percent and 1.4 percent (American College of Obstetricians and Gynecologists, 2012b). There is evidence that the incidence has increased in recent decades, likely due to increasing fetal birthweight (MacKenzie, 2007). Alternatively, this increase may be due to more attention given to appropriate documentation of dystocia (Nocon, 1993).

Maternal and Neonatal Consequences
In general, shoulder dystocia poses greater risk to the fetus than the mother. Postpartum hemorrhage, usually from uterine atony but also from vaginal lacerations, is the main maternal risk (Jangö, 2012; Rahman, 2009). In contrast, significant neonatal neuromusculoskeletal injury and even mortality are concerns. MacKenzie and associates (2007) reviewed 514 cases of shoulder dystocia and found that 11 percent were associated with serious neonatal trauma. Brachial plexus injury was diagnosed in 8 percent, and 2 percent suffered a clavicle, humeral, or rib fracture. Seven percent showed evidence of acidosis at delivery, and 1.5 percent required cardiac resuscitation or developed hypoxic ischemic encephalopathy. Mehta and colleagues (2007) found a similar number of injuries in a study of 205 shoulder dystocia cases, in which 17 percent had injury. Again, most involved the brachial plexus. These specific injuries are described more fully in Chapter 33 (p. 648). Of predictors, increasing fetal weight, maternal body mass index, and second-stage duration and a prior shoulder dystocia appear to raise the neonatal injury risk with shoulder dystocia (Bingham, 2010; Mehta, 2006).

### Prediction and Prevention

There has been considerable evolution in obstetrical thinking regarding the preventability of shoulder dystocia. Although there are clearly several risk factors associated with this complication, identification of individual instances before the fact has proved to be impossible. The American College of Obstetricians and Gynecologists (2012b) reviewed studies and concluded that:

1. Most cases of shoulder dystocia cannot be accurately predicted or prevented.
2. Elective induction of labor or elective cesarean delivery for all women suspected of having a macrosomic fetus is not appropriate.
3. Planned cesarean delivery may be considered for the nondiabetic woman with a fetus whose estimated fetal weight is > 5000 g or for the diabetic woman whose fetus is estimated to weigh > 4500 g.

### Birthweight

Commonly cited maternal characteristics associated with increased fetal birthweight are obesity, postterm pregnancy, multiparity, diabetes, and gestational diabetes. There is universal agreement that increasing birthweight is associated with an increasing incidence of shoulder dystocia. In one study of nearly 2 million vaginal deliveries, Overland and coworkers (2012) noted that in 75 percent of shoulder dystocia cases, newborns weighed > 4000 g. That said, the concept that cesarean delivery is indicated for large fetuses, even those estimated to weigh 4500 g, should be tempered. Rouse and Owen (1999) concluded that a prophylactic cesarean delivery policy for macrosomic fetuses would require more than 1000 cesarean deliveries with attendant morbidity as well as millions of dollars to avert a single permanent brachial plexus injury.

### Intrapartum Factors

Some labor characteristics have been associated with an increased shoulder dystocia risk and include prolonged second-stage labor, operative vaginal delivery, and prior shoulder dystocia (Mehta, 2004; Moragianni, 2012; Overland, 2009). Of these, the risk of recurrent shoulder dystocia ranges from 1 to 13 percent (Bingham, 2010; Moore, 2008; Ouzounian, 2013). For many women with prior shoulder dystocia, a trial of labor may be reasonable. The American College of Obstetricians and Gynecologists (2012b) recommends that estimated fetal weight, gestational age,
maternal glucose intolerance, and severity of prior neonatal injury be evaluated and risks and benefits of cesarean delivery discussed with any woman with a history of shoulder dystocia. After discussion, either mode of delivery is appropriate.

Management

Because shoulder dystocia cannot be accurately predicted, clinicians should be well versed in its management principles. Because of ongoing cord compression with this dystocia, one goal is to reduce the head-to-body delivery time. This is balanced against the second goal, which is avoidance of fetal and maternal injury from aggressive manipulations. Accordingly, an initial gentle attempt at traction, assisted by maternal expulsive efforts, is recommended. Adequate analgesia is certainly ideal. Some clinicians advocate performing a large episiotomy to provide room for manipulations. Of note, Paris (2011) and Gurewitsch (2004) and their colleagues reported no change in the brachial plexus injury rate for groups in which episiotomy was not performed during shoulder dystocia management.

After gentle traction, various techniques can be used to free the anterior shoulder from its impacted position behind the symphysis pubis. Of these, moderate suprapubic pressure can be applied by an assistant, while downward traction is applied to the fetal head. Pressure is applied with the heel of the hand to the anterior shoulder wedged above and behind the symphysis. The anterior shoulder is thus either depressed or rotated, or both, so the shoulders occupy the oblique plane of the pelvis and the anterior shoulder can be freed.

The McRoberts maneuver was described by Gonik and associates (1983) and named for William A. McRoberts, Jr., who popularized its use at the University of Texas at Houston. The maneuver consists of removing the legs from the stirrups and sharply flexing them up onto the abdomen (Fig. 27-7). Gherman and associates (2000) analyzed the McRoberts maneuver using x-ray pelvimetry. They found that the procedure caused straightening of the sacrum relative to the lumbar vertebrae, rotation of the symphysis pubis toward the maternal head, and a decrease in the angle of pelvic inclination. Although this does not increase pelvic dimensions, pelvic rotation cephalad tends to free the impacted anterior shoulder. Gonik and coworkers (1989) tested the McRoberts position objectively with laboratory models and found that the maneuver reduced the forces needed to free the fetal shoulder.
FIGURE 27-7 The McRoberts maneuver. The maneuver consists of removing the legs from the stirrups and sharply flexing the thighs up onto the abdomen. The assistant is also providing suprapubic pressure simultaneously (arrow).
Another maneuver, *delivery of the posterior shoulder*, consists of carefully sweeping the posterior arm of the fetus across its chest, followed by delivery of the arm. The shoulder girdle is then rotated into one of the oblique diameters of the pelvis with subsequent delivery of the anterior shoulder (Fig. 27-8).
FIGURE 27-8 Delivery of the posterior shoulder for relief of shoulder dystocia. A. The operator’s hand is introduced into the vagina along the fetal posterior humerus. B. The arm is splinted and swept across the chest, keeping the arm flexed at the elbow. C. The fetal hand is grasped and the arm extended along the side of the face. The posterior arm is delivered from the vagina.

Woods (1943) reported that by progressively rotating the posterior shoulder 180 degrees in a corkscrew fashion, the impacted anterior shoulder could be released. This is frequently referred to as the *Woods corkscrew maneuver* (Fig. 27-9). Rubin (1964) recommended two maneuvers. First, the fetal shoulders are rocked from side to side by applying force to the maternal abdomen. If this is not successful, the pelvic hand reaches the most easily accessible fetal shoulder, which is then pushed toward the anterior surface of the chest. This maneuver most often abducts both shoulders, which in turn produces a smaller shoulder-to-shoulder diameter. This permits displacement of the anterior shoulder from behind the symphysis (Fig. 27-10).

FIGURE 27-9 Woods maneuver. The hand is placed behind the posterior shoulder of the fetus. The shoulder is then rotated progressively 180 degrees in a corkscrew manner so that the impacted anterior shoulder is released.
FIGURE 27-10 The second Rubin maneuver. A. The shoulder-to-shoulder diameter is aligned vertically. B. The more easily accessible fetal shoulder (the anterior is shown here) is pushed toward the anterior chest wall of the fetus (arrow). Most often, this results in abduction of both shoulders, which reduces the shoulder-to-shoulder diameter and frees the impacted anterior shoulder.

Importantly, progression from one maneuver to the next should be organized and methodical. As noted, the urgency to relieve the dystocia should be balanced against potentially injurious traction forces and manipulations. Lerner and coworkers (2011) in their evaluation of 127 shoulder dystocia cases reported that all neonates without sequelae from shoulder dystocia were born by 4 minutes. Conversely, most depressed neonates—57 percent—had head-to-body delivery intervals > 4 minutes. The percentage of depressed neonates rose sharply after 3 minutes.

Deliberate fracture of the anterior clavicle by using the thumb to press it toward and against the pubic ramus can be attempted to free the shoulder impaction. In practice, however, deliberate fracture of a large neonate clavicle is difficult. If successful, the fracture will heal rapidly and is usually trivial compared with brachial nerve injury, asphyxia, or death.

Hibbard (1982) recommended that pressure be applied to the fetal jaw and neck in the direction of the maternal rectum, with strong fundal pressure applied by an assistant as the anterior shoulder is freed. Strong fundal pressure, however, applied at the wrong time may result in even further impaction of the anterior shoulder. Gross and associates (1987) reported that fundal pressure in the absence of other maneuvers “resulted in a 77-percent complication rate and was strongly associated with (fetal) orthopedic and neurologic damage.”

Sandberg (1985) reported the Zavanelli maneuver for cephalic replacement into the pelvis
followed by cesarean delivery. The first part of the maneuver consists of returning the head to the occiput anterior or posterior position. Terbutaline, 0.25 mg, is given subcutaneously to produce uterine relaxation. The operator flexes the head and slowly pushes it back into the vagina. Cesarean delivery is then performed. Sandberg (1999) reviewed 103 reported cases in which the Zavanelli maneuver was used. It was successful in 91 percent of cephalic cases and in all cases of breech head entrapments. Despite successful replacement, fetal injuries were common but may have resulted from the multiple manipulations used before the Zavanelli maneuver (Sandberg, 2007). Six stillbirths, eight neonatal deaths, and 10 neonates who suffered brain damage were described. Uterine rupture also was reported.

Symphysiotomy, in which the intervening symphyseal cartilage and much of its ligamentous support is cut to widen the symphysis pubis, is described in Chapter 28 (p. 567). It has been used successfully for shoulder dystocia (Hartfield, 1986). Goodwin and colleagues (1997) reported three cases in which symphysiotomy was performed after the Zavanelli maneuver had failed. All three neonates died, and maternal morbidity was significant due to urinary tract injury. Cleidotomy consists of cutting the clavicle with scissors or other sharp instruments and is usually done for a dead fetus (Schramm, 1983).

Hernandez and Wendel (1990) suggested use of a shoulder dystocia drill to better organize emergency management:

1. Call for help—mobilize assistants and anesthesia and pediatric personnel. Initially, a gentle attempt at traction is made. Drain the bladder if it is distended.
2. A generous episiotomy may be desired to afford room posteriorly.
3. Suprapubic pressure is used initially by most practitioners because it has the advantage of simplicity. Only one assistant is needed to provide suprapubic pressure, while normal downward traction is applied to the fetal head.
4. The McRoberts maneuver requires two assistants. Each assistant grasps a leg and sharply flexes the maternal thigh against the abdomen.

These maneuvers will resolve most cases of shoulder dystocia.

If the above listed steps fail, the following steps may be attempted, and any of the maneuvers may be repeated:

5. Delivery of the posterior arm is attempted. With a fully extended arm, however, this is usually difficult to accomplish.
6. Woods screw maneuver is applied.
7. Rubin maneuver is attempted.

Other techniques generally should be reserved for cases in which all other maneuvers have failed. These include intentional fracture of the anterior clavicle and the Zavanelli maneuver. The American College of Obstetricians and Gynecologists (2012b) has concluded that no one maneuver is superior to another in releasing an impacted shoulder or reducing the chance of injury. Performance of the McRoberts maneuver, however, was deemed a reasonable initial approach. The College (2012a) also has created a Patient Safety Checklist to guide the documentation process with shoulder dystocia.

Shoulder dystocia training and protocols using simulation-based education and drills has evidence-based support. These tools improve performance and retention of drill steps (Buerkle,
Typical vaginal delivery may be challenging in women with perineal limitations or with a large anomalous fetus. Delivery in women with prior pelvic reconstructive surgeries and in those with scarring from female genital mutilation is described here. The special needs of women with congenital vaginal septa, giant condyloma, Crohn disease, or connective-tissue disorders are discussed in chapters covering those topics.

Female Genital Mutilation

Inaccurately called female circumcision, mutilation refers to medically unnecessary vulvar and perineal modification. In the United States it is a federal crime to perform unnecessary genital surgery on a girl younger than 18 years. That said, forms of female genital mutilation are practiced in countries throughout Africa, the Middle East, and Asia. As many as 130 million women worldwide have undergone one of these procedures, and approximately 230,000 live in the United States (Nour, 2006). Cultural sensitivity is imperative, because many women may be offended by the suggestion that they have been assaulted or mutilated (American College of Obstetricians and Gynecologists, 2007).

The World Health Organization (1997) classifies genital mutilations into four types (Table 27-1). Complications include infertility, dysmenorrhea, diminished sexual quality of life, and propensity for vulvovaginal infection (Almroth, 2005; Andersson, 2012; Nour, 2006). In general, women with significant symptoms following type III procedures are candidates for corrective surgery. Specifically, division of midline scar tissue to reopen the vulva is termed defibulation or deinfibulation.

Adapted from the World Health Organization, 1997.
Female genital mutilation has been associated with some adverse maternal and neonatal complications. The World Health Organization (2006) estimated that these procedures increased perinatal morbidity rates by 10 to 20 per 1000. Small increased risks for prolonged labor, cesarean delivery, postpartum hemorrhage, and early neonatal death are found by some but not all (Chibber, 2011; Rouzi, 2012; Wuest, 2009). Importantly, the psychiatric consequences can be profound.

For those women who do not desire defibulation until they become pregnant, the procedure can be done at midpregnancy using spinal analgesia (Nour, 2006). Or, as shown in Figure 27-11, another option is to wait until delivery. In women not undergoing defibulation, anal sphincter tear rates with vaginal delivery may be increased (Berggren, 2013; Wuest, 2009). In our experiences, intrapartum defibulation in many cases allows successful vaginal delivery without major complications.

**FIGURE 27-11** Process of defibulation. Although not shown here, lidocaine is first infiltrated along the planned incision. As protection, two fingers of one hand are insinuated behind the shelf created by fused labia but in front of the urethra and crowning head. The shelf is then incised in the midline. After delivery, the raw edges are sutured with rapidly absorbable material to secure hemostasis. (From Rouzi, 2012, with permission.)
These surgeries are performed with increasing frequency in reproductive-aged women, and thus pregnancy following these procedures is not uncommon. Logically, there are concerns for symptom recurrence following vaginal delivery, and high-quality data to aid evidenced-based decisions are limited. For women with prior stress urinary incontinence surgery, slightly greater protection against postpartum incontinence is gained by elective cesarean delivery (Pollard, 2012; Pradhan, 2013). Stated another way, most women with prior anti-incontinence surgery can be delivered vaginally without symptom recurrence. Also, cesarean delivery is not always protective. Obviously, symptom recurrence and the need for additional vaginal surgery should be weighed against the surgical risk of cesarean delivery (Groenen, 2008). In those with prior surgeries for anal incontinence or pelvic organ prolapse, only scant information regarding outcomes is available. Such cases require individualization.

**Anomalous Fetuses**

Rarely, delivery can be obstructed by extreme macrocephaly secondary to hydrocephaly or by massive fetal abdomen enlargement from a greatly distended bladder, ascites, or large kidneys or liver. With milder forms of hydrocephaly, if the biparietal diameter is < 10 cm or if the head circumference is < 36 cm, then vaginal delivery may be permitted (Anteby, 2003).

In rare cases in which neonatal death has occurred or is certain due to associated anomalies, vaginal delivery may be reasonable, but the head or abdomen must be reduced in size for delivery. Removal of fluid by cephalocentesis or paracentesis with sonographic guidance can be performed intrapartum. For hydrocephalic fetuses that are breech, cephalocentesis can be accomplished suprapubically when the aftercoming head enters the pelvis. For those that require cesarean delivery, fluid removal before hysterotomy circumvents extending a low transverse or lengthening a vertical incision.

**THIRD STAGE OF LABOR**

**Delivery of the Placenta**

Third-stage labor begins immediately after fetal birth and ends with placental delivery. Goals include delivery of an intact placenta and avoidance of uterine inversion or postpartum hemorrhage. The latter two are grave intrapartum complications and constitute emergencies, as described in Chapter 41 (p. 783).

Immediately after newborn birth, uterine fundal size and consistency are examined. If the uterus remains firm and there is no unusual bleeding, watchful waiting until the placenta separates is the usual practice. Massage is not employed, but the fundus is frequently palpated to ensure that it does not become atonic and filled with blood from placental separation. To prevent uterine inversion, umbilical cord traction must not be used to pull the placenta from the uterus. Moreover, placental expression is not forced before placental separation. Signs of separation include a sudden gush of blood into the vagina, a globular and firmer fundus, a lengthening of the umbilical cord as the placenta descends into the vagina, and a rise of the uterus into the abdomen. With the last, the placenta, having separated, passes down into the lower uterine segment and vagina. Here, its bulk pushes the uterus upward.

These signs sometimes appear within 1 minute after newborn delivery and usually within 5 minutes. Once the placenta has detached from the uterine wall, it should be determined that the
uterus is firmly contracted. The mother may be asked to bear down, and the intraabdominal pressure often expels the placenta into the vagina. These efforts may fail or may not be possible because of analgesia. After ensuring that the uterus is contracted firmly, pressure is exerted by a hand wrapped around the fundus to propel the detached placenta into the vagina (Fig. 27-12). The umbilical cord is kept slightly taut but is not pulled. Concurrently, the heel of the hand exerts downward pressure between the symphysis pubis and the uterine fundus. This also aids inversion prevention. Once the placenta passes through the introitus, pressure on the uterus is relieved. The placenta is then gently lifted away (Fig. 27-13). Care is taken to prevent placental membranes from being torn off and left behind. If the membranes begin to tear, they are grasped with a clamp and removed by gentle teasing (Fig. 27-14).

**FIGURE 27-12** Expression of placenta. Note that the hand is *not* trying to push the fundus of the uterus through the birth canal! As the placenta leaves the uterus and enters the vagina, the uterus is elevated by the hand on the abdomen while the cord is held in position. The mother can aid in the delivery of the placenta by bearing down. As the placenta reaches the perineum, the cord is lifted, which in turn lifts the placenta out of the vagina.
FIGURE 27-13 The placenta is removed from the vagina by lifting the cord.
Membranes that were somewhat adhered to the uterine lining are separated by gentle traction with a ring forceps.

**Manual Removal of Placenta**

Occasionally, the placenta will not separate promptly. This is especially common with preterm delivery (Dombrowski, 1995). If there is brisk bleeding and the placenta cannot be delivered by the above technique, manual removal of the placenta is indicated, using the safeguards described in Chapter 41 (p. 784). It is unclear how much time should elapse in the absence of bleeding before the placenta is manually removed (Deneux-Tharaux, 2009). If labor analgesia is still intact, some obstetricians practice routine manual removal of any placenta that has not separated spontaneously by the time they have completed delivery of the newborn and care of the cord. The benefits of this practice, however, have not been proven, and most obstetricians await spontaneous placental detachment unless bleeding is excessive. When manual removal is performed, some administer a single dose of intravenous antibiotics similar to that used for cesarean infection prophylaxis (Chap. 30, p. 590). The American College of Obstetricians and Gynecologists (2011) has concluded that there are no data to either support or refute this practice.

**Management of the Third Stage**

Practices within the third stage of labor may be broadly considered as either physiological or active management. Physiological or expectant management involves waiting for placental separation signs and allowing the placenta to deliver either spontaneously or aided by nipple
stimulation or gravity (World Health Organization, 2012). In contrast, active management of third-stage labor consists of early cord clamping, controlled cord traction during placental delivery, and immediate administration of prophylactic uterotonics. The goal of this triad is to limit postpartum hemorrhage (Begley, 2011; Jangsten, 2011; Prendiville, 1988). In addition, uterine massage following placental delivery is recommended by many but not all to prevent postpartum hemorrhage. We support this with the caveat that evidence for this practice is not strong (Abdel-Aleem, 2010). As noted earlier (p. 539), immediate cord clamping does not increase postpartum hemorrhage rates and thus is a less important component of this trio. Similarly, cord traction may also be less critical (Gülmezoglu, 2012).

Therefore, uterotonics appear to be the most important factor to decrease postpartum blood loss. Choices include oxytocin (Pitocin), misoprostol (Cytotec), carboprost (Hemabate), and the ergots, namely ergonovine (Ergotrate) and methylergonovine (Methergine). In addition, a combination agent of oxytocin and ergonovine (Syntometrine) is used outside the United States. Also in other countries, carbetocin (Duratocin), a long-acting oxytocin analogue, is available and effective for hemorrhage prevention during cesarean delivery (Attilakos, 2010; Su, 2012). Of these, the World Health Organization (2012) recommends oxytocin as a first-line agent. Ergot-based drugs and misoprostol are alternatives in settings that lack oxytocin.

Uterotonics may be given before or after placental expulsion without increasing rates of postpartum hemorrhage, placental retention, or third-stage labor length (Soltani, 2010). If they are given before delivery of the placenta, however, they may entrap an undiagnosed, undelivered second twin. Thus, abdominal palpation should confirm no additional fetuses.

**High-Dose Oxytocin**

Synthetic oxytocin is identical to that produced by the posterior pituitary. Its action is noted at approximately 1 minute, and it has a mean half-life of 3 to 5 minutes. When given as a bolus, oxytocin can cause profound hypotension. Secher and coworkers (1978) reported that an intravenous bolus of 10 units of oxytocin caused a marked transient fall in blood pressure with an abrupt increase in cardiac output. Svanström and associates (2008) confirmed those findings in 10 healthy women following cesarean delivery. Mean pulse rate increased 28 bpm, mean arterial pressure decreased 33 mm Hg, and electrocardiogram changes of myocardial ischemia as well as chest pain and subjective discomfort were noted. These hemodynamic changes could be dangerous for women hypovolemic from hemorrhage or those with cardiac disease. Thus, oxytocin should not be given intravenously as a large bolus. Rather, it should be given as a dilute solution by continuous intravenous infusion or as an intramuscular injection.

Water intoxication can result from the antidiuretic action of high-dose oxytocin if administered in a large volume of electrolyte-free dextrose solution (Whalley, 1963). In a case report, Schwartz and Jones (1978) described convulsions in both a mother and her newborn following administration of 6.5 liters of 5-percent dextrose solution and 36 units of oxytocin before delivery. The cord plasma sodium concentration was 114 mEq/L. Accordingly, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the infusion flow rate (Chap. 26, p. 530).

Despite the routine use of oxytocin, no standard prophylactic dose has been established for its use following either vaginal or cesarean delivery. In an analysis of studies that compared oxytocin dosage, investigators found higher infusion doses to be more effective than lower doses or protracted fixed-dose administration (Roach, 2013; Tita, 2012). Our standard practice, if an intravenous infusion is established, is to add 20 units (2 mL) of oxytocin per liter of infusate. This solution is administered after delivery of the placenta at a rate of 10 to 20 mL/min (200 to 400
mU/min) for a few minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate then is reduced to 1 to 2 mL/min until the mother is ready for transfer from the recovery suite to the postpartum unit. The infusion is usually then discontinued. For women without intravenous access, 10 units of intramuscular oxytocin are provided.

**Ergonovine and Methylergonovine**

These ergot alkaloids have similar activity levels in myometrium, and only methylergonovine is currently manufactured in the United States. These agents require very specific storage conditions, as they deteriorate rapidly with exposure to light, heat, and humidity.

Whether given intramuscularly or orally, both are powerful stimulants of myometrial contraction, exerting an effect that may persist for hours. In pregnant women, an intramuscular or oral dose of 0.2 mg results in tetanic uterine contractions. Effects develop within a few minutes after intramuscular or oral administration. Moreover, the response is sustained with little tendency toward relaxation. *Ergots are dangerous for the fetus and mother when given before delivery.*

Moreover, cases of serious injury and death have been reported when methylergonovine was administered accidentally to newborns in the labor and delivery room instead of vitamin K, hepatitis B vaccine, or naloxone (Aeby, 2003; American Regent, 2012a; Bangh, 2005). The Food and Drug Administration (2012) has added a warning to the package insert recommending a 12-hour delay between the last methylergonovine dose and breast feeding. Despite this, no adverse effects attributable to this drug in breast milk have been reported (Briggs, 2011).

In addition to neonatal concerns, parenteral administration of ergot alkaloids, especially by the intravenous route, may induce transient maternal hypertension. Other reported side effects include nausea, vomiting, tinnitus, headache, and painful uterine contractions. Hypertension is more likely to be severe in women with gestational hypertension. These drugs are contraindicated in patients with hypertension, cardiac disease or occlusive vascular disorders, severe hepatic or renal disease, and sepsis (Novartis, 2012; Sanders-Bush, 2011). Moreover, this drug is not routinely given intravenously to avoid inducing sudden hypertensive and cerebrovascular accidents. If considered a lifesaving measure, however, intravenous methylergonovine should be given slowly during no less than 60 seconds with careful monitoring of blood pressure (American Reagent, 2012b).

Ergot alkaloid agents do not provide superior protection against postpartum hemorrhage compared with oxytocin. Moreover, safety and tolerability are greater with oxytocin (Liabsuetrakul, 2007). For these reasons, ergot alkaloid agents are considered second-line for third-stage labor prevention of hemorrhage.

**Misoprostol**

This prostaglandin E₁ analogue has proved inferior to oxytocin for postpartum hemorrhage prevention (Tunçalp, 2012). Although oxytocin is preferred, in resource-poor settings that lack oxytocin, misoprostol is suitable for hemorrhage prophylaxis and is given as a single oral 600-μg dose (Moeen, 2011; World Health Organization, 2012). Side effects include shivering in 30 percent and fever in 5 percent. Unlike some other prostaglandins, nausea or diarrhea is infrequent (Derman, 2006; Lumbiganon, 1999; Walraven, 2005).

“FOURTH STAGE” OF LABOR
The hour immediately following delivery of the placenta is critical, and it has been designated by some as the fourth stage of labor. During this time, lacerations are repaired. Although uterotonics are administered, postpartum hemorrhage as the result of uterine atony is most likely at this time. Hematomas may expand. Consequently, uterine tone and the perineum should be frequently evaluated. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that maternal blood pressure and pulse be recorded immediately after delivery and every 15 minutes for the first 2 hours. The placenta, membranes, and umbilical cord should be examined for completeness and for anomalies, as described in Chapter 6 (p. 117).

### Birth Canal Lacerations

Lower genital tract lacerations may involve the cervix, vagina, or perineum. Those of the cervix and vagina are described in Chapter 41 (p. 788). Perineal tears may follow any vaginal delivery and are classified by their depth. Complete definitions and visual examples are given in Figure 27-15. As noted, third- and fourth-degree lacerations are considered higher-order lacerations. Short-term, these are associated with greater blood loss, puerperal pain, and wound disruption or infection risk. Long-term, they are linked with higher rates of anal incontinence and dyspareunia. The incidence of higher-order lacerations varies from 0.25 to 6 percent (Garrett, 2014; Groutz, 2011; Melamed, 2013; Stock, 2013). Risk factors for these more complex lacerations include midline episiotomy, nulliparity, longer second-stage labor, precipitous delivery, persistent occiput posterior position, operative vaginal delivery, Asian race, and increasing fetal birthweight (Landy, 2011; Melamed, 2013). Epidural analgesia was found to be protective (Jango, 2014).
First-degree lacerations involve the fourchette, perineal skin, and vaginal mucous membrane but not the underlying fascia and muscle. These included periurethral lacerations, which may bleed profusely. Second-degree lacerations involve, in addition, the fascia and muscles of the perineal body but not the anal sphincter. These tears may be midline, but often extend upward on one or both sides of the vagina, forming an irregular triangle. Third-degree lacerations extend farther to involve the external anal sphincter. Fourth-degree lacerations extend completely through the rectal mucosa to expose its lumen and thus involves disruption of both the external and internal anal sphincters. (Used with permission from Drs. Shayzreen Roshanravan and Marlene Corton.)

Morbidity rates rise as laceration severity increases. Stock and coworkers (2013) reported that approximately 7 percent of 909 higher-order lacerations had complications. Williams and Chames (2006) found that mediolateral episiotomy was the most powerful predictor of wound disruption. Goldaber and associates (1993) found that 21 of 390 or 5.4 percent of women with fourth-degree lacerations experienced significant morbidity. There were 1.8 percent dehiscences, 2.8 percent infections plus a dehiscence, and 0.8 percent with isolated infections.

The repair of perineal lacerations is virtually the same as that of episiotomy incisions, albeit sometimes less satisfactory because of tear irregularities. Thus, laceration repair technique is discussed with episiotomy repair.

Episiotomy

The word episiotomy derives from the Greek *episton*—pubic region—plus *–tomy*—to cut. In a strict sense, episiotomy is incision of the pudendum—the external genital organs. Perineotomy is incision of the perineum. In common parlance, however, the term episiotomy often is used synonymously with perineotomy, a practice that we follow here. The incision may be made in the midline, creating a median or midline episiotomy (Fig. 27-16). It may also begin off the midline and directed laterally and downward away from the rectum, termed a mediolateral episiotomy.
Episiotomy Indications and Consequences

Although episiotomy is still a common obstetrical procedure, its use has decreased remarkably over the past 30 years. Oliphant and coworkers (2010) used the National Hospital Discharge Survey to analyze episiotomy rates between 1979 and 2006 in the United States. They noted a 75-percent decline in the episiotomy age-adjusted rate. Through the 1970s, however, it was common practice to cut an episiotomy for almost all women having their first delivery. The reasons for its popularity included substitution of a straight surgical incision, which was easier to repair, for the ragged laceration that otherwise might result. The long-held beliefs that postoperative pain is less and healing improved with an episiotomy compared with a tear, however, appeared to be incorrect (Larsson, 1991).

Another commonly cited but unproven benefit of routine episiotomy was that it prevented pelvic floor disorders. A number of observational studies and randomized trials, however, showed that routine episiotomy is associated with an increased incidence of anal sphincter and rectal tears (Angioli, 2000; Nager, 2001; Rodriguez, 2008).

Carroli and Mignini (2009) reviewed the Cochrane Pregnancy and Childbirth Group trial registry. There were lower rates of posterior perineal trauma, surgical repair, and healing complications in women managed with a restrictive use of episiotomy. Alternatively, the incidence of anterior perineal trauma was lower in the group managed with routine use of episiotomy.

With these findings came the realization that episiotomy did not protect the perineal body but contributed to anal sphincter incontinence by increasing the risk of higher-order lacerations. Signorello and associates (2000) reported that fecal and flatal incontinence was increased four- to
sixfold in women with an episiotomy compared with a group of women delivered with an intact perineum. Even compared with spontaneous lacerations, episiotomy tripled the risk of fecal incontinence and doubled it for flatal incontinence. Episiotomy without extension did not lower this risk. Despite repair of a third-degree extension, 30 to 40 percent of women have long-term anal incontinence (Gjessing, 1998; Poen, 1998). Finally, Alperin and associates (2008) reported that episiotomy performed for the first delivery conferred a fivefold risk for second-degree or higher-order laceration with the second delivery.

The American College of Obstetricians and Gynecologists (2013a) has concluded that restricted use of episiotomy is preferred to routine use. We are of the view that the procedure should be applied selectively for appropriate indications. Thus, episiotomy should be considered for indications such as shoulder dystocia, breech delivery, macrosomic fetuses, operative vaginal deliveries, persistent occiput posterior positions, and other instances in which failure to perform an episiotomy will result in significant perineal rupture. The final rule is that there is no substitute for surgical judgment and common sense.

**Episiotomy Type and Timing**

Before episiotomy, analgesia may be provided by existing labor epidural analgesia, by bilateral pudendal nerve blockade, or by infiltration of 1-percent lidocaine. If performed unnecessarily early, bleeding from the episiotomy may be considerable during the interval between incision and delivery. If it is performed too late, lacerations will not be prevented. Typically, episiotomy is completed when the head is visible during a contraction to a diameter of approximately 4 cm, that is, crowning. When used in conjunction with forceps delivery, most perform an episiotomy after application of the blades (Chap. 29, p. 580).

**Technique**

For midline episiotomy, fingers are insinuated between the crowning head and the perineum. The scissors are positioned at 6 o’clock on the vaginal opening and directed posteriorly (see Fig. 27-16). The incision length varies from 2 to 3 cm depending on perineal length and degree of tissue thinning. The incision is customized for specific delivery needs but should stop well before reaching the external anal sphincter. With mediolateral episiotomy, scissors are positioned at 7 o’clock or at 5 o’clock, and the incision is extended 3 to 4 cm toward the ipsilateral ischial tuberosity.

Differences between the two types of episiotomies are summarized in Table 27-2. Except for the important issue of third- and fourth-degree extensions, midline episiotomy is superior. Anthony and colleagues (1994) presented data from the Dutch National Obstetric Database of more than 43,000 deliveries. They found a more than fourfold decrease in severe perineal lacerations following mediolateral episiotomy compared with rates after midline incision. Proper selection of cases can minimize this one disadvantage. For example, if episiotomy is required during operative vaginal delivery, several studies have reported a protective effect from mediolateral episiotomy against higher-order perineal lacerations (de Leeuw, 2008; de Vogel, 2012; Hirsch, 2008).

Repair of Episiotomy or Perineal Laceration

Typically, episiotomy repair is deferred until the placenta has been delivered. This policy permits undivided attention to the signs of placental separation and delivery. A further advantage is that episiotomy repair is not interrupted or disrupted by the obvious necessity of delivering the placenta, especially if manual removal must be performed that may disrupt a newly repaired episiotomy. The major disadvantage is continuing blood loss until the repair is completed. Direct pressure from an applied gauze sponge will help to limit this loss.

For suitable repair, an understanding of perineal support and anatomy is necessary and is discussed in Chapter 2 (p. 21). Adequate analgesia is imperative, and Sanders and coworkers (2002) emphasized that women without regional analgesia can experience high levels of pain during perineal suturing. Again, local lidocaine can be used solely or as a supplement to bilateral pudendal nerve blockade. In those with epidural analgesia, additional dosing may be necessary.

There are many ways to repair an episiotomy incision, but hemostasis and anatomical restoration without excessive suturing are essential. A technique that commonly is employed for midline repair is shown in Figure 27-17. Some studies have found similar postoperative pain scores using either continuous or interrupted closure (Kindberg, 2008; Valenzuela, 2009). Others note less pain with continuous suturing (Kettle, 2012). Moreover, continuous suturing is faster and uses less suture material. Mornar and Perlow (2008) have shown that blunt needles are suitable and likely decrease the incidence of needlestick injuries. The suture material commonly used is 2-0 chromic catgut. Sutures made of polyglycolic acid derivatives are also frequently used. A decrease in postsurgical pain is cited as the major advantage of synthetic materials. Closures with these materials, however, occasionally require suture removal from the repair site because of pain or dyspareunia. According to Kettle and associates (2002), this disadvantage may be reduced using a rapidly absorbed polyglactin 910 (Vicryl Rapide).

**Type of Episiotomy**
FIGURE 27-17 Repair of midline episiotomy. **A.** Disruption of the hymenal ring and bulbocavernosus and superficial transverse perineal muscles are seen within the diamond-shaped episiotomy incision. **B.** An anchor stitch is placed above the wound apex to begin a running closure. Absorbable 2–0 or 3–0 suture is used for continuous closure of the vaginal mucosa and submucosa with interlocking stitches. **C.** After closing the vaginal incision and reapproximating the cut margins of the hymenal ring, the needle and suture are positioned to close the perineal incision. **D.** A continuous closure with absorbable 2–0 or 3–0 suture is used to close the fascia and muscles of the incised perineum. This aids restoration of the perineal body for long-term support. **E.** The continuous suture is then carried upward as a subcuticular stitch. The final knot is tied proximal to the hymenal ring.

Repair of a mediolateral episiotomy is similar to a midline repair. The technique is shown in Figure 27-18.
FIGURE 27-18 Mediolateral episiotomy repair. The vaginal mucosa is shown as already closed using 2–0 absorbable suture in a running interlocking stitch similar to that for midline repair. As illustrated, perineal reapproximation begins with reunion of bulbocavernosus and transverse perineal muscles. These will assist reestablishment of perineal body support. Distal to these muscles, abundant fat in the ischiorectal fossa is incorporated in the same running closure. A second layer atop this first perineal layer may be required to adequately close dead space. The skin is then closed with a subcuticular stitch as used for midline closure.

Fourth-Degree Laceration Repair
Two methods are used to repair a laceration involving the anal sphincter and rectal mucosa. The first is the end-to-end technique, which we prefer, and the second is the overlapping technique.

The end-to-end technique is shown in Figure 27-19. In all techniques that have been described, it is essential to approximate the torn edges of the rectal mucosa with sutures placed in the rectal muscularis approximately 0.5 cm apart. One suitable choice is 2–0 or 3–0 chromic gut.
This muscular layer then is covered by reapproximation of the internal anal sphincter. Finally, the cut ends of the external anal sphincter are isolated, approximated, and sutured together end-to-end with three or four interrupted stitches. The remainder of the repair is the same as for a midline episiotomy.
FIGURE 27-19 Layered repair of a fourth-degree perineal laceration. A. Approximation of the
anorectal mucosa and submucosa in a running or interrupted fashion using fine absorbable suture such as 3–0 or 4–0 chromic or Vicryl. During this suturing, the superior extent of the anterior anal laceration is identified, and the sutures are placed through the submucosa of the anorectum approximately 0.5 cm apart down to the anal verge. B. A second layer is placed through the rectal muscularis using 3–0 Vicryl suture in a running or interrupted fashion. This “reinforcing layer” should incorporate the torn ends of the internal anal sphincter, which is identified as the thickening of the circular smooth muscle layer at the distal 2 to 3 cm of the anal canal. It can be identified as the glistening white fibrous structure lying between the anal canal submucosa and the fibers of the external anal sphincter (EAS). In many cases, the internal sphincter retracts laterally and must be sought and retrieved for repair. C. In overview, with traditional end-to-end approximation of the EAS, a suture is placed through the EAS muscle, and four to six simple interrupted 2–0 or 3–0 Vicryl sutures are placed at the 3, 6, 9, and 12 o’clock positions through the connective tissue capsule of the sphincter. The sutures through the inferior and posterior portions of the sphincter should be placed first to aid this part of the repair. To begin this portion of the closure, the disrupted ends of the striated EAS muscle and capsule are identified and grasped with Allis clamps. Suture is placed through the posterior wall of the EAS capsule. D. Sutures through the EAS (blue suture) and inferior capsule wall. E. Sutures to reapproximate the anterior and superior walls of the EAS capsule. The remainder of the repair is similar to that described for a midline episiotomy in Figure 27-17.

The overlapping technique is an alternative method to approximate the external anal sphincter. Data based on randomized controlled trials do not support that this method yields superior anatomical or functional results compared with those of the traditional end-to-end method (Farrell, 2012; Fitzpatrick, 2000).

We, as well as others, recommend perioperative antimicrobial prophylaxis for the reduction of infectious morbidity associated with higher-order perineal injury repair (Goldaber, 1993; Stock, 2013). A single dose of a second-generation cephalosporin is suitable, or clindamycin for penicillin-allergic women. Although such prophylaxis has some evidence-based support, the American College of Obstetricians and Gynecologists (2011) has concluded that this practice has not been extensively studied (Duggal, 2008; Stock, 2013). Postoperatively, stool softeners should be prescribed for a week, and enemas and suppositories should be avoided.

Unfortunately, normal function is not always ensured even with correct and complete surgical repair. Some women may experience continuing fecal incontinence caused by injury to the innervation of the pelvic floor musculature (Roberts, 1990).

Postepisiotomy Pain

Pudendal nerve blockade can aid relief of perineal pain postoperatively (Aissaoui, 2008). Locally applied ice packs help reduce swelling and allay discomfort. Topical application of 5-percent lidocaine ointment was not effective in relieving episiotomy or perineal laceration discomfort in one randomized trial (Minassian, 2002). Analgesics such as codeine give considerable relief. Because pain may be a signal of a large vulvar, paravaginal, or ischiorectal fossa hematoma or perineal cellulitis, these sites should be examined carefully if pain is severe or persistent. Management of these complications is discussed in Chapters 37 and 41 (p. 689 and p. 790). In addition to pain, urinary retention may complicate episiotomy recovery (Mulder, 2012). Its management is described in Chapter 36 (p. 676).

For those with second-degree or greater lacerations, intercourse is usually proscribed until after the first puerperal visit at 4 to 6 weeks. Signorello and coworkers (2001) surveyed 615
women 6 months postpartum and reported that those delivered with an intact perineum reported better sexual function compared with those who had perineal trauma. In another follow-up of 2490 women, Rådestad and associates (2008) reported delayed intercourse at 3 and 6 months, but not at 1 year, in women with and without perineal trauma.

Near term, the fetus typically turns spontaneously to a cephalic presentation as the increasing bulk of the buttocks seeks the more spacious fundus. However, if the fetal buttocks or legs enter the pelvis before the head, the presentation is breech. This fetal lie is more common remote from term as each fetal pole is of similar bulk earlier in pregnancy (Fig. 28-1). That said, breech presentation persists at term in 3 to 4 percent of singleton deliveries. The annual rate of breech presentation at delivery in nearly 270,000 singleton newborns at Parkland Hospital has varied from only 3.3 to 3.9 percent during the past 30 years.
Current obstetrical thinking regarding vaginal delivery of the breech fetus has been tremendously influenced by results reported from the Term Breech Trial Collaborative Group (Hannah, 2000). This trial included 1041 women randomly assigned to planned cesarean and 1042 to planned vaginal delivery. In the planned vaginal delivery group, 57 percent were actually delivered vaginally. Planned cesarean delivery was associated with a lower risk of perinatal mortality compared with planned vaginal delivery—3 per 1000 versus 13 per 1000. Cesarean delivery was also associated with a lower risk of “serious” neonatal morbidity—1.4 versus 3.8 percent.

The reaction to these findings by the American College of Obstetricians and Gynecologists (2001) resulted in an abrupt decline in the rate of attempted vaginal breech deliveries. Since those times, however, a more moderate plan was reached for management of breech delivery.

Critics of the Term Breech Trial emphasized that most of the outcomes included in the “serious” neonatal morbidity composite did not actually portend long-term disability. Moreover, as data from countries with low perinatal mortality rates became available, they showed infrequent perinatal deaths, and rates did not differ significantly between mode-of-delivery groups. Also, only nulliparas were included in the Term Breech Trial, and fewer than 10 percent underwent radiological pelvimetry. And last, the 2-year outcomes for children born during the original multicenter trial showed that planned cesarean delivery was not associated with a reduction in the
rate of death or developmental delay (Whyte, 2004). Some of the large studies reporting the safety and risks of vaginal delivery for the term breech singleton are discussed further on page 561.

These findings prompted the American College of Obstetricians and Gynecologists (2012b) to modify its stance on breech presentation, and it currently recommends that “the decision regarding the mode of delivery should depend on the experience of the health care provider” and that “planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines.” This has been echoed by other obstetrical organizations (Carbonne, 2001; Kotaska, 2009; Royal College of Obstetricians and Gynaecologists, 2009).

CLASSIFICATION OF BREECH PRESENTATIONS

The varying relations between the lower extremities and buttocks of breech fetuses form the categories of frank, complete, and incomplete breech presentations. With a frank breech presentation, the lower extremities are flexed at the hips and extended at the knees, and thus the feet lie in close proximity to the head (Fig. 28-2). A complete breech differs in that one or both knees are flexed (Fig. 28-3). With incomplete breech presentation, one or both hips are not flexed, and one or both feet or knees lie below the breech, such that a foot or knee is lowermost in the birth canal (Fig. 28-4). A footling breech is an incomplete breech with one or both feet below the breech.
FIGURE 28-2 Frank breech presentation.
FIGURE 28-3 Complete breech presentation.
In perhaps 5 percent of term breech fetuses, the head may be in extreme hyperextension. These presentations have been referred to as the *stargazer fetus*, and in Britain as the *flying foetus*. With such hyperextension, vaginal delivery may result in injury to the cervical spinal cord. Thus, if present after labor has begun, this is an indication for cesarean delivery (Svenningsen, 1985).

**DIAGNOSIS**

**Risk Factors**

Understanding the clinical settings that predispose to breech presentation can aid early recognition. Other than early gestational age, risk factors include abnormal amnionic fluid volume, multifetal gestation, hydrocephaly, anencephaly, uterine anomalies, placenta previa, fundal placental implantation, pelvic tumors, high parity with uterine relaxation, and prior breech delivery.
Specifically, following one breech delivery, the recurrence rate for a second pregnancy with breech presentation was nearly 10 percent, and that for a subsequent third pregnancy was 27 percent (Ford, 2010). Prior cesarean delivery has also been described by some to increase twofold the incidence of breech presentation (Kalogiannidis, 2010; Vendittelli, 2008). Last, smoking may be a modifiable cause of this presentation (Rayl, 1996; Witkop, 2008).

### Examination

Leopold maneuvers to ascertain fetal presentation are discussed in Chapter 22 (p. 438). With the first maneuver, the hard, round, ballotable fetal head may be found to occupy the fundus. The second maneuver indicates the back to be on one side of the abdomen and the small parts on the other. With the third maneuver, if not engaged, the breech is movable above the pelvic inlet. After engagement, the fourth maneuver shows the firm breech to be beneath the symphysis. The accuracy of this palpation varies (Lydon-Rochelle, 1993; Nassar, 2006). Thus, with suspected breech presentation—or any presentation other than cephalic—sonographic evaluation is indicated.

With a frank breech during vaginal examination, no feet are appreciated, but the fetal ischial tuberosities, sacrum, and anus are usually palpable. After further fetal descent, the external genitalia may also be distinguished. Especially when labor is prolonged, the fetal buttocks may become markedly swollen, rendering differentiation of a face and breech difficult. In some cases, the anus may be mistaken for the mouth and the ischial tuberosities for the malar eminences. With careful examination, however, the finger encounters muscular resistance with the anus, whereas the firmer, less yielding jaws are felt through the mouth. The finger, upon removal from the anus, may become stained with meconium. The mouth and malar eminences form a triangular shape, whereas the ischial tuberosities and anus lie in a straight line. With a complete breech, the feet may be felt alongside the buttocks. In footling presentations, one or both feet are inferior to the buttocks.

The fetal sacrum and its spinous processes are palpated also to establish position. As with cephalic presentations described in Chapter 22 (p. 434), fetal positions are designated as left sacrum anterior (LSA), right sacrum anterior (RSA), left sacrum posterior (LSP), right sacrum posterior (RSP), or sacrum transverse (ST) to reflect the relations of the fetal sacrum to the maternal pelvis.

### ROUTE OF DELIVERY

Multiple factors aid determination of the best delivery route for a given mother-fetus pair. These include fetal characteristics, pelvic dimensions, coexistent pregnancy complications, operator experience, patient preference, and hospital capabilities.

#### Term and Preterm Breech Fetus

Although sharing the similarity of presentation, preterm breech fetuses have distinct risks related to immaturity compared with their term breech counterparts. Accordingly, separation of term and preterm breech fetuses for discussion allows a more accurate evaluation of information.

#### Term Breech Fetus

Data regarding superior perinatal outcomes for planned cesarean delivery of a singleton term
breech are conflicting. As described earlier (p. 558), the Term Breech Trial reported lower neonatal morbidity and mortality rates with planned cesarean delivery for breech presentation. Additional data favoring cesarean delivery comes from the World Health Organization (Lumbiganon, 2010). From their evaluation of more than 100,000 deliveries from nine participating Asian countries, they reported improved perinatal outcomes associated with planned cesarean compared with planned vaginal delivery of the term breech fetus. Other studies have evaluated neonatal outcome with cesarean delivery and also found lowered neonatal morbidity and mortality rates (Hartnack Tharin, 2011; Mailâth-Pokorny, 2009; Rietberg, 2005; Swedish Collaborative Breech Study Group, 2005).

In contrast, the *Presentation et Mode d’Accouchement*—which translates as presentation and mode of delivery (PREMODA)—study showed no differences in corrected neonatal mortality rates and neonatal outcomes according to delivery mode (Goffinet, 2006). This French prospective observational study involved more than 8000 women with term breech singletons. Strict criteria were used to select 2526 of these for planned vaginal delivery, and 71 percent of that group were delivered vaginally. Similarly, data from the Lille Breech Study Group in France showed no excessive morbidity in term breech singletons delivered vaginally provided strict fetal biometric and maternal pelvimetry parameters were applied (Michel, 2011). Other smaller studies also support these findings as long as guidelines are part of the selection process (Alarab, 2004; Albrechtsen, 1997; Giuliani, 2002; Toivonen, 2012). Long-term evidence in support of vaginal breech delivery comes from Eide and associates (2005). These researchers analyzed intelligence testing scores of more than 8000 men delivered breech and found no differences in intellectual performance in those delivered vaginally or by cesarean.

Despite evidence on both sides of the debate, at least in this country, rates of planned vaginal delivery attempts continue to decline (Hehir, 2012). And as predicted, the number of skilled operators able to safely select and vaginally deliver breech fetuses continues to dwindle (Chinnock, 2007). Moreover, obvious medicolegal concerns makes physician training in such deliveries difficult. In response, some institutions have developed birth simulators to improve resident competence in vaginal breech delivery (Deering, 2006; Maslovitz, 2007).

### Preterm Breech Fetus

Although there are no randomized studies regarding delivery of the preterm breech fetus, planned cesarean delivery appears to confer a survival advantage. Reddy and associates (2012) reported data from an National Institutes of Health retrospective multicenter cohort study involving 208,695 deliveries between 24 and 32 weeks’ gestation. For breech fetuses within these gestational ages, attempting vaginal delivery yielded a low completion rate, and those completed were associated with higher neonatal mortality rates compared with planned cesarean delivery. Other studies have reported similar findings (Demirci, 2012; Lee, 1998; Muhuri, 2006). There are, however, a few smaller studies that describe no improved survival rate in fetuses at earlier gestational ages—24 to 29 weeks—delivered by planned cesarean (Kayem, 2008; Stohl, 2011).

There are limited data regarding any preferable delivery route for preterm breech fetuses between 32 and 37 weeks. In these cases, fetal weight rather than gestational age is likely most important. The Maternal Fetal Medicine Committee of the Society of Obstetricians and Gynaecologists of Canada (SOGC) recommend that vaginal breech delivery is reasonable when the estimated fetal weight is > 2500 g (Kotaska, 2009).

### Delivery Complications
Maternal Morbidity and Mortality

Increased rates of maternal and perinatal morbidity can be anticipated with breech presentations. For the mother, with either cesarean or vaginal delivery, genital tract laceration can be problematic. With cesarean delivery, added stretching of the lower uterine segment by forceps or by a poorly molded fetal head can extend hysterotomy incisions. With vaginal delivery, especially with a thinned lower uterine segment, delivery of the aftercoming head through an incompletely dilated cervix or application of forceps may cause vaginal wall or cervical lacerations. Manipulations may also extend an episiotomy, create deep perineal tears, and increase infection risks. Anesthesia sufficient to induce appreciable uterine relaxation during vaginal delivery may cause uterine atony and in turn, postpartum hemorrhage. Death is a rare complication, but rates appear higher in those with planned cesarean delivery for breech presentation—a case fatality rate of 0.47 maternal deaths per 1000 births (Schutte, 2007). Last, as described in Chapter 30 (p. 588), the risks associated with vaginal breech delivery are balanced against general cesarean delivery risks, which include those associated with vaginal birth after cesarean (VBAC) or those with repeated cesarean hysterotomy.

Perinatal Morbidity and Mortality

Preterm delivery is a common association, and there is an increased rate of congenital anomalies. In addition, birth trauma, although uncommon, can contribute to death of the breech fetus. Importantly, these are seen both with vaginal as well as cesarean delivery. Some of the more common injuries are fractures of the humerus, clavicle, and femur (Canpolat, 2010; Matsubara, 2008). In some cases, traction may separate scapular, humeral, or femoral epiphyses.

Rare traumatic injuries may involve bony or soft tissues. Neonatal perineal tears have been reported from fetal scalp electrodes (Freud, 1993). Upper extremity paralysis—Erb or Duchenne—may follow brachial plexus stretching (Al-Qattan, 2010). When the fetus is extracted through a contracted pelvis, spoon-shaped depressions or actual fractures of the skull may result. The spinal cord may be injured or vertebra fractured if great force is employed (Vialle, 2007). Hematomas of the sternocleidomastoid muscles occasionally develop after delivery, although they usually disappear spontaneously. Last, testicular injury may follow breech delivery (Mathews, 1999). These are discussed in further detail in Chapter 33 (p. 645).

Compared with cephalic presentation, umbilical cord prolapse is more frequent with breech fetuses. Huang and coworkers (2012) analyzed 40 cases of prolapse and reported that half were associated with malpresentation or vaginal delivery of a second twin.

Some perinatal outcomes may be inherent to the breech position rather than delivery. For example, development of hip dysplasia is more common in breech compared with cephalic presentation and is unaffected by delivery mode (de Hundt, 2012; Fox, 2010; Ortiz-Neira, 2012).

Imaging Techniques

In many fetuses—especially those that are preterm—the breech is smaller than the aftercoming head. Moreover, unlike cephalic presentations, the head of a breech-presenting fetus does not undergo appreciable molding during labor. Thus, to avoid head entrapment following delivery of the breech, pelvic dimensions should be assessed before vaginal delivery. In addition, fetal size, type of breech, and degree of neck flexion or extension should be identified. To evaluate these, several imaging techniques can be used.
Sonography
In most cases, sonographic fetal evaluation will have been performed as part of prenatal care. If not, gross fetal abnormalities, such as hydrocephaly or anencephaly, can be rapidly ascertained with sonography. This will identify many fetuses not suitable for vaginal delivery and will help to ensure that a cesarean delivery is not performed under emergency conditions for an anomalous fetus with no chance of survival.

Head flexion can usually also be determined sonographically, and for vaginal delivery, the fetal head should not be extended (Fontenot, 1997; Rojansky, 1994). If imaging is uncertain, then simple two-view radiography of the abdomen is useful to define head inclination. The sonographic accuracy of fetal weight estimation does not appear limited by breech presentation (McNamara, 2012). Although variable, many protocols use fetal weights < 2500 g and > 3800 to 4000 g or evidence of growth restriction as exclusion criteria for planned vaginal delivery (Azria, 2012; Kotaska, 2009). Similarly, a biparietal diameter (BPD) > 90 to 100 mm is often considered exclusionary (Giuliani, 2002; Roman, 2008).

Pelvimetry
This assessment of the bony pelvis before vaginal delivery may be completed with one-view computed tomography (CT), magnetic resonance imaging, or plain film radiographs. Although there are no comparative data among these modalities for pelvimetry, computed tomography is favored due to its accuracy, low radiation dose, and widespread availability (Thomas, 1998). At Parkland Hospital, we use CT pelvimetry when possible to assess the critical dimensions of the pelvis (Chap. 2, p. 32). Although variable, some suggest specific measurements to permit a planned vaginal delivery: inlet anteroposterior diameter ≥ 105 mm; inlet transverse diameter ≥ 120 mm; and midpelvic interspinous diameter ≥ 100 mm (Azria, 2012; Vendittelli, 2006). Others use maternal-fetal biometry correlation. Appropriate values include: the sum of the inlet obstetrical conjugate minus the fetal BPD is ≥ 15 mm; the inlet transverse diameter minus the BPD is ≥ 25 mm; and the midpelvis interspinous diameter minus the BPD is ≥ 0 mm (Michel, 2011).

Decision-Making Summary
As outlined by the American College of Obstetricians and Gynecologists (2012b), risks versus benefits are weighed and discussed with the patient. If possible, this is preferably done before admission. A diligent search is made for any other complications, actual or anticipated, that might warrant cesarean delivery. Common circumstances are listed in Table 28-1. For a favorable outcome with any breech delivery, at the very minimum, the birth canal must be sufficiently large to allow passage of the fetus without trauma. The cervix must be fully dilated, and if not, then a cesarean delivery nearly always is the more appropriate method of delivery if suspected fetal compromise develops.

MANAGEMENT OF LABOR AND DELIVERY

Methods of Vaginal Delivery

There are important fundamental differences between labor and delivery in cephalic and breech presentations. With a cephalic presentation, once the head is delivered, the rest of the body typically follows without difficulty. With a breech, however, successively larger and less compressible parts are born. Spontaneous complete expulsion of the fetus that presents as a breech, as subsequently described, is seldom accomplished successfully. Therefore, as a rule, vaginal delivery requires skilled participation for a favorable outcome.

There are three general methods of breech delivery through the vagina:

1. Spontaneous breech delivery. The fetus is expelled entirely spontaneously without any traction or manipulation other than support of the newborn.
2. Partial breech extraction. The fetus is delivered spontaneously as far as the umbilicus, but the remainder of the body is extracted or delivered with operator traction and assisted maneuvers, with or without maternal expulsive efforts.
3. Total breech extraction. The entire body of the fetus is extracted by the obstetrician.

Labor Induction and Augmentation

Induction or augmentation of labor in women with a breech presentation is controversial, and data are limited. Marzouk and associates (2011) found similar perinatal neonatal outcomes with spontaneous labor or with cervical preparation and induced labor. In many studies, improved rates of successful vaginal delivery and neonatal outcome are associated with orderly labor progression. Thus, some protocols avoid augmentation, whereas others recommend it only for hypotonic contractions (Alarab, 2004; Kotaska, 2009). In women with a viable fetus, at Parkland Hospital, we attempt amniotomy induction but prefer cesarean delivery instead of oxytocin induction or augmentation.

Management of Labor

On arrival, rapid assessment should be made to establish the status of the membranes, labor, and fetal condition. Surveillance of fetal heart rate and uterine contractions begins at admission, and immediate recruitment of necessary staff should include: (1) an obstetrician skilled in the art of breech extraction, (2) an associate to assist with the delivery, (3) anesthesia personnel who can
ensure adequate analgesia or anesthesia when needed, and (4) an individual trained in newborn resuscitation.

For the mother, an intravenous catheter is inserted, and crystalloid infusion begun. Emergency induction of anesthesia or maternal resuscitation following hemorrhage from lacerations or from uterine atony are but two of many reasons that may require immediate intravenous access.

Assessment of cervical dilatation and effacement and the station of the presenting part is essential for planning the route of delivery. If labor is too far advanced, there may not be sufficient time to obtain pelvimetry. This alone, however, should not force the decision for cesarean delivery. Commonly, satisfactory progress in labor is the best indicator of pelvic adequacy (Biswas, 1993; Nwosu, 1993). Sonographic fetal biometry and assessment of head flexion are completed. And if not performed as part of earlier prenatal care, fetal anatomy is evaluated. Ultimately, the choice of abdominal or vaginal delivery is based on factors discussed earlier and listed in Table 28-1.

For managing labor and delivery of a breech fetus, additional help is required. One-on-one nursing is ideal during labor because of the risk of cord prolapse or occlusion, and physicians must be readily available for such emergencies. Guidelines for monitoring the high-risk fetus are applied as discussed in Chapter 24 (p. 497). During the first stage of labor, the fetal heart rate is recorded at least every 15 minutes. Most clinicians prefer continuous electronic monitoring. If a nonreassuring fetal heart rate pattern develops, then a decision must be made regarding the necessity of cesarean delivery.

When membranes are ruptured, either spontaneously or artificially, the cord prolapse risk is appreciable and is increased when the fetus is small or when the breech is not frank (Dilbaz, 2006; Erdemoglu, 2010). Therefore, a vaginal examination should be performed following rupture to exclude prolapse, and special attention should be directed to the fetal heart rate for the first 5 to 10 minutes following membrane rupture.

Cardinal Movements with Breech Delivery

Engagement and descent of the breech usually take place with the bitrochanteric diameter in one of the oblique pelvic diameters. The anterior hip usually descends more rapidly than the posterior hip, and when the resistance of the pelvic floor is met, internal rotation of 45 degrees usually follows, bringing the anterior hip toward the pubic arch and allowing the bitrochanteric diameter to occupy the anteroposterior diameter of the pelvic outlet. If the posterior extremity is prolapsed, however, it, rather than the anterior hip, rotates to the symphysis pubis.

After rotation, descent continues until the perineum is distended by the advancing breech, and the anterior hip appears at the vulva. By lateral flexion of the fetal body, the posterior hip then is forced over the perineum, which retracts over the fetal buttocks, thus allowing the infant to straighten out when the anterior hip is born. The legs and feet follow the breech and may be born spontaneously or require aid.

After the birth of the breech, there is slight external rotation, with the back turning anteriorly as the shoulders are brought into relation with one of the oblique diameters of the pelvis. The shoulders then descend rapidly and undergo internal rotation, with the bisacromial diameter occupying the anteroposterior plane. Immediately following the shoulders, the head, which is normally sharply flexed on the thorax, enters the pelvis in one of the oblique diameters and then rotates in such a manner as to bring the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.
The breech may engage in the transverse diameter of the pelvis, with the sacrum directed anteriorly or posteriorly. The mechanism of labor in the transverse position differs only in that internal rotation is through an arc of 90 rather than 45 degrees. Infrequently, rotation occurs in such a manner that the back of the fetus is directed posteriorly instead of anteriorly. Such rotation should be prevented if possible. Although the head may be delivered by allowing the chin and face to pass beneath the symphysis, the slightest traction on the body may cause extension of the head, which increases the diameter of the head that must pass through the pelvis.

**Partial Breech Extraction**

With all breech deliveries, unless there is considerable relaxation of the perineum, an episiotomy should be made and is an important adjunct to delivery. Ideally, the breech is allowed to deliver spontaneously to the umbilicus. Delivery is easier, and in turn, morbidity and mortality rates are, at least intuitively, lower. Delivery of the breech draws the umbilicus and attached cord into the pelvis, which stretches and compresses the cord. Therefore, once the breech has passed beyond the vaginal introitus, the abdomen, thorax, arms, and head must be delivered promptly either spontaneously or assisted, as described here.

The posterior hip will deliver, usually from the 6 o’clock position, and often with sufficient pressure to evoke passage of thick meconium (Fig. 28-5). The anterior hip then delivers, followed by external rotation to a sacrum anterior position. The mother should be encouraged to continue to push. As the fetus continues to descend, the legs are sequentially delivered by splinting the medial aspect of each femur with the operator’s fingers positioned parallel to each femur, and by exerting pressure laterally to sweep each leg away from the midline.

**FIGURE 28-5** The hips of the frank breech are delivering over the perineum. The anterior hip usually is delivered first.
Following delivery of the legs, the fetal bony pelvis is grasped with both hands, using a cloth towel moistened with warm water. The fingers should rest on the anterior superior iliac crests and the thumbs on the sacrum, minimizing the chance of fetal abdominal soft tissue injury (Fig. 28-6). Maternal expulsive efforts are used in conjunction with downward traction to effect delivery.

A cardinal rule in successful breech extraction is to employ steady, gentle, downward traction until the lower halves of the scapulas are delivered, making no attempt at delivery of the shoulders and arms until one axilla becomes visible. As the scapulas become visible, the fetal back tends to turn spontaneously toward the side of the mother to which it was originally directed. The appearance of one axilla indicates that the time has arrived for shoulder delivery. It makes little difference which shoulder is delivered first, and there are two methods for their delivery. In the first method, with the scapulas visible, the trunk is rotated in such a way that the anterior shoulder and arm appear at the vulva and can easily be released and delivered first (Fig. 28-7). The body of the fetus is then rotated 180 degrees in the reverse direction to deliver the other shoulder and arm (Fig. 28-8).

**FIGURE 28-6** Delivery of the body. The hands are applied, but not above the pelvic girdle. With thumbs over the sacrum, gentle downward traction is accomplished until the scapulas are clearly visible.
FIGURE 28-7 Clockwise rotation of the fetal pelvis and abdomen 90 degrees brings the sacrum from anterior to left sacrum transverse (LST). Simultaneously, the application of gentle downward traction effects delivery of the scapula (A) and arm (B–D).
The second method is employed if trunk rotation is unsuccessful. With this maneuver, the posterior shoulder is delivered first. For this, the feet are grasped in one hand and drawn upward over the inner thigh of the mother, toward which the ventral surface of the fetus is directed (Fig. 28-9). In this manner, leverage is exerted on the posterior shoulder, which slides out over the perineal margin, usually followed by the arm and hand. Then, by depressing the body of the fetus, the anterior shoulder emerges beneath the pubic arch, and the arm and hand usually follow spontaneously.
As breech extraction continues, upward traction is employed with the fetus drawn to the mother’s left inner thigh, thus effecting delivery of the posterior shoulder. This is followed by delivery of the posterior arm. The fetal body is then depressed and delivery of the anterior shoulder follows.

These rotational and downward traction maneuvers will decrease the persistence of nuchal arms, which can prevent descent and may result in a traumatic delivery. These maneuvers are frequently most easily effected with the operator at the level of the maternal pelvis and with one knee on the floor.

After both shoulders are delivered, the back of the fetus tends to rotate spontaneously in the direction of the symphysis. If upward rotation fails to occur, it is completed by manual rotation of the body. Delivery of the head may then be accomplished.

Unfortunately, the process is not always so simple, and it is sometimes necessary to assist delivery of the arms. There is more space available in the posterior and lateral segments of the normal pelvis than elsewhere. Therefore, in difficult cases, the posterior arm should be freed first. Because the corresponding axilla is already visible, upward traction on the feet is continued, and two fingers of the other hand are passed along the humerus until the elbow is reached (see Fig. 28-9). The fingers are placed parallel to the humerus and used to splint the arm, which is swept downward and delivered through the vulva. To deliver the anterior arm, depression of the fetal body is sometimes all that is required to allow the anterior arm to slip out spontaneously. In other instances, the anterior arm can be swept down over the thorax using two of the operator’s fingers.
In some cases, the body must be held with the thumbs over the scapulas and rotated to bring the undelivered shoulder near the closest sacrosciatic notch. The legs then are carried upward to bring the ventral surface of the fetus to the opposite inner thigh of the mother. Subsequently, the arm can be delivered posteriorly as described previously. If the arms have become extended over the head, their delivery, although more difficult, usually can be accomplished by the maneuvers just described. In so doing, particular care must be taken by the operator to carry his or her fingers up to the elbow and to use them as a splint to prevent fracture of the fetal humerus.

**Nuchal Arm**

As just mentioned, one or both fetal arms occasionally may be found around the back of the neck—the nuchal arm—and impacted at the pelvic inlet. In this situation, delivery is more difficult. If the nuchal arm cannot be freed in the manner just described, extraction may be aided, especially with a single nuchal arm, by rotating the fetus through a half circle in such a direction that the friction exerted by the birth canal will serve to draw the elbow toward the face (Fig. 28-10). Should rotation of the fetus fail to free the nuchal arm(s), it may be necessary to push the fetus upward in an attempt to release it. If the rotation is still unsuccessful, the nuchal arm often is extracted by hooking a finger(s) over it and forcing the arm over the shoulder, and down the ventral surface for delivery of the arm. In this event, fracture of the humerus or clavicle is common.

**FIGURE 28-10** Reduction of nuchal arm being accomplished by rotating the fetus through half a circle counterclockwise so that the friction exerted by the birth canal will draw the elbow toward the face.
Modified Prague Maneuver

Rarely, the back of the fetus fails to rotate to the anterior. In this situation, rotation of the back to the anterior may be achieved by using stronger traction on the fetal legs or bony pelvis. If the back still remains oriented posteriorly, extraction may be accomplished using the Mauriceau maneuver, described next, and delivering the fetus back down. If this is impossible, the fetus still may be delivered using the modified Prague maneuver, which, as practiced today, consists of two fingers of one hand grasping the shoulders of the back-down fetus from below while the other hand draws the feet up and over the maternal abdomen (Fig. 28-11).

![Delivery of the aftercoming head using the modified Prague maneuver](image)

**FIGURE 28-11** Delivery of the aftercoming head using the modified Prague maneuver necessitated by failure of the fetal trunk to rotate anteriorly.

Delivery of the Aftercoming Head

**Mauriceau Maneuver.** Normally, the fetal head may be extracted with forceps or by one of several maneuvers. With the Mauriceau maneuver, the index and middle finger of one hand are
applied over the maxilla, to flex the head, while the fetal body rests on the palm of the hand and forearm (Fig. 28-12). The operator’s forearm is straddled by the fetal legs. Two fingers of the other hand then are hooked over the fetal neck, and grasping the shoulders, downward traction is concurrently applied until the suboccipital region appears under the symphysis. Gentle suprapubic pressure simultaneously applied by an assistant helps keep the head flexed. The body then is elevated toward the maternal abdomen, and the mouth, nose, brow, and eventually the occiput emerge successively over the perineum. With this maneuver, the operator uses both hands simultaneously and in tandem to exert continuous downward gentle traction simultaneously on the fetal neck and on the maxilla. At the same time, appropriate suprapubic pressure is applied by an assistant (see Fig. 28-12).

**FIGURE 28-12** A. Delivery of the aftercoming head using the Mauriceau maneuver. Note that as the fetal head is being delivered, flexion of the head is maintained by suprapubic pressure provided by an assistant. B. Pressure on the maxilla is applied simultaneously by the operator as upward and outward traction is exerted.

**Forceps to Aftercoming Head.** Specialized forceps can also be used to deliver the aftercoming head. Piper forceps, shown in Figure 28-13, or divergent Laufe forceps may be applied electively or when the Mauriceau maneuver cannot be accomplished easily. The blades of the forceps should not be applied to the aftercoming head until it has been brought into the pelvis by gentle traction, combined with suprapubic pressure, and is engaged. Suspension of the body of the fetus in a towel effectively holds the fetus up and helps keep the arms and cord out of the way as the forceps blades
are applied.
FIGURE 28-13 Piper forceps for delivery of the aftercoming head. A. The fetal body is held elevated using a warm towel and the left blade of forceps is applied to the aftercoming head. B. The right blade is applied with the body still elevated. C. Forceps delivery of the aftercoming head. Note the direction of movement shown by the arrow.

Because the forceps blades are directed upward from the level of the perineum, some choose to apply them from a one-knee kneeling position. Piper forceps have a downward arch in the shank to accommodate the fetal body and lack a pelvic curve. This shape permits a direct application of the cephalic curve of the blade along the length of the maternal vagina and fetal parietal bone. The blade to be placed on the maternal left is held in the operator’s left hand. The right hand slides between the fetal head and left maternal vaginal sidewall to guide the blade inward and around the parietal bone. The opposite blade mirrors this application. Once in place, the blades are articulated, and the fetal body rests across the shanks. The head is delivered by pulling gently outward and raising the handle simultaneously. This rolls the face over the perineum, while the occiput remains beneath the symphysis until after the brow delivers. Ideally, the head and body move in unison to minimize trauma.

**Entrapment of the Aftercoming Head.** Occasionally—especially with a small preterm fetus—the incompletely dilated cervix will constrict around the neck and impede delivery of the aftercoming head. At this point, it must be assumed that there is significant and even total cord compression, and thus time management is essential. With gentle traction on the fetal body, the cervix, at times, may be manually slipped over the occiput. If this is not successful, then Dührssen incisions as shown in Figure 28-14 may be necessary. Other alternatives include intravenous nitroglycerin—typically 100 μg—to provide cervical relaxation (Dufour, 1997; Wessen, 1995). There is, however, no compelling evidence of its efficacy for this purpose. General anesthesia with halogenated agents is another option.
As a last resort, replacement of the fetus higher into the vagina and uterus, followed by cesarean delivery, can be used to rescue an entrapped breech fetus that cannot be delivered vaginally. This maneuver was described for the protruding head with intractable shoulder dystocia and is termed the Zavanelli maneuver as described by Sandberg (1988). It was subsequently reported by Steyr and Pieper (1994) to be used to deliver the entrapped aftercoming head in a 2590-g breech fetus. Sandberg (1999) reviewed 11 breech deliveries in which this maneuver was used.

Symphysiotomy is also used to aid delivery of an entrapped aftercoming head. Using local analgesic, this operation surgically divides the intervening symphyseal cartilage and much of its ligamentous support to widen the symphysis pubis up to 2.5 cm (Basak, 2011). Lack of operator training and potentially serious maternal pelvic or urinary tract injury explain its rare use in the United States. That said, if cesarean section is not available or unsafe for the mother, symphysiotomy may be lifesaving for both mother and baby (Hofmeyr, 2012).

Total Breech Extraction
Complete or Incomplete Breech

At times, total extraction of a complete or incomplete breech may be required. A hand is introduced through the vagina, and both fetal feet are grasped. The ankles are held with the second finger lying between them. With gentle traction, the feet are brought through the introitus. If difficulty is experienced in grasping both feet, first one foot should be drawn into the vagina but not through the introitus, and then the other foot is advanced in a similar fashion. Now both feet are grasped and pulled through the vulva simultaneously (Fig. 28-15).

**FIGURE 28-15** Complete breech extraction begins with traction on the feet and ankles.

As the legs begin to emerge through the vulva, downward gentle traction is continued. As the legs emerge, successively higher portions are grasped, first the calves and then the thighs. When the breech appears at the vaginal outlet, gentle traction is applied until the hips are delivered. As the buttocks emerge, the back of the fetus usually rotates to the anterior. The thumbs are then placed over the sacrum and the fingers over the hips, and breech extraction is completed, as described for partial breech extraction (p. 564). During cesarean delivery, these maneuvers are also used during delivery of a complete, incomplete, or footling breech through the hysterotomy incision.

Frank Breech

During complete extraction of a frank breech, moderate traction is exerted by a finger in each groin and aided by a generous episiotomy (Fig. 28-16). Once the breech is pulled through the introitus, the steps described for partial breech extraction are then completed (p. 564). These maneuvers are also used during cesarean delivery of the frank breech through the hysterotomy incision.
FIGURE 28-16 A. Extraction of frank breech using fingers in groins. B. Once the hips are delivered, each hip and knee is flexed to deliver them from the vagina.

If moderate traction does not effect delivery, then vaginal delivery can be accomplished only by breech decomposition. This procedure involves manipulation within the birth canal to convert the frank breech into a footling breech. It is accomplished more readily if the membranes have ruptured only recently, and it becomes extremely difficult if there is minimal amnionic fluid. In such cases, the uterus may have become tightly contracted around the fetus. Pharmacological relaxation by general anesthesia, intravenous magnesium sulfate, or a betamimetic agent such as terbutaline, 250 μg subcutaneously, may be required.

Breech decomposition is accomplished by the maneuver attributed to Pinard (1889). It aids in bringing the fetal feet within reach of the operator. As shown in Figure 28-17, two fingers are carried up along one extremity to the knee to push it away from the midline. Spontaneous flexion usually follows, and the foot of the fetus is felt to impinge on the back of the hand. The fetal foot
then may be grasped and brought down.

![FIGURE 28-17 Frank breech decomposition using the Pinard maneuver. Two fingers are inserted along one extremity to the knee, which is then pushed away from the midline after spontaneous flexion. Traction is used to deliver a foot into the vagina.](image)

**ANALGESIA AND ANESTHESIA**

Continuous epidural analgesia, as described in Chapter 25 (p. 509), is advocated by some as ideal for women in labor with a breech presentation. This may increase the need for labor augmentation and may prolong second-stage labor (Chadha, 1992; Confino, 1985). These potential disadvantages must be weighed against the advantages of better pain relief and increased pelvic relaxation should extensive manipulation be required. Analgesia must be sufficient for episiotomy, for breech extraction, and for Piper forceps application. Nitrous oxide plus oxygen inhalation provides further relief from pain. If general anesthesia is required, it must be induced quickly.

Anesthesia for breech decomposition and extraction must provide sufficient relaxation to allow intrauterine manipulations. Although successful decomposition has been accomplished using epidural or spinal analgesia, increased uterine tone may render the operation more difficult. Under such conditions, general anesthesia with a halogenated agent may be required.
With this procedure, fetal presentation is altered by physical manipulation, either substituting one pole of a longitudinal presentation for the other, or converting an oblique or transverse lie into a longitudinal presentation. According to whether the head or breech is made the presenting part, the operation is designated cephalic or podalic version, respectively. With external version, the manipulations are performed exclusively through the abdominal wall. With internal version, they are accomplished inside the uterine cavity.

### External Cephalic Version

For breech fetuses near term, the American College of Obstetricians and Gynecologists (2012a,b) recommends that version should be offered and attempted whenever possible. Its success rate ranges from 35 to 86 percent, with an average of 58 percent. For women with a transverse lie, the overall success rate is significantly higher.

#### Indications

In general, external version is attempted before labor in a woman who has reached 36 weeks’ gestation with a breech fetus. Before this time, a breech presentation still has a high likelihood of correcting spontaneously. And, if performed too early, time may allow a return back to breech (Bogner, 2012). Last, if version causes a need for immediate delivery, complications of iatrogenic preterm delivery generally are not severe.

Version is contraindicated if vaginal delivery is not an option. Examples include placenta previa or nonreassuring fetal status. Other contraindications include rupture of membranes, known uterine malformation, multifetal gestation, and recent uterine bleeding. As discussed in Chapter 31 (p. 616), prior uterine incision is a relative contraindication. In a few small studies, external version was not associated with uterine rupture (Abenhaim, 2009; Sela, 2009). At Parkland Hospital, external version is not attempted in these women, but larger studies are needed.

Several factors can improve the chances of a successful version attempt. These include multiparity, abundant amnionic fluid, unengaged presenting part, fetal size 2500 to 3000 g, posterior placenta, and nonobese patient (Buhimschi, 2011; de Hundt, 2012; Kok, 2008, 2009, 2011).

#### Complications

Patient counseling includes projected success rates, conversion back to breech, and risks of the procedure itself. Risks include placental abruption, uterine rupture, fetomaternal hemorrhage, alloimmunization, preterm labor, fetal compromise, and even death. Most worrisome is the report by Stine and coworkers (1985) of a maternal death due to amnionic fluid embolism. That said, fetal deaths are rare, serious complication rates are typically very low, and emergent cesarean rates are 0.5 percent or less (Collaris, 2004; Collins, 2007; Grootscholten, 2008).

Importantly, even after successful version, several reports suggest that the cesarean delivery rate does not completely revert to the baseline for vertex presentations. Specifically, dystocia, malpresentation, and nonreassuring fetal heart patterns may be more common in these fetuses despite successful version (Chan, 2004; Vézina, 2004).

#### Technique

External cephalic version should be carried out in an area that has ready access to a facility equipped to perform an emergency cesarean delivery (American College of Obstetricians and
Gynecologists, 2012a). Sonographic examination is performed to confirm nonvertex presentation, document amniotic fluid volume adequacy, exclude obvious fetal anomalies if not done previously, and identify placental location. External monitoring is performed to assess fetal heart rate reactivity. Anti-D immune globulin is given to Rh-D negative women.

A forward roll of the fetus usually is attempted first. Each hand grasps one fetal pole, and the fetal buttocks are elevated from the maternal pelvis and displaced laterally (Fig. 28-18). The buttocks are then gently guided toward the fundus, while the head is directed toward the pelvis. If the forward roll is unsuccessful, then a backward flip is attempted. Version attempts are discontinued for excessive discomfort, persistently abnormal fetal heart rate, or after multiple failed attempts. Failure is not always absolute. Ben-Meir and colleagues (2007) reported a spontaneous version rate of 7 percent among 226 failed versions—2 percent among nulliparas and 13 percent among parous women.

**FIGURE 28-18** External cephalic version. With an attempted forward roll, clockwise pressure is exerted against the fetal poles.

If version is successful, the nonstress test is repeated until a normal test result is obtained. If
version is completed before 39 weeks’ gestation, then awaiting spontaneous labor and fetal
maturity is preferred.

**Tocolysis**

Existing evidence may support the use of tocolytic agents during external version attempts
(American College of Obstetricians and Gynecologists, 2012a). Agents investigated include
betamimetics, such as terbutaline, ritodrine, or salbutamol; calcium-channel blockers, such as
nifedipine; and nitric oxide donors, such as nitroglycerin. Most randomized investigations have
evaluated betamimetics. In one such trial, Fernandez and coworkers (1996) reported that the
success rate with subcutaneous terbutaline—52 percent—was significantly higher than without—
27 percent. Other studies of betamimetics support their efficacy, although not universally
(Marquette, 1996; Robertson, 1987; Vani, 2009). There is less evidence to support the use of
nifedipine and nitroglycerin (Cluver, 2012; Wilcox, 2011). Our policy at Parkland Hospital is to
administer 250 $\mu$g of terbutaline subcutaneously to most women before attempted version. When
maternal tachycardia—a known side effect of terbutaline—is noted, then the version attempt is
begun.

**Conduction Analgesia**

Epidural analgesia has been reported to increase version success rates (Mancuso, 2000; Schorr,
1997). But Sullivan and associates (2009) noted no improvement with combined spinal-epidural
analgesia. In two small randomized trials, Weiniger and associates (2007, 2010) reported that
spinal analgesia increased version success rate. In the trials by Dugoff (1999) and Delisle (2003)
and their colleagues, spinal analgesia was not of benefit. According to the American College of
Obstetricians and Gynecologists (2012a), there is not enough consistent evidence to recommend
conduction analgesia routinely for external version.

With the exception of rare severe complications, Collaris and Oei (2004) concluded that
external cephalic version is safe. One caveat was that complications were more common when
conduction analgesia was used. Use of nitrous oxide or conduction analgesia was associated with
twice as many abnormal fetal heart rate tracings. Moreover, vaginal bleeding and procedure-
related emergency cesarean deliveries were increased tenfold. These reviewers concluded that
diminished pain in these women likely encouraged overzealous application of force during the
version attempts. In another small study, however, Suen and associates (2012) showed that the
force applied during version under spinal analgesia was actually less.

**Other Methods**

There are some unconventional interventions that have been used to help effect version. Moxibustion is a traditional Chinese medicine technique that burns a cigarette-shaped stick of
ground *Artemisia vulgaris*—which is also known as mugwort or in Japanese as *moxa*. At the BL
67 acupuncture point, the stick is directly placed against the skin or indirectly heats an acupuncture
needle at the site to increase fetal movement and promote spontaneous breech version. It is
performed usually between 33 and 36 weeks’ gestation to permit a trial of external cephalic
version if not successful. Results from randomized controlled studies are conflicting. However, a
Cochrane Database review found some evidence to support moxibustion use when combined with

**Internal Podalic Version**
This maneuver is used only for delivery of a second twin. With the membranes preferably still intact, a hand is inserted into the uterine cavity to turn the fetus manually. The operator seizes one or both feet and draws them through the fully dilated cervix, while using the other hand transabdominally to push the upper portion of the fetal body in the opposite direction as shown in Chapter 45 (p. 918). This is then followed by breech extraction.

REFERENCES

American College of Obstetricians and Gynecologists: Mode of term singleton breech delivery. Committee Opinion No. 265, December 2001

Operative deliveries are vaginal deliveries accomplished with the use of a vacuum device or forceps. Once either is applied to the fetal head, outward traction generates forces that augment maternal pushing to deliver the fetus vaginally. The most important function of both devices is traction. In addition, however, forceps may also be used for rotation, particularly from occiput transverse and posterior positions.

The precise frequency of operative vaginal delivery in the United States is unknown. According to the birth certificate data from the National Vital Statistics Report, forceps- or vacuum-assisted vaginal delivery was used for 3.6 percent of births in the United States in 2010. According to Yeomans (2010), the vacuum-to-forceps delivery ratio is 4:1. **Figure 29-1** depicts the decline in the rates of this type of delivery since 1990. In general, operative vaginal delivery attempts are successful. In the United States in 2006, only 0.4 percent of forceps trials and 0.8 percent of vacuum extraction attempts failed to result in vaginal delivery (Osterman, 2009).
INDICATIONS

If it is technically feasible and can be safely accomplished, termination of second-stage labor by operative vaginal delivery is indicated in any condition threatening the mother or fetus that is likely to be relieved by delivery. Some fetal indications for operative vaginal delivery include nonreassuring fetal heart rate pattern and premature placental separation. In the past, forceps delivery was believed to be somewhat protective of the fragile preterm infant head. Subsequent studies, however, reported no significant differences in outcomes for neonates who weighed 500 to 1500 g between those delivered spontaneously and those delivered by outlet forceps (Fairweather, 1981; Schwartz, 1983).

Some maternal indications include heart disease, pulmonary injury or compromise, intrapartum infection, and certain neurological conditions. The most common are exhaustion and prolonged second-stage labor. For nulliparas, the latter is defined as > 3 hours with or > 2 hours without regional analgesia (American College of Obstetricians and Gynecologists, 2012). In parous women, it is defined as > 2 hours with and > 1 hour without regional analgesia.

Operative vaginal delivery should generally be performed from either a low or outlet station. Additionally, forceps or vacuum delivery generally should not be used electively until the criteria for an outlet delivery have been met. In these circumstances, operative vaginal delivery is a simple and safe operation, although with some risk of maternal lower reproductive tract injury (Yancey, 1991). Moreover, there is no evidence that use of prophylactic operative delivery is beneficial in the otherwise normal delivery.

CLASSIFICATION AND PREREQUISITES

The American College of Obstetricians and Gynecologists (2012) classifies operative vaginal deliveries as summarized in Table 29-1. It emphasizes that the two most important discriminators of risk for both mother and infant are station and rotation. Station is measured in centimeters, −5 to
Zero station reflects a line drawn between the ischial spines. Deliveries are categorized as outlet, low, and midpelvic procedures. High forceps, in which instruments are applied above 0 station, have no place in contemporary obstetrics.

### Prerequisites

- Experienced operator
- Engaged head
- Ruptured membranes
- Vertex presentation\(^b\)
- Completely dilated cervix
- Precisely assessed fetal head position
- Cephalopelvic disproportion not suspected
- No fetal coagulopathy or bone demineralization disorder

\(^a\)Classification for the vacuum delivery system is the same as for forceps except that vacuum is used for traction but not rotation.

\(^b\)Forceps, but not vacuum extractor, may be used for delivery of a face presentation with mentum anterior.
34 weeks gestational age, and although infrequently used in the United States, fetal scalp blood sampling should not have been recently performed.

Regional analgesia or general anesthesia is preferable for low forceps or midpelvic procedures, although pudendal blockade may prove adequate for outlet forceps. Before operative vaginal delivery, the bladder should also be emptied to provide additional pelvic space and minimize bladder trauma.

MORBIDITY

In general, a higher station and/or greater degrees of rotation increase the chance of maternal or fetal injury. In the discussion of operative vaginal delivery, morbidity is most properly compared with morbidity from cesarean delivery, and not with that from spontaneous vaginal delivery. This is because the alternative to indicated operative vaginal delivery is cesarean delivery. As examples, postpartum uterine infection and pelvic cellulitis are more frequent, and often more severe, in women following cesarean delivery compared with that following operative vaginal delivery (Robertson, 1990). Moreover, in a study of more than 1 million births, Spiliopoulos and associates (2011) reported cesarean delivery, but not operative vaginal delivery, as a risk for peripartum hysterectomy.

Maternal Morbidity

Lacerations

The very conditions that lead to indications for operative vaginal delivery also increase the need for episiotomy and the likelihood of lacerations (de Leeuw, 2008). That said, operative vaginal delivery is associated with higher rates of third- and fourth-degree lacerations as well as vaginal wall and cervical lacerations (Hamilton, 2011; Hirayama, 2012; Landy, 2011). These appear to occur more frequently with forceps compared with vacuum extraction, and especially if there is a midline episiotomy (Kudish, 2006; O’Mahony, 2010). Hagadorn-Freathy and coworkers (1991) reported a 13-percent rate of third- and fourth-degree episiotomy extensions and vaginal lacerations for outlet forceps, 22 percent for low forceps with less than 45-degree rotation, 44 percent for low forceps with more than 45-degree rotation, and 37 percent for midforceps deliveries.

In an effort to lower rates of third- and fourth-degree lacerations, and coincident with overall efforts to reduce routine episiotomy use, many advocate only indicated episiotomy with operative vaginal delivery. For example, Ecker and colleagues (1997) reported a significant decrease in the episiotomy rate with both forceps—96 to 30 percent—as well as vacuum—89 to 39 percent—deliveries from 1984 to 1994. During this time, there was a decrease in fourth-degree but no change in third-degree lacerations. If episiotomy is required, several studies have reported a protective effect from mediolateral episiotomy against these more extensive perineal lacerations (de Leeuw, 2008; de Vogel, 2012; Hirsch, 2008). But as discussed in Chapter 27 (p. 551), this is balanced against the additional potential morbidity compared with a midline episiotomy. Early disarticulation of forceps and cessation of maternal pushing during disarticulation can also be protective. Last, these injuries are more common with operative vaginal delivery from an occiput posterior position (Damron, 2004). Thus, manual or forceps rotation from occiput posterior to occiput anterior position and then subsequent operative vaginal delivery may decrease lower-
reproductive-tract injury.

**Pelvic Floor Disorders**

This term encompasses urinary incontinence, anal incontinence, and pelvic organ prolapse. Operative vaginal delivery has been suggested as a possible risk for each of these. Proposed mechanisms include structural compromise and/or pelvic floor denervation secondary to forces exerted during delivery.

Urinary retention and bladder dysfunction are often short-term effects of forceps and vacuum deliveries (Mulder, 2012). Importantly, episiotomy and epidural analgesia, both common associates of operative vaginal delivery, are also identified risks for urinary retention. Symptoms are brief and typically resolve with 24 to 48 hours of passive catheter bladder drainage.

Regarding more sustained urinary dysfunction, parity and specifically vaginal delivery are known risk factors for urinary incontinence (Gyhagen, 2013; Rortveit, 2003). And, a few studies show a greater attributable risk with operative vaginal delivery (Baydock, 2009; Handa, 2011). But, many studies do not support an increased risk compared with vaginal delivery alone (Handa, 2012; Leijonhufvud, 2011; MacArthur, 2006; Thom, 2011).

Evidence linking anal incontinence with operative vaginal delivery is conflicting. Some studies show that anal sphincter disruption caused by higher-order episiotomy, but not delivery mode, is the main etiological factor strongly associated with anal incontinence (Baud, 2011; Bols, 2010; Evers, 2012; Nygaard, 1997). In contrast, others directly link operative vaginal delivery with this complication (MacArthur, 2005; Pretlove, 2008). But, these studies may not be incongruous as operative vaginal delivery, as previously discussed, is associated with increased rates of higher-order episiotomy. Importantly, several studies and reviews have not found cesarean delivery to be protective for anal incontinence (Nelson, 2010).

Last, evidence linking pelvic organ prolapse with operative vaginal delivery also shows mixed results (Gyhagen, 2013; Handa, 2011). Interestingly, Glazener and associates (2013) evaluated women 12 years after delivery by means of a symptom questionnaire and physical examination. Complaints of prolapse symptoms were linked to operative vaginal delivery, but true objective measurement of prolapse showed a protective effect from this delivery mode compared with vaginal delivery alone.

**Perinatal Morbidity**

**Acute Perinatal Injuries**

These are more frequent with operative vaginal deliveries than with cesarean delivery or spontaneous vaginal delivery alone. Although these may be seen with either method, they are more commonly seen with vacuum extraction. Some injuries include cephalohematoma, subgaleal hemorrhage, retinal hemorrhage, neonatal jaundice secondary to these hemorrhages, shoulder dystocia, clavicular fracture, and scalp lacerations. Cephalohematoma and subgaleal hemorrhage are both extracranial lesions described in Chapter 33 (p. 646).

In 1998, the Food and Drug Administration issued a Public Health Advisory regarding the possible association of vacuum-assisted delivery with serious fetal complications, including death. In response, the American College of Obstetricians and Gynecologists (1998) issued a Committee Opinion recommending the continued use of vacuum-assisted delivery devices where appropriate. At that time, they estimated that there was approximately one adverse event per 45,455 vacuum extractions per year.
In contrast, forceps-assisted vaginal delivery has higher rates of facial nerve injury, brachial plexus injury, depressed skull fracture, and corneal abrasion (Demissie, 2004; Dupuis, 2005; American College of Obstetricians and Gynecologists, 2012). And while some studies have associated vacuum extraction with higher rates of intracranial hemorrhage, others show similar rates with either of the two methods (Towner, 1999; Wen, 2001; Werner, 2011).

As a group, if operative vaginal delivery is compared with cesarean delivery, rates of extracranial hematoma, skull fracture, facial nerve or brachial plexus injury, retinal hemorrhage, and facial or scalp laceration are lower with cesarean delivery, and shoulder dystocia is eliminated. Importantly, however, fetal acidemia rates are not increased with operative vaginal delivery (Contag, 2010; Walsh, 2013). Intracranial hemorrhage rates are similar among infants delivered by vacuum extraction, forceps, or cesarean delivery during labor (Towner, 1999). But, these rates are higher than among those delivered spontaneously or by cesarean delivery before labor. These authors suggest that the common risk factor for intracranial hemorrhage is abnormal labor. Werner and associates (2011), in their evaluation of more than 150,000 singleton deliveries, reported that forceps-assisted delivery was associated with fewer total neurological complications compared with vacuum-assisted or cesarean delivery. However, as a subset, subdural hemorrhage was significantly more frequent in both operative vaginal delivery cohorts compared with infants in the cesarean delivery group.

Reports of neonatal morbidity rates compared between midforceps and cesarean delivery are conflicting. In the study by Towner and colleagues (1999), similar risks were reported for intracranial hemorrhage. Bashore and associates (1990) observed comparable Apgar scores, cord blood acid-base values, neonatal intensive care unit admission, and birth trauma between these two. In another study, however, Robertson and coworkers (1990) reported significantly higher rates of these adverse outcomes in the midforceps group. And Hagadorn-Freathy and colleagues (1991) reported an increased risk for facial nerve palsy—9 percent—with midforceps delivery.

Mechanisms of Acute Injury

In general, with operative vaginal delivery, the types of fetal injury can usually be explained by the forces exerted. In cases of cephalohematoma or subgaleal hemorrhage, suction and perhaps rotation during vacuum extraction may lead to a primary vessel laceration (Fig. 33-1, p. 647). Intracranial hemorrhage may result from skull fracture and vessel laceration or from vessel laceration alone due to exerted forces. With facial nerve palsy, one of the forceps blades may compress the nerve against the facial bones (Duval, 2009; Falco, 1990). The higher rates of shoulder dystocia seen with vacuum extraction may result from the angle of traction. With the vacuum, this angle creates vector forces that actually pull the anterior shoulder into the symphysis pubis (Caughey, 2005). To explain brachial plexus injury, Towner and Ciotti (2007) proposed that as the fetal head descends down the birth canal, the shoulders may stay above the pelvic inlet. Thus, similar to shoulder dystocia at the symphysis, this “shoulder dystocia at the pelvic inlet” is overcome by traction forces but with concomitant stretch on the brachial plexus.

Long-Term Infant Morbidity

Evidence regarding long-term neurodevelopmental outcomes in children delivered by operative vaginal delivery is reassuring. Seidman and colleagues (1991) evaluated more than 52,000 Israeli Defense Forces draftees at age 17 years and found that regardless of delivery mode, there were similar rates of physical or cognitive impairments. Wesley and associates (1992) noted similar intelligence scores among 5-year-olds following spontaneous, forceps, or vacuum deliveries. Murphy and coworkers (2004) found no association between forceps delivery and epilepsy in a
cohort of 21,441 adults. In their epidemiological review, O’Callaghan and colleagues (2011) found no association between cerebral palsy and operative vaginal delivery. A prospective study by Bahl and associates (2007) included children of 264 women who underwent operative delivery. Their incidence of neurodevelopmental morbidity was similar in those undergoing successful forceps delivery, failed forceps with cesarean delivery, or cesarean delivery without forceps.

Data regarding midforceps deliveries are for the most part reassuring. Broman and coworkers (1975) reported that infants delivered by midforceps had slightly higher intelligence scores at age 4 years compared with those of children delivered spontaneously. Using the same database, however, Friedman and associates (1977, 1984) analyzed intelligence assessments at or after age 7 years. They concluded that children delivered by midforceps had lower mean intelligence quotients compared with children delivered by outlet forceps. In yet another report from this same database, Dierker and colleagues (1986) compared long-term outcomes of children delivered by midforceps with those of children delivered by cesarean after dystocia. The strength of this study is the appropriateness of the control group. These investigators reported that delivery by midforceps was not associated with neurodevelopmental disability. Last, Nilsen (1984) evaluated 18-year-old men and found that those delivered by Kielland forceps had higher intelligence scores than those delivered spontaneously, by vacuum extraction, or by cesarean. As discussed on page 582, Burke and coworkers (2012) reported 144 cases of attempted Kielland forceps rotation and described minimal morbidity.

## TRIAL OF OPERATIVE VAGINAL DELIVERY

If an attempt to perform an operative vaginal delivery is expected to be difficult, then it should be considered a trial. Delivery is conducted preferably in an operating room equipped and staffed for immediate cesarean delivery. If forceps cannot be satisfactorily applied, then the procedure is stopped and either vacuum extraction or cesarean delivery is performed. With the former, if there is no descent with traction, the trial should be abandoned and cesarean delivery performed.

With such caveats, cesarean delivery after an attempt at operative vaginal delivery was not associated with adverse neonatal outcomes if there was a reassuring fetal heart rate tracing (Alexander, 2009). A similar study evaluated 122 women who had a trial of midcavity forceps or vacuum extraction in a setting with full preparations for cesarean delivery (Lowe, 1987). Investigators found no significant difference in immediate neonatal or maternal morbidity compared with that of 42 women delivered for similar indications by cesarean but without such a trial. Conversely, in 61 women who had “unexpected” vacuum or forceps failure in which there was no prior preparation for immediate cesarean delivery, neonatal morbidity was higher.

Factors associated with operative delivery failure are persistent occiput posterior position, absence of regional or general anesthesia, and birthweight > 4000 g (Ben-Haroush, 2007). In general, to avert morbidity with failed forceps or vacuum delivery, the American College of Obstetricians and Gynecologists (2012) cautions that these trials should be attempted only if the clinical assessment is highly suggestive of a successful outcome. We also emphasize proper training.

Sequential instrumentation most frequently involves an attempt at vacuum extraction followed by one with forceps. This most likely stems from the higher completion rate with forceps compared with vacuum extraction noted earlier (p. 574). There is no evidence to justify this practice, as it significantly increases risks for fetal trauma (Dupuis, 2005; Murphy, 2001;
Because of these adverse outcomes, the American College of Obstetricians and Gynecologists (2012) recommends against the sequential use of instruments unless there is a “compelling and justifiable reason.”

**TRAINING**

As the rate of operative vaginal delivery has declined, so have opportunities for training. Fifteen years ago, Hankins and colleagues (1999) reported that fewer than half of residency directors expected proficiency with midforceps delivery. From the data shown in Figure 29-1, we, and others, would expect that number to be much lower today (Miller, 2014). In many programs, training in even low and outlet forceps procedures has reached critically low levels. For residents completing training in 2012, the Accreditation Council for Graduate Medical Education (2012) lists a median of only six forceps deliveries, and that for vacuum deliveries was 16.

Because traditional hands-on training has evolved, residency programs should have readily available skilled operators to teach these procedures by simulation as well as through actual cases (Spong, 2012). And, the effectiveness of simulation training has been reported (Bahl, 2009; Dupuis, 2006, 2009; Leslie, 2005). In one program, there were lowered rates of maternal and neonatal morbidity associated with operative vaginal delivery after the implementation of a formal education program that included a manikin and pelvic model (Cheong, 2004). In another, assignment of a labor and delivery attending with the specific goal to increase forceps delivery education led to a 59-percent increase in forceps-assisted vaginal delivery rates.

**FORCEPS DELIVERY**

**Forceps Design**

These instruments consist basically of two crossing branches. Each branch has four components: blade, shank, lock, and handle. Each blade has two curves: the outward cephalic curve conforms to the round fetal head, and the upward pelvic curve corresponds more or less to the axis of the birth canal. Some varieties have an opening within or a depression along the blade surface and are termed fenestrated or pseudofenestrated, respectively (Fig. 29-2). These blade modifications permit a firmer grasp of the fetal head, but at the expense of increased blade thickness, which may increase vaginal trauma. In general, Simpson or Elliot forceps, with their fenestrated blades, are used to deliver a fetus with a molded head, as is common in nulliparous women. The Tucker-McLane forceps have thin smooth blades and are often used for a fetus with a rounded head, which is more characteristic in multiparas (Fig. 29-3). In most situations, however, any of these are appropriate.
FIGURE 29-2 Elliot forceps. A. Note the ample pelvic curve in the blades. B. The cephalic curve, which accommodates the fetal head, is evident in the articulated blades. The fenestrated blade and the overlapping shank in front of the English-style lock characterize these forceps.

FIGURE 29-3 Tucker–McLane forceps. The blade is solid, and the shank is narrow.

The blades are connected to the handles by shanks. The common method of articulation, the
English lock, consists of a socket located on the shank at the junction with the handle, into which fits a socket similarly located on the opposite shank (see Fig. 29-3). A sliding lock is used in some forceps, such as Kielland forceps (Fig. 29-4).

**FIGURE 29-4** Kielland forceps. The characteristic features are minimal pelvic curvature (A), sliding lock (B), and light weight.

**Forceps Blade Application and Delivery**

Forceps blades grasp the head and are applied according to fetal head position. If the head is in an occiput anterior position, two or more fingers of the right hand are introduced inside the left posterior portion of the vulva and then into the vagina beside the fetal head. The handle of the left branch is grasped between the thumb and two fingers of the left hand (Fig. 29-5). The blade tip is then gently passed into the vagina between the fetal head and the palmar surface of the fingers of the right hand (Fig. 29-6). For application of the right blade, two or more fingers of the left hand are introduced into the right posterior portion of the vagina to serve as a guide for the right blade. This blade is held in the right hand and introduced into the vagina as described for the left blade. After positioning, the branches are articulated (Fig. 29-7). If the head is positioned in a left occiput anterior or right occiput anterior position, then the lower of the two blades is typically placed first.
FIGURE 29-5 The left handle of the forceps is held in the left hand. The blade is introduced into the left side of the pelvis between the fetal head and the fingers of the operator’s right hand.
FIGURE 29-6 A. Continued insertion of the left blade. The right hand, not shown here, guides the blade during placement. Note the arc of the handles as they rotate to be applied to the mother’s left. B. First blade in place. An assistant’s hand can hold this handle in place as the second blade is applied.

FIGURE 29-7 The vertex is now occiput anterior, and the forceps are symmetrically placed and articulated.

The blades are constructed so that their cephalic curve is closely adapted to the sides of the fetal head. The biparietal diameter of the fetal head corresponds to the greatest distance between
appropriately applied blades. Consequently, the fetal head is perfectly grasped only when the long axis of the blades corresponds to the occipitomental diameter. These diameters are depicted in Figure 7-12 (p. 140). As a result, most of the blade lies over the face. If the fetus is in an occiput anterior position, then the concave arch of the blades is directed toward the sagittal suture. If the fetus is in an occiput posterior position, then the concave arch is directed toward the fetal face.

For the occiput anterior position, appropriately applied blades are equidistant from the sagittal suture, and each blade is equidistant from its adjacent lambdoidal suture. In the occiput posterior position, the blades are equidistant from the midline of the face and brow. Also for occiput posterior position, blades are symmetrically placed relative to the sagittal suture and each coronal suture. Applied in this way, the forceps should not slip, and traction may be applied most advantageously. With most forceps, if one blade is applied over the brow and the other over the occiput, the instrument cannot be locked, or if locked, the blades will slip off when traction is applied (Fig. 29-8). For these reasons, the forceps must be applied directly to the sides of the fetal head along the occipitomental diameter.

**FIGURE 29-8** Incorrect application of forceps. A. One blade over the occiput and the other over
the brow. Forceps cannot be locked. B. With incorrect placement, blades tend to slip off with traction.

If necessary, rotation to occiput anterior is performed before traction is applied (Fig. 29-9). When it is certain that the blades are placed satisfactorily, then gentle, intermittent, horizontal traction is exerted concurrent with maternal efforts until the perineum begins to bulge (Fig. 29-10). With traction, as the vulva is distended by the occiput, an episiotomy may be performed if indicated. Additional horizontal traction is applied, and the handles are gradually elevated, eventually pointing almost directly upward as the parietal bones emerge (Figs. 29-11 and 29-12). As the handles are raised, the head is extended. During the birth of the head, spontaneous delivery should be simulated as closely as possible.

**FIGURE 29-9** Forceps have been locked. Vertex is rotated from left occiput anterior to occiput anterior (arrow).
FIGURE 29-10 Occiput anterior. Delivery by low forceps. The direction of gentle traction for delivery of the head is indicated (arrow).

FIGURE 29-11 Upward arching traction (arrow) is used as the head is delivered.
FIGURE 29-12 Upward traction is continued as the head is delivered.

The force produced by the forceps on the fetal skull is a complex function of both traction and compression by the forceps, as well as friction produced by maternal tissues. It is impossible to ascertain the amount of force exerted by forceps for an individual patient. Traction should therefore be intermittent, and the head should be allowed to recede between contractions, as in spontaneous labor. Except when urgently indicated, as in severe fetal bradycardia, delivery should be sufficiently slow, deliberate, and gentle to prevent undue head compression. It is preferable to apply traction only with each uterine contraction. Maternal pushing will augment these efforts.

After the vulva has been well distended by the head, the delivery may be completed in several ways. Some clinicians keep the forceps in place to control the advance of the head. If done, however, the thickness of the blades adds to vulvar distention, thus increasing the likelihood of laceration or necessitating a large episiotomy. To prevent this, the forceps may be removed, and delivery is then completed by maternal pushing (Fig. 29-13). Importantly, if blades are disarticulated and removed too early, the head may recede and lead to a prolonged delivery. Pushing in some cases may be aided by addition of the modified Ritgen maneuver.
FIGURE 29-13 Forceps may be disarticulated as the head is delivered. Modified Ritgen maneuver may be used to complete delivery of the head.

Delivery of Occiput Posterior Positions

Prompt delivery may at times become necessary when the small occipital fontanel is directed toward one of the sacroiliac synchondroses, that is, in right occiput or left occiput posterior positions. When delivery is required in either instance, the head is often imperfectly flexed. In some cases, when the hand is introduced into the vagina to locate the posterior ear, the occiput rotates spontaneously toward the anterior, indicating that manual rotation of the fetal head might easily be accomplished.
With manual rotation, an open hand is inserted into the vagina. The palm straddles the sagittal suture of the fetal head. The operator’s fingers wrap around one side of the fetal face and thumb extends along the other side. If the occiput is in a right posterior position, rotation is clockwise to bring it to a right occiput anterior or to a straight occiput anterior position. With left occiput posterior position, rotation is counterclockwise. If resistance is met during rotation, the head may be slightly elevated but should not be disengaged, as this risks cord prolapse. After the occiput has reached the anterior position, labor may be allowed to continue, or forceps can be applied. Le Ray and colleagues (2007, 2013) reported a success rate of greater than 90 percent with manual rotation.

Manual rotations are most easily completed in multiparas. If manual rotation cannot be easily accomplished, application of forceps blades to the head in the posterior position and delivery from the occiput posterior position may be the safest procedure (Fig. 29-14). In many cases, the cause of the persistent occiput posterior position and of the difficulty in accomplishing rotation is an anthropoid pelvis. This architecture opposes rotation and predisposes to posterior delivery (Fig. 2-20, p. 34).

**FIGURE 29-14** Outlet forceps delivery from an occiput posterior position. The head should be flexed after the bregma passes under the symphysis.

With forceps delivery from an occiput posterior position, horizontal traction should be applied until the base of the nose is under the symphysis. The handles should then be slowly elevated until the occiput gradually emerges over the anterior margin of the perineum. Then, the forceps are directed in a downward motion, and the nose, mouth, and chin successively emerge from the vulva.

Occiput posterior delivery causes greater distention of the vulva, and a large episiotomy may be needed. Pearl and associates (1993) reviewed 564 occiput posterior deliveries and compared them with 1068 occiput anterior deliveries as controls. The occiput posterior group had a higher incidence of severe perineal lacerations and extensive episiotomy compared with the occiput anterior.
anterior group. From The Netherlands, de Leeuw and associates (2008) studied more than 28,500 operative vaginal deliveries and reported similar findings. Consequences of these perineal tears are discussed in Chapter 27 (p. 536). Also, infants delivered from the occiput posterior position had a higher incidence of Erb and facial nerve palsies, 1 and 2 percent, respectively, than did those delivered from the occiput anterior position. As expected, rotations to occiput anterior ultimately decrease perineal delivery trauma (Bradley, 2013).

For rotations from the occiput posterior position, Tucker-McLane, Simpson, or Kielland forceps may be used. The oblique occiput may be rotated 45 degrees to the posterior position, or 135 degrees to the anterior position. If rotation is performed with Tucker-McLane or Simpson forceps, the head must be flexed, but this is not necessary with Kielland forceps because they have a less pronounced pelvic curve. In rotating the occiput anteriorly with Tucker-McLane or Simpson forceps, the pelvic curvature, originally directed upward, is, at the completion of rotation, inverted and directed posteriorly. Attempted delivery with the instrument in this position is likely to cause vaginal sulcus tears and sidewall lacerations. To avoid such trauma, it is essential to remove and reapply the instrument as previously described for occiput anterior delivery.

Rotation from Occiput Transverse Positions

When the occiput is obliquely anterior, it gradually rotates spontaneously to the symphysis pubis as traction is exerted. When it is directly transverse, however, a rotary motion of the forceps is required. When the occiput is directed toward the patient’s left, rotation counterclockwise from the left side toward the midline is required. For right occiput transverse positions, clockwise rotation is required.

With experienced operators, high success rates with minimal maternal morbidity can be achieved (Burke, 2012; Stock, 2013). Either standard forceps, such as Simpson, or specialize forceps, such as Kielland, are employed. The latter have a sliding lock and almost no pelvic curve (see Fig. 29-4). On each handle is a small knob that indicates the direction of the occiput. The station of the fetal head must be accurately ascertained to be at, or preferably below, the level of the ischial spines, especially in the presence of extreme molding.

Kielland described two methods of applying the anterior blade. The first is the wandering or gliding method in which the anterior blade is introduced at the side of the pelvis over the brow or face. The blade is then arched around the brow or face to an anterior position, with the handle of the blade held close to the opposite maternal buttock throughout the maneuver. The second blade is introduced posteriorly and the branches are locked.

The second is the classic application in which the anterior blade is introduced first with its cephalic curve directed upward, curving under the symphysis. After it has been advanced far enough toward the upper vagina, it is turned on its axis through 180 degrees to adapt the cephalic curvature to the head. For a more detailed description of Kielland forceps procedures, see the second edition of Operative Obstetrics (Gilstrap, 2002).

Application of forceps to an occiput transverse positioned fetus in these women with a platypelloid pelvis should not be attempted until the fetal head has reached or approached the pelvic floor. Regardless of the original position of the head, after rotation, delivery eventually is accomplished by exerting traction downward until the occiput appears at the vulva. After this, the rest of the operation is completed as previously described for occiput anterior delivery.

Face Presentation Forceps Delivery
With a mentum anterior face presentation, forceps can be used to effect vaginal delivery. The blades are applied to the sides of the head along the occipitomental diameter, with the pelvic curve directed toward the neck. Downward traction is exerted until the chin appears under the symphysis. Then, by an upward movement, the face is slowly extracted, with the nose, eyes, brow, and occiput appearing in succession over the anterior margin of the perineum. Forceps should not be applied to the mentum posterior presentation because vaginal delivery is impossible except in very small fetuses.

**VACUUM EXTRACTION**

**Vacuum Extractor Design**

With vacuum delivery technique, suction is created within a cup placed on the fetal scalp such that traction on the cup aids fetal expulsion. In the United States, *vacuum extractor* is the preferred term for the devices shown in Figure 29-15, whereas in Europe it is commonly called a *ventouse*—from French, literally, “soft cup.” Theoretical advantages of this tool compared with forceps include simpler requirements for precise positioning on the fetal head and avoidance of space-occupying blades within the vagina, thereby lowering maternal trauma rates.

*FIGURE 29-15 Vacuum delivery systems. A. The* Kiwi OmniCup *contains a handheld vacuum-generating pump, which is attached via flexible tubing to a rigid plastic mushroom cup. B. The* Mityvac Mystic II MitySoft Bell Cup *has a soft bell cup attached by a semirigid shaft to a handheld pump.*

As noted, vacuum devices contain a cup, shaft, handle, and vacuum generator. Vacuum cups may be metal, hard plastic, or soft plastic and may also differ in their shape, size, and reusability.
In the United States, nonmetal cups are generally preferred, and there are two main types. The soft cup is a pliable funnel- or bell-shaped dome, whereas the rigid type has a firm flattened mushroom-shaped cup and circular ridge around the cup rim (Table 29-2). When compared, rigid mushroom cups generate significantly more traction force (Hofmeyr, 1990; Muise, 1993). With occiput posteriorly positioned heads or with asynclitism, the flatter cup also permits improved placement at the flexion point, which is typically less accessible with these head positions. The trade-off is that the flatter cups have higher scalp laceration rates. Thus, many manufacturers recommend soft bell cups for more straightforward occiput anterior deliveries. Rigid mushroom cups may be preferred for occiput posterior or transverse presentation or for asynclitism.

<sup>a</sup>Reusable cups.

<sup>b</sup>Suitable for occiput posterior positions or asynclitism.

<sup>c</sup>For extractions through a hysterotomy incision during cesarean delivery.

Several investigators have compared outcomes with various rigid and soft cups. Metal cups provide higher success rates but greater rates of scalp injuries, including cephalohematomas (O'Mahony, 2010). In another study, Kuit and coworkers (1993) found that the only advantage of the soft cups was a lower incidence of scalp injury. They reported a 14-percent episiotomy
extension rate with both rigid and pliable cups. Associated perineal lacerations occurred with 16 percent of rigid cup extractions and 10 percent with the pliable cup. In a review, Vacca (2002) concluded that there were fewer scalp lacerations with the soft cup, but that the rate of cephalohematomas and subgaleal hemorrhage was similar between soft and rigid cups. Importantly, high-pressure vacuum generates large amounts of force regardless of the cup used (Duchon, 1998).

Aside from the cup, the shaft that connects the cup and handle may be flexible or semiflexible. Tubing-like flexible shafts may be preferred for occiput posterior or asynclitic presentation to permit better seating of the cup (see Fig. 29-15A). Last, the vacuum generator may be handheld and actuated by the operator or may be held and operated by an assistant.

Technique

An important step in vacuum extraction is proper cup placement over the flexion point. This pivot point maximizes traction, minimizes cup detachment, flexes but averts twisting of the fetal head, and delivers the smallest head diameter through the pelvic outlet. This improves success rates, lowers fetal scalp injury rates, and lessens perineal trauma because the smallest fetal head diameter distends the vulva (Baskett, 2008).

The flexion point is found along the sagittal suture, approximately 3 cm in front of the posterior fontanel and approximately 6 cm from the anterior fontanel. Because cup diameters range from 5 to 6 cm, when properly placed, the cup rim lies 3 cm from the anterior fontanel (Fig. 29-16). Placement of the cup more anteriorly on the fetal cranium—near the anterior fontanel—should be avoided as it leads to cervical spine extension during traction unless the fetus is small. Such placement also delivers a wider fetal head diameter through the vaginal opening. Last, asymmetrical placement relative to the sagittal suture may worsen asynclitism. For elective use, cup placement in occiput anterior positions is seldom difficult. In contrast, when the indication for delivery is failure to descend caused by occipital malposition—with or without asynclitism or deflexion—cup positioning can be difficult.
During cup placement, maternal soft tissue entrapment predisposes the mother to lacerations and virtually ensures cup dislodgement. Thus, the entire cup circumference should be palpated both before and after the vacuum has been created as well as prior to traction to exclude such entrapment. Gradual vacuum creation is advocated by some and is generated by increasing the suction in increments of 0.2 kg/cm$^2$ every 2 minutes until a total negative pressure of 0.8 kg/cm$^2$ is reached (Table 29-3). That said, other studies have shown that negative pressure can be increased to 0.8 kg/cm$^2$ in $< 2$ minutes without a significant difference in efficacy or in maternal and fetal outcomes (Suwannachat, 2011, 2012).

Once suction is created, the instrument handle is grasped, and traction is initiated (Fig. 29-17).
Effort should be intermittent and coordinated with maternal expulsive efforts. Similar to forceps delivery, traction is usually directed initially downward, then progressively extended upward as the head emerges. Manual torque to the cup is avoided as it may cause cup displacement or cephalohematomas and with metal cups, “cookie-cutter”–type scalp lacerations. Thus, occiput anterior oblique positions are corrected not by rotation, but solely by downward outward traction. During pulls, the operator should place the nondominant hand within the vagina, with the thumb on the extractor cup and one or more fingers on the fetal scalp. So positioned, descent of the presenting part can be judged and the traction angle can be adjusted with head descent. In addition, the relationship of the cup edge to the scalp can be assessed to help detect cup separation.

**FIGURE 29-17** Cup placed before application of traction.

Between contractions, some physicians will lower the suction levels to decrease rates of scalp injury, whereas others will maintain suction in cases of nonreassuring fetal heart tones to aid rapid delivery. No differences in maternal or fetal outcome could be demonstrated if the level of vacuum was decreased between contractions or if an effort was made to prevent fetal loss of station (Bofill, 1997). Once the head is extracted, the vacuum pressure is relieved, the cup removed, and the usual techniques to complete vaginal delivery are followed.

Vacuum extraction should be considered a trial. Without early and clear evidence of descent toward delivery, an alternative delivery approach should be considered. As a general guideline, progressive descent should accompany each traction attempt. Neither data nor consensus are available regarding the number of pulls required to effect delivery, the maximum number of cup “pop-offs” that can be tolerated, or optimal total duration of the procedure. Some manufacturers have recommendations regarding these in their instructional literature (Clinical Innovations, LLC 2013; CooperSurgical, 2011).
During a vacuum extraction trial, cup dislodgement due to technical failure or less than optimal placement should not be equated with dislodgement under ideal conditions of exact cup placement and optimal vacuum maintenance. These cases may merit either additional attempts at placement or alternatively, a trial of forceps (Ezenagu, 1999; Williams, 1991). The least desirable cases are those in which traction without progress or multiple disengagements occur following correct cup application and appropriate traction. As with forceps procedures, there should be a willingness to abandon attempts at vacuum extraction if satisfactory progress is not made (American College of Obstetricians and Gynecologists, 2012).

Cesarean delivery defines the birth of a fetus via laparotomy and then hysterotomy. The origin of caesarean is uncertain and was reviewed in the 23rd edition of Williams Obstetrics (Cunningham, 2010). There are two general types of cesarean delivery—primary refers to a first-time hysterotomy and secondary denotes a uterus with one or more prior hysterotomy incisions. Neither definition includes removal of the fetus from the abdominal cavity in the case of uterine rupture or with abdominal pregnancy. Rarely, hysterotomy is performed in a woman who has just died or in whom death is expected soon—postmortem or perimortem cesarean delivery (Chap. 47, p. 956).

In some instances, and most often because of emergent complications such as intractable hemorrhage, abdominal hysterectomy is indicated following delivery. When performed at the time of cesarean delivery, the operation is termed cesarean hysterectomy. If done within a short time after delivery, it is termed postpartum hysterectomy. Peripartum hysterectomy is a broader term that combines these two. In most cases, hysterectomy is total, but supracervical hysterectomy is also an option. The adnexa are not typically removed.
From 1970 to 2010, the cesarean delivery rate in the United States rose from 4.5 percent of all deliveries to 32.8 percent. In 2010, this rate actually declined from a peak of 32.9 percent in 2009 (Martin, 2012). The other, albeit brief, decline was between 1989 and 1996 (Fig. 31-1, p. 610). This more profound decrease was largely due to a significantly increased rate of *vaginal birth after cesarean (VBAC)* and to a closely mirrored decrease in the primary rate. These trends were short lived, and in 2007, the primary cesarean delivery rate was above 30 percent, whereas VBAC rates had dropped to 8 percent (MacDorman, 2011).

The reasons for the continued increase in the cesarean rates are not completely understood, but some explanations include the following:

1. Women are having fewer children, thus, a greater percentage of births are among *nulliparas*, who are at increased risk for cesarean delivery.
2. The average *maternal age* is rising, and older women, especially nulliparas, are at increased risk of cesarean delivery.
3. The use of *electronic fetal monitoring* is widespread. This technique is associated with an increased cesarean delivery rate compared with intermittent fetal heart rate auscultation (Chap. 24, p. 496). Cesarean delivery performed primarily for “fetal distress” comprises only a minority of all such procedures. In many more cases, concern for an abnormal or “nonreassuring” fetal heart rate tracing lowers the threshold for cesarean delivery.
4. Most fetuses presenting as *breech* are now delivered by cesarean. As discussed in Chapter 28 (p. 561), concern for fetal injury, as well as the infrequency with which a breech presentation meets criteria for a labor trial, almost guarantee that most will be delivered by cesarean.
5. The frequency of *forceps* and *vacuum deliveries* has decreased (Chap. 29, p. 574).
6. Rates of *labor induction* continue to rise, and induced labor, especially among nulliparas, increases the cesarean delivery rate (Chap. 26, p. 523).
7. The prevalence of *obesity* has risen dramatically, and obesity increases the cesarean delivery risk (Chap. 48, p. 965).
8. Rates of cesarean delivery for women with preeclampsia have increased, whereas labor induction rates for these patients have declined.
10. Elective cesarean deliveries are increasingly being performed for a variety of indications including concern for *pelvic floor injury* associated with vaginal birth, medically indicated *preterm birth*, reduction of *fetal injury risk*, and for *maternal request*.

**CESAREAN DELIVERY INDICATIONS AND RISKS**

Some indications for performing cesarean delivery are shown in Table 30-1. More than 85 percent of these operations are performed for four reasons—prior cesarean delivery, dystocia, fetal jeopardy, or abnormal fetal presentation.

### Maternal Mortality and Morbidity

To provide accurate informed consent, understanding both maternal and neonatal risks and benefits with surgery is essential. As a broad overview, cesarean delivery has higher maternal surgical risks for the current and subsequent pregnancies. This is balanced against lower rates of perineal injury and short-term pelvic floor disorders, described in Chapter 27 (p. 536). For the neonate,
Cesarean delivery offers lower rates of birth trauma and stillbirth. Conversely, rates of initial respiratory difficulties are greater with cesarean delivery.

For the mother, death attributable solely to cesarean delivery is rare in the United States. Even so, numerous studies attest to increased mortality risks. Clark and colleagues (2008), in a review of nearly 1.5 million pregnancies, found maternal mortality rates of 2.2 per 100,000 cesarean deliveries compared with 0.2 per 100,000 vaginal births. In a metaanalysis of 203 studies, Guise and coworkers (2010) reported a maternal mortality rate of 13 per 100,000 with elective repeat cesarean delivery compared with 4 per 100,000 women undergoing a trial of labor during VBAC attempt.

Similar to mortality rates, the frequency of some maternal complications is increased with all cesarean compared with vaginal deliveries (Table 30-2). Villar and associates (2007) reported that maternal morbidity rates increased twofold with cesarean compared with vaginal delivery. Principal among these are infection, hemorrhage, and thromboembolism. In addition, anesthetic complications, which also rarely include death, have a greater incidence with cesarean compared with vaginal delivery (Cheesman, 2009; Hawkins, 2011). Adjacent organs may be injured. The bladder laceration rate is 1 to 3 per 1000 cesarean deliveries, whereas that for ureteral injury approximates 0.3 per 1000 cases (Güngördük, 2010; Phipps, 2005; Rajasekar, 1997). Bowel damage occurs in approximately 1 in 1000 cesarean deliveries (Silver, 2006).

Women expressing a desire for elective primary cesarean delivery may be counseled that surgery offers decreased risks for hemorrhage and chorioamnionitis compared with planned primary vaginal birth. But this is again balanced against higher maternal rates of thromboembolism, hysterectomy, and rehospitalization for infection or wound complications; longer initial hospital stays; and greater rates of uterine rupture or abnormal placental implantation in subsequent pregnancies (Declercq, 2007; Geller, 2010; Liu, 2007).

Women who undergo a cesarean delivery are much more likely to be delivered by a repeat operation in subsequent pregnancies. For women undergoing subsequent cesarean, the maternal risks just described are even greater (Cahill, 2006; Marshall, 2011; Silver, 2006).

As an advantage, there is evidence that cesarean delivery is associated with lower rates of urinary incontinence and pelvic organ prolapse (Glazener, 2013; Gyhagen, 2013; Handa, 2011; Leijonhufvud, 2011; Rortveit, 2003). This protective advantage may persist to some degree over time, but cesarean delivery is not wholly protective (Dolan, 2010; MacArthur, 2011; Rortveit, 2001). Finally, cesarean delivery is not protective long-term for fecal incontinence (MacArthur, 2011, 2013; Nelson, 2010).

Healthy women with a singleton gestation and no previous cesarean delivery who underwent cesarean delivery for breech presentation were used as a surrogate for a low-risk planned cesarean delivery group.

Data are shown as number (%).

Nonsignificant comparison. For all other comparisons $p < 0.05$.

Modified from Liu, 2007.
Neonatal Morbidity

Cesarean delivery is associated with less risk of fetal trauma. And this in many instances influences the choice of cesarean delivery despite the associated maternal risks. Alexander and colleagues (2006) found that fetal injury complicated 1 percent of cesarean deliveries. Skin laceration was most common, but others included cephalohematoma, clavicular fracture, brachial plexopathy, skull fracture, and facial nerve palsy. Cesarean deliveries following a failed operative vaginal delivery attempt had the highest injury rate, whereas the lowest rate—0.5 percent—occurred in the elective cesarean delivery group. That said, Worley and colleagues (2009) found that approximately a third of pregnant women who were delivered at Parkland Hospital entered spontaneous labor at term, and 96 percent of these delivered vaginally without adverse neonatal outcomes.

Although physical injury risks are lower, cesarean delivery per se may have no bearing on the neurodevelopmental prognosis of the infant. Scheller and Nelson (1994) in a report from the National Institutes of Health and Lien and associates (1995) presented data specifically refuting any association between cesarean delivery and lower rates of either cerebral palsy or seizures. Moreover, as discussed in Chapter 33 (p. 638), the incidences of neonatal seizures or cerebral palsy have not diminished as the rate of cesarean delivery has increased (Miller, 2008; Miller, 2013).

Patient Choice in Cesarean Delivery

As women have taken a more active role in their obstetrical care, some request elective cesarean delivery. Data regarding the true incidence of cesarean delivery on maternal request (CDMR) are limited, however, estimates are a 1- to 7-percent rate in the United States in 2003 (Gossman, 2006; Menacker, 2006).

Reasons for requested cesarean delivery include reduced risk of fetal injury, avoidance of the uncertainty and pain of labor, protection of pelvic floor support, and convenience. Thus, the debate surrounding CDMR includes its medical rationale from both a maternal and fetal-neonatal standpoint, the concept of informed free choice by the woman, and the autonomy of the physician in offering this choice.

To address this, the National Institutes of Health (2006) held a State-of-the-Science Conference on Cesarean Delivery on Maternal Request. A panel of experts critically reviewed available literature to form recommendations based on identified risks and benefits. It is noteworthy that most of the maternal and neonatal outcomes examined had insufficient data to permit such recommendations. Indeed, one of the main conclusions of the conference was that more high-quality research is needed to fully evaluate the issues. The American College of Obstetricians and Gynecologists (2013) concluded that data comparing planned cesarean and planned vaginal delivery were minimal and thus should be interpreted cautiously.

The panel was able to draw a few conclusions from existing information. Cesarean delivery or maternal request should not be performed before 39 weeks’ gestation unless there is evidence of fetal lung maturity. It should be avoided in women desiring several children because of the risk of placental implantation abnormalities and cesarean hysterectomy. Finally, it should not be motivated by the unavailability of effective pain management.

PATIENT PREPARATION
**Delivery Availability**

There is no nationally recognized standard of care that codifies an acceptable time interval to begin performance of a cesarean delivery. Previously, a 30-minute decision-to-incision interval was recommended. In most instances, however, operative delivery is not necessary within this 30-minute time frame. Bloom and coworkers (2001) reported for the Maternal-Fetal Medicine Units Network that 69 percent of 7450 cesareans performed in labor commenced more than 30 minutes after the decision to operate. In a second study, Bloom and colleagues (2006) evaluated cesarean deliveries performed for emergency indications. They reported that failure to achieve a cesarean delivery decision-to-incision time of less than 30 minutes was not associated with a negative neonatal outcome. On the other hand, when faced with an acute, catastrophic deterioration in fetal condition, cesarean delivery usually is indicated as rapidly as possible, and thus purposeful delays are inappropriate. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that facilities giving obstetrical care should have the ability to initiate cesarean delivery in a time frame that best incorporates maternal and fetal risks and benefits.

**Informed Consent**

Obtaining informed consent is a process and not merely a medical record document (American College of Obstetricians and Gynecologists, 2012a). This conversation between a clinician and patient should enhance a woman’s awareness of her diagnosis and contain a discussion of medical and surgical care alternatives, procedure goals and limitations, and surgical risks. For women with a prior cesarean delivery, the option of a trial of labor should be included for suitable candidates. Also, in those desiring permanent sterilization, consenting for tubal ligation, as described in Chapter 39 (p. 720), can be completed at this time.

**Timing of Scheduled Cesarean Delivery**

Adverse neonatal sequelae from neonatal immaturity with elective delivery before 39 completed weeks are appreciable (Clark, 2009; Tita, 2009a). To avoid these, assurance of fetal maturity before scheduled elective surgery is essential as outlined by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) and discussed in Chapter 31 (p. 615). To assist with this and other components of cesarean delivery planning, the American College of Obstetricians and Gynecologists (2011a,c) has created Patient Safety Checklists to be completed before the planned surgery.

**Perioperative Care**

If cesarean delivery is scheduled, a sedative may be given at bedtime the night before surgery. In general, no other sedatives, narcotics, or tranquilizers are administered until after the fetus is born. Oral intake is stopped at least 8 hours before the procedure. The woman scheduled for repeat cesarean delivery typically is admitted the day of surgery and evaluated by the obstetrical and anesthesia teams. Recently performed hematocrit and indirect Coombs test are reviewed, and if the latter is positive, then availability of compatible blood must be ensured.

As discussed in Chapter 25 (p. 509), regional analgesia is preferred for cesarean delivery. An antacid is given shortly before regional analgesia or induction with general anesthesia. One
example is Bicitra, 30 mL orally in a single dose. This minimizes the lung injury risk from gastric acid aspiration. Once the woman is supine, a wedge beneath the right hip creates a left lateral tilt to aid venous return and avoid hypotension. According to the American College of Obstetricians and Gynecologists (2010), there are insufficient data to determine the value of fetal monitoring before scheduled cesarean delivery in women without risk factors. That said, fetal heart sounds should be documented in the operating room prior to surgery.

For further preparation, if hair obscures the operative field it should be removed the day of surgery by clipping. This is associated with fewer surgical site infections compared with shaving (Tanner, 2011). An indwelling bladder catheter is typically placed at Parkland Hospital to collapse the bladder away from the hysterotomy incision, to avert urinary retention secondary to regional analgesia, and to allow accurate postoperative urine measurement. Small studies support the nonuse of catheterization in hemodynamically stable women to minimize urinary infections (Li, 2011; Nasr, 2009).

The risk of thromboembolism is increased with pregnancy and almost doubled in those undergoing cesarean delivery (James, 2006). For this reason, for all women not already receiving thromboprophylaxis, the American College of Obstetricians and Gynecologists (2011d) recommends initiation of pneumatic compression hose before cesarean delivery. These are usually discontinued once the woman ambulates. In contrast, we favor the recommendations of American College of Chest Physicians for early ambulation for women without risk factors who are undergoing cesarean delivery (Bates, 2012). For women already receiving prophylaxis or those with increasing risk factors, prophylaxis is escalated as discussed in Chapter 52 and shown in Table 52-8 (p. 1046).

Some women scheduled for cesarean delivery have concurrent comorbidity that requires specific management in anticipation of surgery. Among others, these include insulin-requiring or gestational diabetes, coagulopathy or thrombophilia, chronic corticosteroid use, and significant reactive airway disease. Preparations for surgery in these women are discussed in the respective chapters covering these topics.

**Infection Prevention**

Febrile morbidity is frequent after cesarean delivery. Numerous good-quality trials have proved that a single dose of an antimicrobial agent given at the time of cesarean delivery significantly decreases infection morbidity. Although more obvious for women undergoing unscheduled cesarean delivery, this practice also significantly lowers the postoperative infection rate in women undergoing elective surgery (American College of Obstetricians and Gynecologists, 2011b). Depending on drug allergies, most recommend a single intravenous dose of a β-lactam antimicrobial—either a cephalosporin or extended-spectrum penicillin derivative. A 1-g dose of cefazolin is an efficacious and cost-effective choice. For obese women, a 2-g dose usually provides adequate coverage, although Pevzner and associates (2011) showed this dose may be inadequate for those with body mass index > 40. In women with significant penicillin or cephalosporin allergy, a single 600-mg intravenous dose of clindamycin combined with a weight-based dose of aminoglycoside is an alternative. A 900-mg clindamycin dose is used for obese patients.

Antimicrobial administration before surgical incision has been shown to lower postoperative infection rates without adverse neonatal effects compared with drug administration after umbilical cord clamping (Sullivan, 2007; Tita, 2009b; Witt, 2011). For this reason, the American College of Obstetricians and Gynecologists (2011b) recommends that prophylaxis be administered within the
60 minutes prior to the start of planned cesarean delivery. For emergent delivery, prophylaxis should be given as soon as feasible.

Preoperative preparation of the abdominal wall skin is effective to prevent wound infection. Either chlorhexidine or povidone-iodine solutions can be used. In addition, to prevent postoperative metritis following cesarean delivery, preoperative vaginal cleansing with a povidone-iodine scrub has been evaluated in small randomized trials (Haas, 2013). Some show benefit, whereas others do not (Reid, 2001; Starr, 2005; Yildirim, 2012). Vaginal cleansing is not a part of preoperative preparation at Parkland Hospital.

Antibiotic prophylaxis against infective endocarditis is not recommended for most with cardiac conditions—exceptions are women with cyanotic heart disease, prosthetic valves, or both (American College of Obstetricians and Gynecologists, 2011b). Regimens selected for routine cesarean infection prophylaxis will also serve as appropriate endocarditis coverage (Chap. 49, p. 991).

**Surgical Safety**

The Joint Commission (2013) established a protocol to prevent surgical errors that encompasses three components: (1) preprocedure verification of all relevant documents, (2) marking the operative site, and (3) completion of a “time out” before procedure initiation. The “time out” requires attention of the entire team to confirm that the patient, site, and procedure are correct. Important discussions also include introduction of the patient-care team members, verification of prophylactic antibiotics, estimation of procedure length, and communication of anticipated complications. Additionally, requests for special instrumentation should be addressed preoperatively to prevent potential patient compromise and intraoperative delays.

An instrument, sponge, and needle count before and after surgery and vaginal delivery is crucial to surgical safety. If counts are not reconciled following abdominal or vaginal examination, then radiographic imaging for retained foreign objects is obtained (American College of Obstetricians and Gynecologists, 2012b).

**TECHNIQUE FOR CESAREAN DELIVERY**

With minor variations, surgical performance of cesarean delivery is comparable worldwide. Most steps are founded on evidence-based data, and these have been reviewed by Dahlke (2013) and Hofmeyr (2009) and their associates. As with all surgery, a clear understanding of relevant anatomy is essential, and this is described and illustrated in Chapter 2 (p. 16).

**Abdominal Incision**

In obstetrics, usually a midline vertical or a suprapubic transverse incision is chosen for laparotomy. Transverse abdominal entry is by either Pfannenstiel or Maylard incisions. Of these, the Pfannenstiel incision is selected most frequently for cesarean delivery. Transverse incisions follow Langer lines of skin tension, and superior cosmetic results compared with vertical incisions can be achieved. Additionally, decreased rates of postoperative pain, fascial wound dehiscence, and incisional hernia compared with vertical entry are benefits. Use of the Pfannenstiel incision, however, is often discouraged for cases in which a large operating space is essential or in which
access to the upper abdomen may be needed. Because of the layers created during incision of the internal and external oblique aponeuroses with transverse incisions, purulent fluid can collect between these. Therefore, cases with high infection risks may favor a midline incision. Last, neurovascular structures, which include the ilioinguinal and iliohypogastric nerves and superficial and inferior epigastric vessels, are often encountered with transverse incisions. Logically, bleeding, wound hematoma, and neurological disruption may more frequently complicate these incisions compared with vertical incision. With repeat cesarean delivery, reentry through a Pfannenstiel incision usually is more time consuming and difficult because of scarring.

The Maylard incision differs mainly from the Pfannenstiel in that the bellies of the rectus abdominis muscles are transected horizontally to widen the operating space. It is technically more difficult due to its required isolation and ligation of the inferior epigastric arteries, which lie lateral to these muscle bellies.

Vertical infraumbilical incisions provide quick entry to shorten incision-to-delivery time (Wylie, 2010). Moreover, this incision has minimal blood loss, superior access to the upper abdomen, generous operating room, and the flexibility for easy wound extension if greater space or access is needed. No important neurovascular structures traverse this incision, and aponeuroses at the linea alba are fused. Main disadvantages are poorer cosmetic results, higher fascial dehiscence or incisional hernia rates, and greater postoperative pain. For morbidly obese patients, a vertical incision that extends up and around the umbilicus may be preferable to avoid cutting through a large pannus (Fig. 48-7, p. 968).

Transverse Incisions
With the Pfannenstiel incision, the skin and subcutaneous tissue are incised using a low, transverse, slightly curvilinear incision. This is made at the level of the pubic hairline, which is typically 3 cm above the superior border of the symphysis pubis. The incision is extended somewhat beyond the lateral borders of the rectus abdominis muscles. It should be of adequate width to accommodate delivery—12 to 15 cm is typical.

Sharp dissection is continued through the subcutaneous layer to the fascia. The superficial epigastric vessels can usually be identified halfway between the skin and fascia, several centimeters from the midline, and coagulated. If lacerated, these may be suture ligated with 3-0 plain gut suture or coagulated with an electrosurgical blade.

The fascia is then incised sharply at the midline. The anterior abdominal fascia is typically composed of two visible layers, the aponeurosis from the external oblique muscle and a fused layer containing aponeuroses of the internal oblique and transverse abdominis muscles. Ideally, the two layers are individually incised during lateral extension of the fascial incision. The inferior epigastric vessels typically lie outside the lateral border of the rectus abdominis muscle and beneath the fused aponeuroses of the internal oblique and transverse abdominis muscles. Thus, although infrequently required, extension of the fascial incision further laterally may cut these vessels. Therefore, if lateral extension is needed, these vessels should be identified and coagulated or ligated to prevent bleeding and vessel retraction.

Once the fascia is incised, the inferior fascial edge is grasped with suitable clamps and elevated by the assistant as the operator separates the fascial sheath from the underlying rectus muscles either bluntly or sharply until the superior border of the symphysis pubis is reached. Any blood vessels coursing between the sheath and muscles are clamped, cut, and ligated, or they are coagulated with an electrosurgery blade. Next, the superior fascial edge is grasped and again, separation of fascia from the rectus muscles is completed. Meticulous hemostasis is imperative to lower rates of infection and bleeding. The fascial separation is carried near enough to the
umbilicus to permit an adequate midline longitudinal incision of the peritoneum. The rectus abdominis and pyramidalis muscles are then separated in the midline by sharp and blunt dissection to expose the transversalis fascia and peritoneum.

The transversalis fascia and preperitoneal fat are dissected carefully to reach the underlying peritoneum. The peritoneum near the upper end of the incision is opened carefully, either bluntly or by elevating it with two hemostats placed approximately 2 cm apart. The tented fold of peritoneum between the clamps is examined and palpated to ensure that omentum, bowel, or bladder is not adjacent. The peritoneum is then incised. The incision is extended superiorly to the upper pole of the incision and downward to just above the peritoneal reflection over the bladder. Importantly, in women who have had previous intraabdominal surgery, including cesarean delivery, omentum or bowel may be adhered to the undersurface of the peritoneum. Moreover, in women with obstructed labor, the bladder may be pushed cephalad almost to the level of the umbilicus.

**Vertical Incision**

An infraumbilical midline vertical incision begins 2 to 3 cm above the superior margin of the symphysis and should be of sufficient length to allow fetal delivery without difficulty. Therefore, its length should correspond with the estimated fetal size, and 12 to 15 cm is typical. Sharp or electrosurgical dissection is performed to the level of the anterior rectus sheath. A small opening is made sharply with scalpel in the upper half of the linea alba. Placement here avoids potential cystotomy. Index and middle fingers are placed beneath the fascia, and the fascial incision is extended superiorly and inferiorly with scissors or scalpel. Midline separation of the rectus muscles and pyramidalis muscles and peritoneal entry are then similar to those with the Pfannenstiel incision.

**Hysterotomy**

Most often, the lower uterine segment is incised transversely as described by Kerr in 1921. Occasionally, a low-segment vertical incision as described by Krönig in 1912 may be used. The classical incision is a vertical incision into the body of the uterus above the lower uterine segment and reaches the uterine fundus. In practice, however, the classical incision is similar to the low-vertical incision, which is typically extended cephalad only to the extent required for fetal delivery. For most cesarean deliveries, the transverse incision is preferred. Compared with a classical incision, it is easier to repair, is located in the inactive segment and thus least likely to rupture during a subsequent pregnancy, causes less incision-site bleeding, and promotes less bowel or omentum adherence to the myometrial incision.

**Low Transverse Cesarean Incision**

Before any hysterotomy, the surgeon should palpate the fundus and adnexa to identify degrees of uterine rotation. The uterus may be dextrorotated so that the left round ligament is more anterior and closer to the midline. In such cases, hysterotomy placement is modified to keep the incision centered within the lower segment. This avoids extension into and laceration of the left uterine artery. With thick meconium or infected amniotic fluid, some surgeons prefer to put a moistened laparotomy sponge in each lateral peritoneal gutter to absorb fluid and blood that escape from the opened uterus. A moist sponge may also be used to pack protruding bowel away from the operative field.

The reflection of peritoneum above the upper margin of the bladder and overlying the anterior lower uterine segment—termed the bladder flap—is grasped in the midline with forceps and
incised transversely with scissors (Fig. 30-1). Bladder flap creation effectively moves the bladder away from the planned hysterotomy site and prevents bladder laceration if an unintended inferior hysterotomy extension occurs during fetal delivery.

FIGURE 30-1 The loose vesicouterine serosa above the bladder reflection is grasped with forceps and incised with Metzenbaum scissors.

Following this initial incision, scissors are inserted between the vesicouterine serosa and myometrium of the lower uterine segment. The scissors are pushed laterally from the midline on each side to further open the visceral peritoneum and expose the myometrium. This transverse peritoneal incision extends almost the full length of the lower uterine segment. As the lateral margin on each side is approached, the scissors are directed somewhat more cephalad (Fig. 30-2). The lower edge of peritoneum is elevated, and the bladder is gently separated from the underlying myometrium with blunt or sharp dissection within this vesicouterine space (Fig. 30-3).
FIGURE 30-2 The loose serosa above the upper margin of the bladder is elevated and incised laterally.
FIGURE 30-3 Cross section shows blunt dissection of the bladder off the uterus to expose the lower uterine segment.

In general, this caudal separation of bladder does not exceed 5 cm and usually is less. It is possible, especially with an effaced, dilated cervix, to dissect downward so caudally as to inadvertently expose and then enter the underlying vagina rather than the lower uterine segment. However, in instances in which cesarean hysterectomy is planned or anticipated, extended caudal bladder dissection is recommended to aid total hysterectomy and decrease the risk of cystotomy.

Some surgeons do not create a bladder flap. The main advantage is a shorter skin incision-to-delivery time, however, data supporting this practice are limited (Hohlagschwandtner, 2001; Tuuli, 2012).

The uterus is entered through the lower uterine segment approximately 1 cm below the upper margin of the peritoneal reflection. It is important to place the uterine incision relatively higher in women with advanced or complete cervical dilatation. Failure to adjust increases the risk of lateral extension of the incision into the uterine arteries. It may also lead to incision of the cervix or vagina rather than the lower uterine segment. Such incisions into the cervix can create significant postoperative distortion of cervical anatomy. Correct placement uses the vesicouterine serosal reflection as a guide.

**Uterine Incision.** The uterus can be incised by a variety of techniques. Each is initiated by using a scalpel to transversely incise the exposed lower uterine segment for 1 to 2 cm in the midline (Fig.
This must be done carefully to avoid fetal laceration. Careful blunt entry using hemostats or fingertip to split the muscle may be helpful. Once the uterus is opened, the incision can be extended by simply spreading the incision, using lateral and slightly upward pressure applied with each index finger (Fig. 30-5). Alternatively, if the lower uterine segment is thick, then cutting laterally and then slightly upward with bandage scissors will extend the incision. Importantly, when scissors are used, the index and midline fingers of the nondominant hand should be insinuated beneath the myometrium and above fetal parts to prevent fetal laceration. Comparing blunt and sharp extensions of the initial uterine incision, sharp extension is associated with an increased estimated blood loss, but postoperative hematocrit changes, need for transfusion, and infection rates are not different (Xu, 2013).

**FIGURE 30-4** The myometrium is carefully incised to avoid cutting the fetal head.
FIGURE 30-5 After entering the uterine cavity, the incision is extended laterally with fingers or with bandage scissors (inset).

The uterine incision should be made large enough to allow delivery of the head and trunk of the fetus without either tearing into or having to cut into the uterine vessels that course along the lateral uterine margins. If the placenta is encountered in the incision line, it must be either detached or incised. *When the placenta is incised, fetal hemorrhage may be severe. Thus, delivery and cord clamping should be performed as soon as possible.*

At times, a low-transverse hysterotomy is selected but provides inadequate room for delivery. In such instances, one corner of the hysterotomy incision is extended cephalad into the contractile portion of the myometrium—a *J incision*. If this is completed bilaterally, a *U incision* is formed. Last, some prefer to extend in the midline—a *T incision*. As expected, these have been linked with higher intraoperative blood loss (Boyle, 1996; Patterson, 2002). Moreover, as these extend into the contractile portion, a trial of labor and vaginal delivery are more likely contraindicated in future pregnancies.
Delivery of the Fetus. In a cephalic presentation, a hand is slipped into the uterine cavity between the symphysis and fetal head. The head is elevated gently with the fingers and palm through the incision. Once the head enters the incision, delivery may be aided by modest transabdominal fundal pressure (Fig. 30-6).

After a long labor with cephalopelvic disproportion, the fetal head may be tightly wedged in the birth canal. This situation can have disastrous results, and there are three considerations for delivery. First, a "push" method may be used. With this, upward pressure exerted by a hand in the vagina by an assistant will help to dislodge the head and allow its delivery above the symphysis. Relief of such head impaction increases the risk of hysterotomy extension and associated blood loss as well as fetal skull fracture. As an alternative, a "pull" method is used in which the fetal legs are grasped and delivered through the hysterotomy opening. The fetus is then delivered by traction as one would complete a breech extraction. Support for this latter approach comes only from small randomized trials and case series (Bastani, 2012; Shazly, 2013; Veisi, 2012). Last, a low vertical hysterotomy incision, which will give more room for the "pull" technique, may be selected. If a low transverse incision has already been made, then this can be extended to a J-, U-, or T-incision for room.

Conversely, in women without labor, the fetal head may be unmolded and without a leading cephalic point. The round head may be difficult to lift through the uterine incision in a relatively thick lower segment that is unattenuated by labor. In such instances, either forceps or a vacuum device may be used to deliver the fetal head as shown in Figure 30-7.
FIGURE 30-7 A. The first cesarean forceps blade is placed. B. Slight upward and outward traction is used to lift the head through the incision.

After head delivery, a finger should be passed across the fetal neck to determine whether it is encircled by one or more umbilical cord loops. If an umbilical cord coil is felt, it should be slipped over the head. The head is rotated to an occiput transverse position, which aligns the fetal bisacromial diameter vertically. The sides of the head are grasped with two hands, and gentle downward traction is applied until the anterior shoulder enters the hysterotomy incision (Fig. 30-8). Next, by upward movement, the posterior shoulder is delivered. During delivery, abrupt or powerful force is avoided to avert brachial plexus injury. With steady outward traction, the rest of the body then readily follows. Gentle fundal pressure may aid this.
The anterior (A) and then the posterior (B) shoulder are delivered.

With some exceptions, current American Heart Association neonatal resuscitation recommendations eschew suctioning immediately following birth, even with meconium present (Kattwinkel, 2010). A fuller discussion of this and the timing of umbilical cord clamping as it relates to neonatal outcome are found in Chapter 27 (p. 539). The umbilical cord is clamped, and the newborn is given to the team member who will conduct resuscitative efforts as needed (Chap. 32, p. 625).

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that “a qualified person who is skilled in neonatal resuscitation should be in the delivery room, with all equipment needed for neonatal resuscitation, to care for the neonate.” Jacob and Phenninger (1997) compared 834 cesarean deliveries with 834 low-risk vaginal deliveries. They found that with regional analgesia, there is rarely a need for infant resuscitation after elective repeat cesarean delivery or cesarean delivery for dystocia without fetal heart rate abnormalities and that a pediatrician may not be necessary at such deliveries. At Parkland Hospital, pediatric nurse practitioners attend uncomplicated, scheduled cesarean deliveries.

After birth, an intravenous infusion containing two ampules or 20 units of oxytocin per liter of crystalloid is infused at 10 mL/min. Some prefer higher infusion dosages, however, bolus doses are avoided because of associated hypotension (Roach, 2013). Once the uterus contracts satisfactorily, the rate can be reduced. An alternative is carbetocin—a longer-acting oxytocin derivative that is not available in the United States—that provides suitable, albeit more expensive,
hemorrhage prophylaxis (Su, 2012). Second-tier agents are ergot-alkaloids, which carry hypertensive side effects, and misoprostol, which provides inferior postpartum hemorrhage protection compared with oxytocin. Last, the use of tranexamic acid (Cyklokapron) has recently been described in a few small studies to lower blood loss during cesarean delivery (Abdel-Aleem, 2013; Güngördük, 2011). Its antifibrinolytic action and effects on thromboembolism rates in pregnant surgical patients are unclear, and larger trials are needed before widespread use. Additional discussions of all these agents are found in Chapters 27 (p. 547) and 41 (p. 785).

Placental Delivery. The uterine incision is observed for any vigorously bleeding sites. These should be promptly clamped with Pennington or ring forceps. The placenta is then delivered unless it has already done so spontaneously. Many surgeons prefer manual removal, but spontaneous delivery, as shown in Fig. 30-9, along with some cord traction may reduce the risk of operative blood loss and infection (Anorlu, 2008; Baksu, 2005). Fundal massage may begin as soon as the fetus is delivered to hasten placental separation and delivery.

FIGURE 30-9 Placenta bulging through the uterine incision as the uterus contracts. A hand gently massages the fundus to help aid placental separation.

Immediately after delivery and gross inspection of the placenta, the uterine cavity is suctioned and wiped out with a gauze sponge to remove avulsed membranes, vernix, and clots. Previously,
double-gloved fingers or ring forceps placed through the hysterotomy incision were used to dilate an ostensibly closed cervix. This practice does not improve infection rates from potential hematometra and is not recommended (Güngördük, 2009; Liabsuetrakul, 2011).

**Uterine Repair.** After placental delivery, the uterus is lifted through the incision onto the draped abdominal wall, and the fundus is covered with a moistened laparotomy sponge. Although some clinicians prefer to avoid such uterine exteriorization, it often has benefits that outweigh its disadvantages. For example, the relaxed, atonic uterus can be recognized quickly and massage applied. The incision and bleeding points are more easily visualized and repaired, especially if there have been extensions. Adnexal exposure is superior, and thus, tubal sterilization is easier. The principal disadvantage is discomfort and vomiting caused by traction in cesarean deliveries performed under regional analgesia. Importantly, rates of febrile morbidity or blood loss do not appear to be increased with uterine exteriorization (Coutinho, 2008; Walsh, 2009).

Before hysterotomy closure, previously clamped large vessels may be ligated separately or incorporated within the running incision closure. One angle of the uterine incision is grasped to stabilize and maneuver the incision. The uterine incision is then closed with one or two layers of continuous 0- or No. 1 absorbable suture (Fig. 30-10). Chromic suture is used by many, but some prefer synthetic delayed-absorbable sutures. Single-layer closure is typically faster and is not associated with higher rates of infection or transfusion (CAESAR study collaborative group, 2010 Dodd, 2008; Hauth, 1992). Moreover, most studies observed that the type of uterine closure does not significantly affect complications in the next pregnancy (Chapman, 1997; Durnwald, 2003; Roberge, 2011).
FIGURE 30-10 The cut edges of the uterine incision are approximated with a running-lock suture anchored at either angle of the incision.

At Parkland Hospital, we favor the one-layer uterine closure. The initial suture is placed just beyond one angle of the uterine incision. A running-lock suture for hemostasis is then performed, with each suture penetrating the full thickness of the myometrium. Concern has been expressed by some clinicians that sutures through the decidua may lead to endometriosis or adenomyosis in the hysterotomy scar, but this is rare. It is important to carefully select the site of each stitch and to avoid withdrawing the needle once it penetrates the myometrium. This minimizes perforation of unligated vessels and subsequent bleeding. The running-lock suture is continued just beyond the opposite incision angle. If approximation is not satisfactory after a single-layer continuous closure or if bleeding sites persist, then more sutures are required. Either another layer of running suture is placed to achieve approximation and hemostasis, or individual bleeding sites can be secured with figure-of-eight or mattress sutures.

Traditionally, serosal edges overlying the uterus and bladder have been approximated with a continuous 2-0 chromic catgut suture. Multiple randomized trials suggest that omission of this step
causes no postoperative complications (Grundsell, 1998; Irion, 1996; Nagele, 1996). If tubal sterilization is to be performed, it is now done as described in Chapter 39 (p. 720).

**Adhesions**

Following cesarean delivery, adhesions commonly form within the vesicouterine space or between the anterior abdominal wall and uterus. And with each successive pregnancy, the percentage of affected women and adhesion severity increases (Morales, 2007; Tulandi, 2009). Adhesions can significantly lengthen incision-to-delivery times and total operative time (Rossouw, 2013; Sikirica, 2012). Although occurring infrequently, rates of cystotomy and bowel injury are also increased (Rahman, 2009; Silver, 2006).

Intuitively, scarring can be reduced by handling tissues delicately, achieving hemostasis, and minimizing tissue ischemia, infection, and foreign-body reaction. Data are conflicting regarding closure of the bladder flap (visceral peritoneum) or of the abdominal cavity (parietal peritoneum) and its effect on subsequent adhesions. Some note benefit from closure of one, but not the other, or neither (CAESAR study collaborative group, 2010; Cheong, 2009; Kapustian, 2012; Lyell, 2005, 2012).

Benefit from placement of an adhesion barrier at the repaired hysterotomy site is limited to only two nonrandomized studies (Chapa, 2011; Fushiki, 2005). Currently, there is an ongoing multicenter randomized trial to evaluate use of the barrier Seprafilm at the time of cesarean delivery (National Institutes of Health, 2012).

**Abdominal Closure**

Any laparotomy sponges are removed, and the paracolic gutters and cul-de-sac are gently suctioned of blood and amniotic fluid. Some surgeons irrigate the gutters and cul-de-sac, especially in the presence of infection or meconium. Routine irrigation in low-risk women, however, leads to greater intraoperative nausea and without lower postoperative infection rates (Harrigill, 2003; Viney, 2012).

After sponge and instrument counts are found to be correct, the abdominal incision is closed in layers. Many surgeons omit the parietal peritoneal closure. In addition to ambiguity regarding adhesion prevention, data are also conflicting as to whether nonclosure of parietal peritoneum decreases postoperative discomfort and analgesia requirements (Chanrachakul, 2002; Lyell, 2005; Rafique, 2002). However, if there is distended bowel in the incision site, we find that peritoneal closure may help to protect the bowel when fascial sutures are placed.

As each layer is closed, bleeding sites are located, clamped, and ligated or coagulated with an electrosurgical blade. The rectus abdominis muscles are allowed to fall into place. With significant diastasis, the rectus muscles may be approximated with one or two figure-of-eight sutures of 0 or No. 1 chromic gut suture. The overlying rectus fascia is closed by a continuous, nonlocking technique with a delayed-absorbable suture. In patients with a higher risk for infection, there may be theoretical value in selecting a monofilament suture here rather than braided material.

The subcutaneous tissue usually need not be closed if it is less than 2 cm thick. With thicker layers, however, closure is recommended to minimize seroma and hematoma formation, which can lead to wound infection and/or disruption (Bohman, 1992; Chelmow, 2004). Addition of a subcutaneous drain does not prevent significant wound complications (Hellums, 2007; Ramsey, 2005). Skin is closed with a running subcuticular stitch using 4-0 delayed-absorbable suture or with staples. In comparison, final cosmetic results and infection rates appear similar, skin suturing takes longer, but wound separation rates are higher with staples (Basha, 2010; Figueroa, 2013;
Joel-Cohen and Misgav-Ladach Techniques

The Pfannenstiel-Kerr technique just described has been used for decades. More recently, the Joel-Cohen and Misgav-Ladach modifications have been described. These differ from traditional Pfannenstiel-Kerr entry mainly by their initial incision placement and greater use of blunt dissection.

The Joel-Cohen technique creates a straight 10-cm transverse skin incision 3 cm below the level of the anterior superior iliac spines. The subcutaneous tissue layer is opened sharply 2 to 3 cm in the midline. This is carried down, without lateral extension, to the fascia. A small transverse incision is made in the fascia, and a finger from each hand is hooked into the lateral angles of this fascial incision. The incision is then stretched transversely. Once the fascia is opened and rectus abdominis muscle bellies identified, an index finger from each hand is inserted between the bellies. One is moved cranially and the other caudally, in opposition, to further separate the bellies. Index finger dissection is used to enter the peritoneum, and again, cranial and caudal opposing stretch with index fingers will open this layer. All the layers of the abdominal wall are then manually stretched laterally in opposition to further open the incision. The visceral peritoneum is incised in the midline above the bladder, and the bladder is bluntly reflected inferiorly to separate it from the underlying lower uterine segment. The myometrium is incised transversely in the midline and then opened and extended laterally with one finger hooked into each corner of the hysterotomy incision. Interrupted sutures are used for hysterotomy closure. Neither visceral nor parietal peritoneum is closed. The Misgav-Ladach technique is similar and differs mainly in that myometrial incision closure is completed with a single-layer locking continuous suture (Hofmeyr, 2009; Holmgren, 1999).

These techniques have been associated with shorter operative times and with lower rates of intraoperative blood loss and postoperative pain (Hofmeyr, 2008). They may, however, prove difficult for women with anterior rectus fibrosis and peritoneal adhesions (Bolze, 2013). Moreover, long-term outcomes with these techniques, such as subsequent uterine rupture, are unknown.

Classical Cesarean Incision

This incision is usually avoided because it encompasses the active upper uterine segment and thus is prone to rupture with subsequent pregnancies.

Indications. A classical incision is occasionally preferred for delivery. Some indications stem from difficulty in exposing or safely entering the lower uterine segment. For example, a densely adhered bladder from previous surgery is encountered; a leiomyoma occupies the lower uterine segment; the cervix has been invaded by cancer; or massive maternal obesity precludes safe access to the lower uterine segment. A classical incision is also preferred in some cases of placenta previa with anterior implantation, especially those complicated by placenta accrete syndromes.

In other instances, fetal indications dictate the need. Transverse lie of a large fetus, especially if the membranes are ruptured and the shoulder is impacted in the birth canal, usually necessitates a classical incision. A fetus presenting as a back-down transverse lie is particularly difficult to deliver through a transverse uterine incision. In instances when the fetus is very small, especially if breech, a classical incision may be preferable (Osmundson, 2013). In such cases, the poorly developed lower uterine segment provides inadequate space for the manipulations required for
breech delivery. Or, less commonly, the small fetal head may become entrapped by a contracting uterine fundus following membrane rupture. Last, with multiple fetuses, a classical incision again may be needed to provide suitable room for extraction of fetuses that may be malpositioned or preterm.

**Uterine Incision and Repair.** A vertical uterine incision is initiated with a scalpel beginning as low as possible and preferably within the lower uterine segment (Fig. 30-11). If adhesions, insufficient exposure, a tumor, or placenta percreta preclude development of a bladder flap, then the incision is made above the level of the bladder. Once the uterus is entered with a scalpel, the incision is extended cephalad with bandage scissors until it is long enough to permit delivery of the fetus. With scissor use, the fingers of the nondominant hand are insinuated between the myometrium and fetus to prevent fetal laceration. As the incision is opened, numerous large vessels that bleed profusely are commonly encountered within the myometrium. The remainder of fetal and placental delivery mirrors that with a low transverse hysterotomy.
FIGURE 30-11 An initial small vertical hysterotomy incision is made in the lower uterine segment. Fingers are insinuated between the myometrium and fetus to avoid fetal laceration. Scissors extend the incision cephalad as needed for delivery.

For incision closure, one method employs a layer of 0- or No. 1 chromic catgut with a continuous stitch to approximate the deeper halves of the incision (Fig. 30-12). The outer depth of myometrium is then closed with similar suture and with a running stitch or figure-of-eight sutures. No unnecessary needle tracks should be made lest myometrial vessels be perforated, leading to subsequent hemorrhage or hematomas. To achieve good approximation and to prevent the suture from tearing through the myometrium, it is helpful to have an assistant compress the uterus on each side of the wound toward the midline as each stitch is placed.
FIGURE 30-12 Classical incision closure. The deeper half (A) and superficial half (B) of the incision are closed in a running fashion.
PERIPARTUM HYSTERECTOMY

Indications

Hysterectomy is more commonly performed during or after cesarean delivery but may be needed following vaginal birth. If all deliveries are considered, the rate ranges from 0.4 to 2.5 per 1000 births and has risen significantly during the past few decades. During a 25-year period, the rate of peripartum hysterectomy at Parkland Hospital was 1.7 per 1000 births (Hernandez, 2012). Most of this increase is attributed to the increasing rates of cesarean delivery and its associated complications in subsequent pregnancy (Bateman, 2012; Bodelon, 2009; Flood, 2009; Orbach, 2011). Of hysterectomies, approximately one half to two thirds are total, whereas the remaining cases are supracervical (Rossi, 2010; Shellhaas, 2009).

Cesarean hysterectomies are most commonly performed to arrest or prevent hemorrhage from intractable uterine atony or abnormal placentation (Bateman, 2012; Hernandez, 2012; Owolabi, 2013). These as well as other less frequent indications are found in Table 30-3. For example, large leiomyomas may preclude satisfactory hysterotomy closure and necessitate hysterectomy. Or, postpartum infectious morbidity from an infected, necrotic uterus will prompt uterine removal for recovery (Fig. 37-4, p. 688). Logically, risk factors for peripartum hysterectomy mirror the risks of these indicated complications, which are described throughout the text.

Major complications of peripartum hysterectomy include increased blood loss and greater risk of urinary tract damage. Blood loss is usually appreciable because hysterectomy is being performed for hemorrhage that frequently is torrential, and the procedure itself is associated with substantial blood loss. Although many cases with such hemorrhage cannot be anticipated, those with abnormal implantation can often be identified antepartum. Preoperative preparations for placenta accreta are discussed in Chapter 41 (p. 807) and have also been outlined by the Society for Maternal-Fetal Medicine (2010) and American College of Obstetricians and Gynecologists (2012c).
An important factor affecting the cesarean hysterectomy complication rate is whether the operation is performed electively or emergently (Briery, 2007). After anticipated or planned cesarean hysterectomy, there are lower rates of blood loss, less need for blood transfusions, and fewer urinary tract complications compared with emergent procedures (Briery, 2007; Glaze, 2008; Sakse, 2007).

**Peripartum Hysterectomy Technique**

Supracervical or total hysterectomy is performed using standard operative techniques. For this, adequate exposure is essential. Initially, placement of a self-retaining retractor such as a Balfour is not necessary. Rather, satisfactory exposure is obtained with cephalad traction on the uterus by an assistant, along with handheld retractors such as a Richardson or Deaver. The bladder flap is deflected downward to the level of the cervix if possible to permit total hysterectomy. In cases in which cesarean hysterectomy is planned or strongly suspected, extended bladder flap dissection is ideally completed before initial hysterotomy. Later attempts at bladder dissection may be obscured by bleeding, or excess blood may be lost while this dissection is performed.

After cesarean delivery, the placenta is typically removed. In cases of placenta accrete syndromes, in which hysterectomy is already planned, the placenta is usually left undisturbed in situ. In either situation, if the hysterotomy incision is bleeding appreciably, it can be sutured or Pennington or sponge forceps can be applied for hemostasis. If bleeding is minimal, neither maneuver is necessary.

The round ligaments are divided close to the uterus between Kocher clamps and doubly ligated (Fig. 30-13). Either 0 or No. 1 suture can be used in either chromic gut or delayed-absorbable material. The incision in the vesicouterine serosa that was made to mobilize the bladder is extended laterally and upward through the anterior leaf of the broad ligament to reach the incised round ligaments. The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tubes, uteroovarian ligaments, and ovarian vessels (Fig. 30-14). These structures together are then doubly clamped close to the uterus and divided, and the lateral pedicle is doubly ligated (Fig. 30-15). The posterior leaf of the broad ligament is divided toward the uterosacral ligaments (Fig. 30-16). Next, the bladder and attached peritoneal flap are further deflected and dissected as needed from the lower uterine segment and retracted out of the operative field. If the bladder flap is unusually adhered, as it may be after previous hysterotomy incisions, careful sharp dissection may be necessary (Fig. 30-17).
FIGURE 30-13 The round ligaments are clamped, doubly ligated, and transected bilaterally.
FIGURE 30-14 The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tube, uteroovarian ligaments, and ovarian vessels.
FIGURE 30-15 The uteroovarian ligament and fallopian tube are doubly clamped and cut bilaterally. The lateral pedicle is doubly ligated.
FIGURE 30-16 The posterior leaf of the broad ligament is divided inferiorly toward the uterosacral ligament.
Special care is required from this point on to avoid injury to the ureters, which pass beneath the uterine arteries. To help accomplish this, an assistant places constant traction to pull the uterus in the direction away from the side on which the uterine vessels are being ligated. The ascending uterine artery and veins on either side are identified near their origin. These pedicles are then doubly clamped immediately adjacent to the uterus, divided, and doubly suture ligated. As shown in Figure 30-18, we prefer to use three heavy clamps—Heaney or Ballantine—to incise the tissue between the most medial clamps, and then ligate the pedicle in the clamps lateral to the uterus.
FIGURE 30-18 A. The uterine artery and veins on either side are doubly clamped immediately adjacent to the uterus and divided. A third medial clamp will prevent “back bleeding.” B&C. The vascular pedicle is doubly suture ligated.

With cesarean hysterectomy, it may be more advantageous in cases of profuse hemorrhage to rapidly double clamp and divide all of the vascular pedicles between clamps to gain hemostasis. The operator can then return to ligate all of the pedicles.

Total Hysterectomy

Even if total hysterectomy is planned, we find it in many cases technically easier to finish the operation after amputating the uterine fundus and placing Ochsner or Kocher clamps on the cervical stump for traction and hemostasis. Self-retaining retractors also may be placed at this time. To remove the cervix, the bladder is mobilized further if needed. This carries the ureters
caudad as the bladder is retracted beneath the symphysis and will prevent laceration or suturing of the bladder during cervical excision and vaginal cuff closure.

If the cervix is effaced and dilated considerably, its softness may obscure palpable identification of the cervicovaginal junction. The junction location can be ascertained through a vertical uterine incision made anteriorly in the midline, either through the open hysterotomy incision or through an incision created at the level of the ligated uterine vessels. A finger is directed inferiorly through the incision to identify the free margin of the dilated, effaced cervix and the anterior vaginal fornix. The contaminated glove is replaced. Another useful method to identify the cervical margins is to transvaginally place four metal skin clips or brightly colored sutures at 12, 3, 6, and 9 o’clock positions on the cervical edges in cases of planned hysterectomy.

The cardinal ligaments, the uterosacral ligaments, and the many large vessels these ligaments contain are clamped systematically with Heaney-type curved or straight clamps (Fig. 30-19). The clamps are placed as close to the cervix as possible, taking care not to include excessive tissue in each clamp. The tissue between the pair of clamps is incised, and the lateral pedicle is suture ligated. These steps are repeated caudally until the level of the lateral vaginal fornix is reached. In this way, the descending branches of the uterine vessels are clamped, cut, and ligated as the cervix is dissected from the cardinal ligaments.
The cardinal ligaments are clamped, incised, and ligated. Immediately below the level of the cervix, a curved clamp is placed across the lateral vaginal fornix, and the tissue is incised above the clamp (Fig. 30-20). The excised lateral vaginal fornix can be simultaneously doubly ligated and sutured to the stump of the cardinal ligament. The cervix is inspected to ensure that it has been completely removed, and the vagina is then repaired. Each of the angles of the lateral vaginal fornix is secured to the cardinal and uterosacral ligaments to mitigate later vaginal prolapse (Fig. 30-21). Following this step, some surgeons prefer to close the vagina using figure-of-eight sutures. Others achieve hemostasis by using a running-lock stitch placed through the mucosa and adjacent endopelvic fascia around the circumference of the vaginal cuff (Fig. 30-22).
FIGURE 30-20 A curved clamp is placed across the lateral vaginal fornix below the level of the cervix, and the tissue incised medially to the point of the clamp.
FIGURE 30-21 The lateral angles of the vaginal cuff are secured to the cardinal and uterosacral ligaments.
If a self-retaining retractor has not already been placed, some clinicians choose to insert one at this point. The bowel is then packed out of the field, and all sites are examined carefully for bleeding. One technique is to perform a systematic bilateral survey from the fallopian tube and ovarian ligament pedicles to the vaginal vault and bladder flap. Bleeding sites are ligated with care to avoid the ureters. The abdominal wall normally is closed in layers, as previously described for cesarean delivery (p. 597).

**Supracervical Hysterectomy**

To perform a subtotal hysterectomy, the uterine body is amputated immediately above the level of uterine artery ligation. The cervical stump may be closed with continuous or interrupted chromic catgut sutures of 0 or No. 1 gauge. Subtotal hysterectomy is often all that is necessary to stop hemorrhage. It may be preferred for women who would benefit from a shorter surgery or for those with extensive adhesions that threaten significant urinary tract injury.

**Salpingo-Oophorectomy**

Because of the large adnexal vessels and their close proximity to the uterus, it may be necessary to remove one or both adnexa to obtain hemostasis. Briery and colleagues (2007) reported unilateral or bilateral oophorectomy in a fourth of cases. Preoperative counseling should include this
Cystotomy

Rarely, and usually in women who have had a previous cesarean delivery, the bladder may be lacerated. This complication may occur during cesarean delivery, but it is more common with cesarean hysterectomy, especially if there is abnormal placental implantation.

Bladder injury is typically identified at the time of surgery, and initially, a gush of clear fluid into the operating field may be seen. If cystotomy is suspected, it may be confirmed with retrograde instillation of sterile infant formula through a Foley catheter into the bladder. Leakage of opaque milk aids in laceration identification and delineation of its borders. In some cases, cystoscopy may be indicated to further define bladder injury. Primary repair is preferred and lowers the risk of postoperative vesicovaginal fistula formation. Once ureteral patency is confirmed, the bladder may be closed with a two- or three-layer running closure using a 3-0 absorbable or delayed-absorbable suture (Fig. 30-23). The first layer inverts the mucosa into the bladder, and subsequent layers reapproximate bladder muscularis. Postoperative care requires continuous bladder drainage for 7 to 10 days.
**FIGURE 30-23** Cystotomy repair. **A.** The primary layer inverts the bladder mucosa with running or interrupted sutures of 3-0 delayed-absorbable or absorbable suture. **B.** Second and possibly a third layer approximate the bladder muscularis to reinforce the incision closure.

## PERIPARTUM MANAGEMENT

### Intravenous Fluids
During and after cesarean delivery, requirements for intravenous fluids can vary considerably. Intravenously administered fluids consist of either lactated Ringer solution or a similar crystalloid solution with 5-percent dextrose. Typically, at least 2 to 3 L is infused during surgery. Blood loss with uncomplicated cesarean delivery approximates 1000 mL. The average-sized woman with a hematocrit of 30 percent or more and with a normally expanded blood and extracellular fluid volume most often will tolerate blood loss up to 2000 mL without difficulty. Unappreciated bleeding through the vagina during the procedure, bleeding concealed in the uterus after its closure, or both commonly lead to underestimation.

Blood loss averages 1500 mL with elective cesarean hysterectomy, although this is variable (Pritchard, 1965). Most peripartum hysterectomies are unscheduled, and blood loss in these cases is correspondingly greater. Thus, in addition to close monitoring of vital signs and urine output, the hematocrit should be determined intra- or postoperatively as indicated (Chap. 41, p. 781).

### Recovery Suite
Close monitoring of the amount of vaginal bleeding is necessary for at least an hour in the immediate postoperative period. The uterine fundus is also identified frequently by palpation to ensure that the uterus remains firmly contracted. Unfortunately, as conduction analgesia fades or the woman awakens from general anesthesia, abdominal palpation is likely to produce pain. An analgesic given by intermittent intravenous injection can be effective (Table 30-4). A sterile thin abdominal wound dressing is sufficient, and indeed, a thick, heavily taped padded dressing will interfere with fundal palpation and massage. Deep breathing and coughing are encouraged. Once regional analgesia begins to fade or the woman becomes fully awake following general anesthesia, criteria for transfer to the postpartum ward include minimal bleeding, stable vital signs, and adequate urine output.

### Table 30-4

<table>
<thead>
<tr>
<th>Typical Settings for Administration of Intravenous Opioids via a Patient-Controlled Analgesia Pump</th>
</tr>
</thead>
</table>

Hospital Care until Discharge

Analgesia, Vital Signs, Intravenous Fluids

A number of schemes are suitable for postoperative pain control. Some basic regimens are shown in Table 30-4. In a trial at Parkland Hospital, Yost and associates (2004) found that morphine provided superior pain relief to meperidine and was associated with significantly higher rates of breast feeding and continuation of infant rooming in. Breast feeding can be initiated the day of surgery. If the mother elects not to breast feed, a binder that supports the breasts without marked compression usually will minimize discomfort (Chap. 36, p. 675).

After transfer to her room, the woman is assessed at least hourly for 4 hours, and thereafter at...
intervals of 4 hours. Vital signs, uterine tone, urine output, and bleeding are evaluated. The hematocrit is routinely measured the morning after surgery. It is checked sooner if there was unusual blood loss or if there is hypotension, tachycardia, oliguria, or other evidence to suggest hypovolemia. If the hematocrit is decreased significantly from the preoperative level, the measurement is repeated and a search is instituted to identify the cause. If the hematocrit stabilizes, the mother can be allowed to ambulate, and if there is little likelihood of further blood loss, iron therapy is preferred to transfusion.

As described in Chapter 36 (p. 671), the puerperium is characterized by excretion of fluid that was retained during pregnancy. At least with elective cesarean delivery, significant extracellular fluid sequestration in the bowel wall and lumen does not occur, unless perhaps it was necessary to pack the bowel away from the operative field. Thus, the woman who undergoes routine cesarean delivery rarely develops fluid sequestration in the extracellular space. On the contrary, she normally begins surgery with a physiologically enlarged extravascular volume acquired during pregnancy that she mobilizes and excretes after delivery. As a generalization, 3 L of fluid should prove adequate during the first 24 hours after surgery. If urine output falls below 30 mL/hr, however, the woman should be reevaluated promptly. The cause of the oliguria may range from unrecognized blood loss to an antidiuretic effect from infused oxytocin.

Women undergoing unscheduled cesarean delivery may have pathological retention or constriction of the extracellular fluid compartment caused by severe preeclampsia, sepsis syndrome, vomiting, prolonged labor without adequate fluid intake, and increased blood loss.

**Bladder and Bowel Function**

The Foley catheter most often can be removed by 12 hours postoperatively, or more conveniently, the morning after surgery. The prevalence of urinary retention following cesarean delivery approximates 3 to 7 percent. Regional analgesia and failure to progress in labor are identified risks (Chai, 2008; Liang, 2007). Thus, surveillance for bladder overdistention should be implemented as with vaginal delivery.

In uncomplicated cases, solid food may be offered within 8 hours of surgery (Bar, 2008; Orji, 2009). Although some degree of adynamic ileus follows virtually every abdominal operation, in most cases of cesarean delivery, it is negligible. Symptoms include abdominal distention, gas pains, and an inability to pass flatus or stool. The pathophysiology of postoperative ileus is complex and involves inflammatory and neural factors that are incompletely understood (van Bree, 2012). If associated with otherwise unexplained fever, an unrecognized bowel injury may be responsible. Treatment for ileus has changed little during the past several decades and involves intravenous fluid and electrolyte supplementation. If severe, nasogastric decompression is necessary.

**Ambulation and Wound Care**

As discussed on page 590, women undergoing cesarean delivery have an increased risk of venous thromboembolism compared with those delivering vaginally. Additional risks include age > 35; obesity; parity > 3; emergency cesarean; cesarean hysterectomy; concurrent infection, major illness, preeclampsia, or gross varicosities; recent immobility; and prior deep-vein thrombosis or thrombophilia (Marik, 2008). Postoperative thromboprophylaxis is discussed in Chapter 52 (p. 1045). Early ambulation lowers the risk of venous thromboembolism. In most instances, by the day after surgery, a woman should get briefly out of bed with assistance at least twice to walk. Ambulation can be timed so that a recently administered analgesic will minimize discomfort. By the second day, she may walk without assistance.
The incision is inspected each day, and skin sutures or clips often can be removed on the fourth postoperative day. If there is concern, however, for superficial wound separation—for example, in obese patients—the suture or clips should remain in place for 7 to 10 days. By the third postpartum day, showering is not harmful to the incision.

**Hospital Discharge**

Unless there are complications during the puerperium, the mother generally is discharged on the third or fourth postpartum day (Buie, 2010). Data from small studies suggest that earlier discharge may be feasible for properly selected and motivated women (Strong, 1993; Tan, 2012). Activities during the first week should be restricted to self-care and newborn care with assistance. Driving can be resumed when pain does not limit the ability to brake quickly and when narcotic medications are not in use. Return to work is variable. Six weeks is commonly cited, although many women use the Family and Medical Leave Act to allow up to 12 weeks for recovery and newborn bonding.

Once a cesarean, always a controversy.
Flamm, 1997

Few issues in modern obstetrics have been as controversial as the management of the woman who has undergone a prior cesarean delivery. As we approach the 100th anniversary of the oft-quoted remark by Cragin, the issue remains unsettled.

100 YEARS OF CONTROVERSY

Management of the woman who has undergone a previous cesarean delivery has been—for good reasons—a controversial topic for more than 100 years. By the beginning of the 20th century, cesarean delivery had become relatively safe. But, as women survived the first operation and conceived again, they were now at risk for uterine rupture. This was because of the prevailing use
of vertical hysterotomy—and especially the classical incision (Williams, 1903). The inherent dangers of uterine rupture led to the dictum above by Edwin B. Cragin (1916). It was not until later that Kerr (1921) described use of a transverse low-segment uterine incision that was predicted to be less likely to rupture with subsequent labor.

Perhaps contrary to popular belief, these events did not result in strict adherence to repeat cesarean delivery. In the 10th edition of *Williams Obstetrics*, Eastman (1950) stated a preference for vaginal delivery in these women and described a 30-percent vaginal delivery rate at Johns Hopkins Hospital. But while only 2 percent of women who labored had a uterine rupture, they had a 10-percent maternal mortality rate. Subsequent observational studies from the 1960s also suggested that vaginal delivery was a reasonable option (Pauerstein 1966, 1969). Germane to this is that through the 1960s, the overall cesarean delivery rate was only approximately 5 percent. Beginning then, however, well-intentioned efforts to improve perinatal outcomes were accompanied by a rapidly escalating cesarean delivery rate that exceeded 20 percent by 1985 (Chap. 30, p. 587). In addition, the concept of *cesarean delivery on maternal request* has increased the primary operation rate (American College of Obstetricians and Gynecologists 2013b). And as expected, as the primary cesarean rate increased, the rate for repeat operations followed (Rosenstein, 2013).

To address this, a National Institutes of Health (NIH) Consensus Development Conference (1981) was convened, and it questioned the necessity of routine repeat cesarean delivery. With support and encouragement from the American College of Obstetricians and Gynecologists (1988, 1994), enthusiastic attempts were begun to increase the use of *vaginal birth after cesarean*—*VBAC*. These attempts were highly successful, and VBAC rates increased from 3.4 percent in 1980 to a peak of 28.3 percent in 1996. These rates, along with a concomitant decline in total cesarean delivery rates for the United States, are shown in Figure 31-1.
As the vaginal delivery rate increased, so did reports of uterine rupture-related maternal and perinatal morbidity and mortality (McMahon, 1996; Sachs, 1999). These dampened prevailing enthusiasm for a trial of labor and stimulated the American College of Obstetricians and Gynecologists (1998) to caution that such trials should be attempted only in appropriately equipped institutions with physicians readily available to provide emergency care. Less than a year later, the College (1999) recommended that physicians should be immediately available. Many believe that this one-word change—from readily to immediately available—was in large part responsible for the decade-long decline in national VBAC rates illustrated in Figure 31-1 (Cheng, 2014; Leeman, 2013). The VBAC rate leveled at approximately 8 percent by 2009 and 2010, while the total cesarean delivery rate increased to 32.8 percent in 2011 (Martin, 2011, 2012a,b). Because the success rate of a trial of labor resulting in a VBAC is not 100 percent another way of examining these changes was described by Uddin and colleagues (2013). These investigators reported the proportion of women with a prior cesarean delivery who underwent a trial of labor. This number peaked in 1997, when slightly more than half of all of these women chose a trial of labor. Thereafter, this percentage plummeted and reached a nadir of about 16 percent in 2005. Since that time, the proportion has increased and averaged 20 to 25 percent through 2009. Ironically, during this same decade, there were continuing reports that described the success and safety of VBAC in selected clinical settings.

In reality, there are several other interrelated factors—both medical and nonmedical—that have undoubtedly contributed to declining VBAC rates. Because of their complexity and importance, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) and the Office of Medical Applications of Research (OMAR) convened a National Institutes of Health Consensus Development Conference Panel (2010) to study these issues. The Panel report includes a contemporaneous summary concerning the risks and benefits of repeat cesarean versus vaginal delivery. These findings are subsequently described along with summaries of current recommendations by various professional organizations. However, data from California indicate that VBAC rates have not perceptibly increased since the 2010 NIH Consensus Conference that encouraged greater access to a trial of labor after cesarean delivery (Barger, 2013).

**FACTORS THAT INFLUENCE A TRIAL OF LABOR**

Delivery planning for the woman who has had a previous cesarean delivery can begin with preconceptional counseling, but should definitely be addressed early in prenatal care. Importantly, any decision arrived at is subject to continuing revisions as dictated by exigencies that arise during the course of pregnancy. Assuming no mitigating circumstances, there are two basic choices. First is a trial of labor after cesarean (TOLAC) with the goal of achieving VBAC. If cesarean delivery becomes necessary during the trial, then it is termed a “failed trial of labor.” A second choice is elective repeat cesarean delivery (ERCD). This includes scheduled cesarean delivery as well as unscheduled but planned cesarean delivery for spontaneous labor or another indication.

Selection should consider factors known to influence a successful trial of labor as well as
benefits and risks. In general, appropriately selected women who attempt VBAC have success rates that approximate 75 percent. These rates vary between institutions and providers and are affected by prepregnancy, antepartum, intrapartum, and nonmedical factors.

Some medical variables that influence a successful trial of labor are listed in Table 31-1. As for economical and medicolegal factors, professional liability concerns and insufficient resources to provide adequate staffing for hospitals to accommodate a trial of labor weigh heavily.

### TRIAL OF LABOR VERSUS REPEAT CESAREAN DELIVERY

As evidence mounted that the risk of uterine rupture and perinatal morbidity and mortality might be greater than expected, the American College of Obstetricians and Gynecologists (1988, 1998, 1999, 2013a) issued updated Practice Bulletins supporting labor trials but also urging a more cautious approach. It is problematic that both options have risks and benefits to mother and fetus but that these are not always congruent.

### Maternal Risks
Uterine rupture and its associated complications clearly are increased with a trial of labor. It is this increased risk that underpins most of the angst in attempting a trial of labor. Despite this, some have argued that these factors should weigh only minimally in the decision to attempt a trial because their absolute risk is low. One of the largest and most comprehensive studies designed to examine risks associated with vaginal birth in women with a prior cesarean delivery was conducted by the Maternal-Fetal Medicine Units (MFMU) Network (Landon, 2004). In this prospective study conducted at 19 academic medical centers, the outcomes of nearly 18,000 women who attempted a trial of labor were compared with those of more than 15,000 women who underwent elective repeat cesarean delivery. As shown in Table 31-2, although the risk of uterine rupture was higher among women undergoing a trial of labor, the absolute risk was small—only 7 per 1000. To the contrary, however, there were no uterine ruptures in the elective cesarean delivery group. Not surprisingly, rates of stillbirth and hypoxic ischemic encephalopathy were significantly greater in the trial of labor arm. Others have reported similar results (Chauhan, 2003; Mozurkewich, 2000). In one study of nearly 25,000 women with a prior cesarean delivery, perinatal death risk was 1.3 per 1000 among the 15,515 women who had a trial of labor (Smith, 2002). Although the absolute risk is small, it is 11 times greater than the risk found in 9014 women with a planned repeat cesarean delivery.

| Table 31-2. Complications in Women with a Prior Cesarean Delivery Enrolled in the NICHD Maternal-Fetal Medicine Units Network, 1999–2002 |
Most studies suggest that the maternal mortality rate does not differ significantly between women undergoing a trial of labor compared with those undergoing an elective repeat cesarean delivery (Landon, 2004; Mozurkewich, 2000). One outlier was a retrospective cohort study of more than 300,000 Canadian women with a prior cesarean delivery (Wen, 2005). In this study, the maternal death rate for women undergoing an elective repeat cesarean delivery was 5.6 per 100,000 compared with 1.6 per 100,000 for those having a trial of labor.

Estimates of maternal morbidity have also produced conflicting results. In the metaanalysis by Mozurkewich and Hutton (2000), women undergoing a trial of labor were approximately half as likely to require a blood transfusion or hysterectomy compared with those undergoing repeat cesarean delivery. Conversely, in the MFMU Network study, Landon and coworkers (2004) observed that the risks of transfusion and infection were significantly greater for women attempting a trial of labor (see Table 31-2). Rossi and D’Addario (2008) reported similar findings in their metaanalysis. McMahon and associates (1996), in a population-based study of 6138 women, found that major complications—hysterectomy, uterine rupture, or operative injury—were almost twice as common in women undergoing a trial of labor compared with those undergoing an elective cesarean delivery. Importantly, compared with a successful trial of labor, the risk of these major complications was fivefold greater in women whose attempted vaginal delivery failed.

*Denominator is 15,338 for the trial of labor group and 15,014 for the elective repeat cesarean delivery group.

CI = confidence interval; HIE = hypoxic ischemic encephalopathy; NA = not applicable; NICHD = National Institute of Child Health and Human Development; NS = not significant.

Adapted from Landon, 2004.
The metaanalysis cited above also reported an increased incidence of overall maternal complications when women with a failed vaginal delivery were compared with those undergoing successful vaginal delivery—17 versus 3 percent, respectively (Rossi, 2008). Similar findings have been reported from the Network Cesarean Registry (Babbar, 2013).

### Fetal and Neonatal Risks

The Panel found little or no evidence regarding short- and long-term neonatal outcomes after TOLAC versus ERCD. Most of the available evidence documents differences comparing actual rather than intended mode of delivery and is of low quality. A trial of labor is associated with significantly higher perinatal mortality rates compared with ERCD—perinatal mortality rate 0.12 versus 0.05 percent; neonatal mortality rate 0.11 versus 0.06 (Guise, 2010). A trial of labor also appears to be associated with a higher risk of hypoxic ischemic encephalopathy (HIE) than ERCD. The Maternal-Fetal Medicine Networks Unit study reported the incidence of HIE at term be 46 per 100,000 trials of labor compared with zero cases in women undergoing ERCD (Landon, 2004).

Analysis of pooled data suggests that the absolute risk of transient tachypnea of the newborn is slightly higher with ERCD compared with TOLAC—4.2 versus 3.6 percent (Guise, 2010). But neonatal bag and mask ventilation was used more often in infants delivered following TOLAC than in those delivered by ERCD—5.4 versus 2.5 percent. Finally, there are no significant differences in 5-minute Apgar scores or neonatal intensive care unit admissions for infants delivered by TOLAC compared with those delivered by ERCD. Birth trauma from lacerations is more commonly seen in infants born by ERCD.

### Maternal versus Fetal Risks

Relative risks for mother and baby differ between modes of delivery. Regarding overall risks, the Panel (2010) concluded that in a hypothetical group of 100,000 women of any gestational age who undergo TOLAC, there will be 4 maternal deaths, 468 cases of uterine rupture, and 133 perinatal deaths. In comparison, in a hypothetical group of 100,000 women of any gestational age who undergo ERCD, there will be 13 maternal deaths, 26 uterine ruptures, and 50 perinatal deaths.

Despite potential concerns of increased complications, an elective repeat cesarean delivery is considered by many women to be preferable to a trial of labor. Frequent reasons include the convenience of a scheduled delivery and the fear of a prolonged and potentially dangerous labor. In an earlier study, Abitbol and colleagues (1993) found that these preferences persisted despite extensive antepartum counseling.

### CANDIDATES FOR A TRIAL OF LABOR

There are few high-quality data available to guide selection of trial of labor candidates (Guise, 2004; Hashima, 2004). That said, having fewer complicating risk factors increases the likelihood of success (Gregory, 2008). Several algorithms and nomograms have been developed to aid prediction, but none has demonstrated reasonable prognostic value (Grobman, 2007b, 2008, 2009; Macones, 2006; Metz, 2013; Srinivas, 2007). Use of a predictive model for failed trial of labor, however, was found to be somewhat predictive of uterine rupture or dehiscence (Stanhope, 2013).
Despite these limitations for precision, several points are pertinent to the evaluation of these women and are described in the next sections. Current recommendations of the American College of Obstetricians and Gynecologists (2013a) are that most women with one previous cesarean delivery with a low-transverse hysterotomy are candidates, and if appropriate, they should be counseled regarding a trial of labor versus elective repeat cesarean delivery.

**Prior Uterine Incision**

**Prior Incision Type**

The type and number of prior cesarean deliveries are overriding factors in recommending a trial of labor. Women with one prior low-transverse hysterotomy have the lowest risk of symptomatic scar separation (Table 31-3). The highest risks are with prior vertical incisions extending into the fundus, such as the classical incision shown in Figure 31-2 (Society for Maternal Fetal Medicine, 2013). Importantly, in some women, the classical scar will rupture before the onset of labor, and this can happen several weeks before term. In a review of 157 women with a prior classical cesarean delivery, one woman had a complete uterine rupture before the onset of labor, whereas 9 percent had a uterine dehiscence (Chauhan, 2002).

Data from the American College of Obstetricians and Gynecologists, 2013a; Cahill, 2010b; Chauhan, 2002; Landon, 2006; Macones, 2005; Martin, 1997; Miller, 1994; Sciscione, 2008; Society for Maternal-Fetal Medicine, 2012; Tahseen, 2010.
The risk of uterine rupture in women with a prior vertical incision that did not extend into the fundus is unclear. Martin (1997) and Shipp (1999) and their coworkers reported that these low-vertical uterine incisions did not have an increased risk for rupture compared with low-transverse incisions. The American College of Obstetricians and Gynecologists (2013a) concluded that although there is limited evidence, women with a prior vertical incision in the lower uterine segment without fundal extension may be candidates for a trial of labor. This is in contrast to prior classical or T-shaped uterine incisions, which are considered by most as contraindications to labor.

Currently, there are few indications for a primary vertical incision (Osmundson, 2013). In those instances—for example, preterm breech fetus with an undeveloped lower segment—the "low vertical" incision almost invariably extends into the active segment. It is not known, however, how far upward the incision has to extend before risks become those of a true classical incision. It is helpful in the operative report to document its exact extent.

Prior preterm cesarean delivery may have an increased risk for rupture. Although the type of prior incision was not known, Sciscione and associates (2008) reported that women who had a
prior preterm cesarean delivery were twice as likely to suffer a uterine rupture compared with those with a prior term cesarean delivery. This may be in part explained by the increased likelihood with a preterm fetus of extension of the uterine incision into the contractile portion. Conversely, Harper and colleagues (2009) did not find a significantly increased rate of rupture during subsequent VBAC in women with a prior cesarean delivery performed at or before 34 weeks.

There are special considerations for women with uterine malformations who have undergone cesarean delivery. Earlier reports suggested that the uterine rupture risk in a subsequent pregnancy was increased compared with the risk in those with a prior low-transverse hysterotomy and normally formed uterus (Ravasia, 1999). But, in a study of 103 women with müllerian duct anomalies who had one prior cesarean delivery and who attempted a trial of labor, there were no cases of uterine rupture (Erez, 2007). Given the wide range of risk for uterine rupture associated with the various uterine incision types, it is not surprising that most fellows of the American College of Obstetricians and Gynecologists consider the type of prior incision to be the most important factor when considering a trial of labor (Coleman, 2005).

Prior Incision Closure
As discussed in Chapter 30 (p. 596), the low-transverse hysterotomy incision can be sutured in either one or two layers. Whether the risk of subsequent uterine rupture is affected by these is unclear. Chapman (1997) and Tucker (1993) and their associates found no relationship between a one- and two-layer closure and the risk of subsequent uterine rupture. And although Durnwald and Mercer (2003) also found no increased risk of rupture, they reported that uterine dehiscence was more common after single-layer closure. In contrast, Bujold and coworkers (2002) found that a single-layer closure was associated with nearly a fourfold increased risk of rupture compared with a double-layer closure. In response, Vidaeff and Lucas (2003) argued that experimental models have not demonstrated advantages of a double-layer closure and that the evidence is insufficient to routinely recommend a double-layer closure. At Parkland Hospital we routinely suture the low-segment incision with one running locking suture.

Number of Prior Cesarean Incisions
There are at least three studies that reported a doubling of the rupture rate—from approximately 0.6 to 1.85 percent—in women with two versus one prior transverse hysterotomy incision (Macones, 2005a; Miller, 1994; Tahseen, 2010). In contrast, analysis of the MFMU Network database by Landon and colleagues (2006) did not confirm this. Instead, they reported an insignificant difference in the uterine rupture rate in 975 women with multiple prior cesarean deliveries compared with 16,915 women with a single prior operation—0.9 versus 0.7 percent, respectively. As discussed subsequently, other serious maternal morbidity increases along with the number of prior cesarean deliveries (Marshall, 2011).

Imaging of Prior Incision
Sonographic measurement of a prior hysterotomy incision has been used to predict the likelihood of rupture with a trial of labor. Large defects in the hysterotomy scar in a nonpregnant uterus forecast a greater risk for rupture (Osser, 2011). Naji and associates (2013a,b) found that the residual myometrial thickness decreased as pregnancy progressed and that rupture correlates with a thinner scar. From their review, however, Jastrow and coworkers (2010) found no ideal thickness to be suitably predictive. The optimal safe threshold value for the lower uterine segment—smallest measurement from amnionic fluid to bladder—ranged from 2.0 to 3.5 mm. For the
myometrial layer—smallest measurement of the hypoechoic portion of the lower segment, it was 1.4 to 2.0 mm. With a lower segment < 2.0 mm, the risk of uterine rupture was increased 11-fold. With myometrial thickness < 1.4 mm, uterine rupture was increased fivefold. The measurements, however, are not predictive for an individual woman (Bergeron, 2009).

Prior Uterine Rupture

Women who have previously sustained a uterine rupture are at increased risk for recurrence during a subsequent attempted VBAC. As shown in Table 31-3, those with a previous low-segment rupture have a 2- to 6-percent recurrence risk, whereas prior upper segment uterine rupture confers a 9- to 32-percent risk (Reyes-Ceja, 1969; Ritchie, 1971). We believe that women with a prior uterine rupture or classical or T-shaped incision ideally should undergo repeat cesarean delivery when fetal pulmonary maturity is assured, and preferably before the onset of labor. They should also be counseled regarding the hazards of unattended labor and signs of possible uterine rupture.

Interdelivery Interval

Magnetic resonance imaging studies of myometrial healing suggest that complete uterine involution and restoration of anatomy may require at least 6 months (Dicle, 1997). To explore this further, Shipp and colleagues (2001) examined the relationship between interdelivery interval and uterine rupture in 2409 women who had one prior cesarean delivery. There were 29 women with a uterine rupture—1.4 percent. Interdelivery intervals of ≤ 18 months were associated with a threefold increased risk of symptomatic rupture during a subsequent trial of labor compared with intervals > 18 months. Similarly, Stamilio and coworkers (2007) noted a threefold increased risk of uterine rupture in women with an interpregnancy interval of < 6 months compared with one ≥ 6 months. But they also reported that interpregnancy intervals of 6 to 18 months did not significantly increase the risk.

Prior Vaginal Delivery

Prior vaginal delivery, either before or after a cesarean birth, significantly improves the prognosis for a subsequent vaginal delivery with either spontaneous or induced labor (Grinstead, 2004; Hendler, 2004; Mercer, 2008). Prior vaginal delivery also lowers the risk of subsequent uterine rupture and other morbidities (Cahill, 2006; Hochler, 2014; Zelop, 2000). Indeed, the most favorable prognostic factor is prior vaginal delivery.

Indication for Prior Cesarean Delivery

Considering all women who elect trial of labor, 60 to 80 percent will have a successful vaginal delivery (American College of Obstetricians and Gynecologists, 2013a). Women with a nonrecurring indication—for example, breech presentation—have the highest success rate of nearly 90 percent (Wing, 1999). Those with a prior cesarean delivery for fetal compromise have an approximately 80-percent success rate, and for those done for labor arrest, success rates approximate 60 percent (Bujold, 2001; Peaceman, 2006). Prior second-stage cesarean delivery can be associated with second-stage uterine rupture in a subsequent pregnancy (Jastrow, 2013).
Fetal Size
Most studies show that increasing fetal size is inversely related to successful trial of labor. The risk for uterine rupture is less robust. Zelop and associates (2001) compared the outcomes of almost 2750 women undergoing a trial of labor, and 1.1 percent had a uterine rupture. The rate increased—albeit not significantly—with increasing fetal weight. The rate was 1.0 percent for fetal weight < 4000 g, 1.6 percent for > 4000 g, and 2.4 percent for > 4250 g. Similarly, Elkousy and colleagues (2003) reported that the relative risk of rupture doubled if birthweight was > 4000 g. Conversely, Baron and coworkers (2013a) did not find increased uterine rupture with birthweights > 4000 g.

Fetal size at the opposite end of the spectrum may increase the chances of a successful VBAC. Specifically, women who attempt a trial of labor with a preterm fetus have higher successful VBAC rates and lower rupture rates (Durnwald, 2006; Quiñones, 2005).

Multifetal Gestation
Perhaps surprisingly, twin pregnancy does not appear to increase the uterine rupture risk with trial of labor. Ford and associates (2006) analyzed the outcomes of 1850 such women and reported a 45-percent successful vaginal delivery rate and a rupture rate of 0.9 percent. Similar studies by Cahill (2005) and Varner (2007) and their colleagues reported rupture rates of 0.7 to 1.1 percent and vaginal delivery rates of 75 to 85 percent. According to the American College of Obstetricians and Gynecologists (2013a), women with twins and a prior low-transverse hysterotomy who are otherwise candidates for vaginal delivery can safely undergo a trial of labor.

Maternal Obesity
Obesity decreases the success rate of trial of labor. Hibbard and coworkers (2006) reported the following vaginal delivery rates: 85 percent with a normal body mass index (BMI), 78 percent with a BMI between 25 and 30, 70 percent with a BMI between 30 and 40, and 61 percent with a BMI of 40 or greater. Similar findings were reported by Juhasz and associates (2005).

Fetal Death
Most women with a prior cesarean delivery and fetal death in the current pregnancy would prefer a VBAC. Although fetal concerns are obviated, available data suggest that maternal risks are increased. Nearly 46,000 women with a prior cesarean delivery in the Network database had a total of 209 fetal deaths (Ramirez, 2010). There were 76 percent who had a trial of labor with a success rate of 87 percent. Overall, the rupture rate was 2.4 percent. Four of five ruptures were during induction in 116 women with one prior transverse incision—3.4 percent.

LABOR AND DELIVERY CONSIDERATIONS
If elective repeat cesarean delivery is planned, it is essential that the fetus be mature. As shown in Figure 31-3, significant and appreciable adverse neonatal morbidity has been reported with elective delivery before 39 completed weeks (Chiossi, 2013; Clark, 2009; Tita, 2009). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists...
(2012) have established the following guidelines for timing an elective operation, and at least one of these three must be documented:

1. Ultrasound measurement < 20 weeks supports a gestational age of ≥ 39 weeks.
2. Fetal heart sounds have been documented for 30 weeks by Doppler ultrasound.
3. A positive serum or urine β-hCG test result has been documented for ≥ 36 weeks.

![Graph](image)

FIGURE 31-3 Neonatal morbidity and mortality rates seen with 13,258 elective repeat cesarean deliveries. Any adverse outcome includes death. Sepsis includes suspected and proven. RDS = respiratory distress syndrome; TTN = transient tachypnea of the newborn. (From Tita, 2009.)

Accurate gestational dating is suitable using any of the above criteria. Other options are to await spontaneous labor or to document fetal pulmonary maturation by amnionic-fluid analysis (Chap. 34, p. 655).

### Informed Consent

The risks and benefits of a trial of labor versus a repeat cesarean delivery should be thoroughly discussed, and the decision to attempt a trial of labor is made by the informed woman in conjunction with her health-care provider (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). As previously emphasized, no woman with a prior uterine incision should be forced to undergo a trial of labor.

### Intrapartum Care

Because of the risks of uterine rupture for women undergoing a trial of labor, the American Academy of Pediatricians and the American College of Obstetricians and Gynecologists (2012) recommend that such trials be undertaken only in facilities with staff immediately available to provide emergency care. Moreover, these centers should have a plan for managing uterine rupture.
Some argue that these provisions deny women full access to choices. For example in an earlier survey of Ohio hospitals, 15 percent of Level I, 63 percent of Level II, and 100 percent of Level II institutions met these requirements (Lavin, 2002). Moreover, an obstetrical anesthesia workforce survey reported that these rules were in place in 86 percent of hospitals with ≥ 1500 annual deliveries, in 45 percent of those with 500 to 1499 deliveries, and in 33 percent of those with < 500 deliveries.

### Cervical Ripening and Labor Stimulation

As discussed, labor induction is associated with a higher failure rate for a trial of labor. The risks for uterine rupture, however, are less clear with induction or augmentation, with the exception of prostaglandin E\(_1\)—misoprostol—which is contraindicated (American College of Obstetricians and Gynecologists, 2013a; Ophir, 2012). While most institutions are not so conservative, we do not induce or augment labor pharmaceutically in these women at Parkland Hospital. Instead, we attempt induction by amniotomy. Other considerations are to avoid induction or augmentation in women with an unknown prior incision type, an unfavorable cervix, or pregnancy > 40 weeks.

#### Oxytocin

Induction or augmentation of labor with oxytocin has been implicated in increased rates of uterine rupture in some studies (Zelop, 1999). In the Network study reported by Landon and colleagues (2004), uterine rupture was more frequent in women induced—1.1 percent—than in those in spontaneous labor—0.4 percent. Among women in this trial who had never had a prior vaginal delivery, the uterine rupture risk associated with an oxytocin induction was 1.8 percent—a fourfold increased risk compared with spontaneous labor (Grobman, 2007a). In contrast, in one case-control study, induction was not associated with a higher risk for rupture (Harper, 2012a). In an observational study, the success rate of induction was 67 percent (Shatz, 2012).

Cahill and coworkers (2008) reported a dose-related risk of rupture with oxytocin. At an infusion dose of 21 to 30 mU/min, the uterine rupture risk was fourfold greater than that in women not given oxytocin. Goetzl and associates (2001) described similar findings. They concluded, however, that differences in the dose or patterns of oxytocin use associated with uterine rupture were not substantive enough to require development of different induction protocols.

#### Prostaglandins

Various prostaglandin preparations that are commonly employed for cervical ripening or labor induction are discussed in Chapter 26 (p. 526). Safety with their use in women with a prior cesarean delivery is not clear because of conflicting data. For example, Wing and colleagues (1998) described a comparative study of PGE\(_1\)—misoprostol—versus oxytocin for labor induction in women with a prior cesarean delivery. They terminated their trial after two of the first 17 women assigned to misoprostol developed a uterine rupture. Other studies confirmed this, and most consider misoprostol to be contraindicated (American College of Obstetricians and Gynecologists, 2013a).

Studies to evaluate other prostaglandins for induction have mixed results. Ravasia and coworkers (2000) compared uterine rupture in 172 women given PGE\(_2\) gel with 1544 women in spontaneous labor. The rupture rate was significantly greater in women treated with PGE\(_2\) gel—2.9 percent—compared with 0.9 percent in those with spontaneous labor. Lydon-Rochelle and associates (2001) also reported that induction with prostaglandins for a trial of labor increased the...
uterine rupture risk.

Not all studies report an increased risk of uterine rupture with prostaglandins. In the Network study cited previously, there was a uterine rupture rate of 1.4 percent when any prostaglandin was used in combination with oxytocin (Landon, 2004). But in the subgroup of 227 women in whom labor was induced with a prostaglandin only, there were no ruptures. Similar findings were reported in that intravaginal prostaglandins were not found to be associated with an increased uterine rupture risk (Macones, 2005b). These latter investigators, along with Kayani and colleagues (2005), found that sequential use of a prostaglandin followed by oxytocin was associated with a threefold-increased risk of rupture compared with spontaneous labor.

After reviewing these more contemporaneous reports, the American College of Obstetricians and Gynecologists (2013a) concluded that labor induction for some women who attempt a trial of labor is a reasonable option. The College also concluded that it is reasonable to (1) avoid misoprostol, (2) select women most likely to have a successful trial of labor, and (3) avoid sequential use of prostaglandins and oxytocin.

### Epidural Analgesia

Concerns that epidural analgesia for labor might mask the pain of uterine rupture have not been verified. Fewer than 10 percent of women with scar separation experience pain and bleeding, and fetal heart rate decelerations are the most likely sign of rupture (Kieser, 2002). That said, Cahill and coworkers (2010a) documented that more frequent episodes of epidural dosing were associated with increasing uterine rupture rates. Successful VBAC rates are similar, and in some cases higher, among women with labor epidural analgesia compared with those using other forms of analgesia (Landon, 2005). Perhaps related, almost a fourth of successful VBAC deliveries were completed with either forceps or vacuum (Inbar, 2013). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) have concluded that epidural analgesia may safely be used during a trial of labor.

### Uterine Scar Exploration

Some clinicians routinely document the integrity of a prior scar by placing a hand through the dilated cervix and along the inner surface of the lower uterine segment following successful vaginal delivery. However, routine uterine exploration is considered by others to be unnecessary. Currently, the benefits of scar evaluation in the asymptomatic woman are unclear. There is general agreement, however, that surgical correction of a scar dehiscence is necessary only if significant bleeding is encountered. Our practice is to routinely examine these prior incision sites. Any decision for laparotomy and repair takes into consideration the extent of the tear, whether the peritoneal cavity has been entered, and the presence of active bleeding.

### External Cephalic Version

External cephalic version for breech presentation is acceptable in women with a prior cesarean delivery who are contemplating a trial of labor (American College of Obstetricians and Gynecologists, 2013a). This procedure is addressed in Chapter 28 (p. 570).
Classification

Uterine rupture typically is classified as either (1) complete when all layers of the uterine wall are separated, or (2) incomplete when the uterine muscle is separated but the visceral peritoneum is intact. Incomplete rupture is also commonly referred to as uterine dehiscence. As expected, morbidity and mortality rates are appreciably greater when rupture is complete. The greatest risk factor for either form of rupture is prior cesarean delivery. In a review of all uterine rupture cases in Nova Scotia between 1988 and 1997, Kieser and Baskett (2002) reported that 92 percent were in women with a prior cesarean birth. Holmgren and associates (2012) described 42 cases of rupture in women with a prior hysterotomy. Of these, 36 were in labor at the time of rupture.

Diagnosis

Progress of labor in women attempting VBAC is similar to regular labor, and there is no specific pattern that presages uterine rupture (Graseck, 2012; Harper, 2012b). Before hypovolemic shock develops, symptoms and physical findings in women with uterine rupture may appear bizarre unless the possibility is kept in mind. For example, hemoperitoneum from a ruptured uterus may result in diaphragmatic irritation with pain referred to the chest—directing one to a diagnosis of pulmonary or amnionic fluid embolism instead of uterine rupture. The most common sign of uterine rupture is a nonreassuring fetal heart rate pattern with variable heart rate decelerations that may evolve into late decelerations and bradycardia as shown in Figure 31-4 (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). In 36 cases of such rupture during a trial of labor, there were fetal signs in 24, maternal in eight, and both in three (Holmgren, 2012). Few women experience cessation of contractions following uterine rupture, and the use of intrauterine pressure catheters has not been shown to assist reliably in the diagnosis (Rodriguez, 1989).

FIGURE 31-4 Fetal heart rate tracing in a woman whose uterus ruptured during labor while pushing. The rupture apparently stimulated a reflex push, after which uterine tone diminished and
fetal bradycardia worsened.

In some women, the appearance of uterine rupture is identical to that of placental abruption. In most, however, there is remarkably little appreciable pain or tenderness. Also, because most women in labor are treated for discomfort with either narcotics or epidural analgesia, pain and tenderness may not be readily apparent. The condition usually becomes evident because of fetal distress signs and occasionally because of maternal hypovolemia from concealed hemorrhage.

If the fetal presenting part has entered the pelvis with labor, loss of station may be detected by pelvic examination. If the fetus is partly or totally extruded from the uterine rupture site, abdominal palpation or vaginal examination may be helpful to identify the presenting part, which will have moved away from the pelvic inlet. A firm contracted uterus may at times be felt alongside the fetus.

### Decision-to-Delivery Time

With rupture and expulsion of the fetus into the peritoneal cavity, the chances for intact fetal survival are dismal, and reported mortality rates range from 50 to 75 percent. *Fetal condition depends on the degree to which the placental implantation remains intact, although this can change within minutes.* With rupture, the only chance of fetal survival is afforded by immediate delivery—most often by laparotomy—otherwise, hypoxia is inevitable. If rupture is followed by immediate total placental separation, then very few intact fetuses will be salvaged. *Thus, even in the best of circumstances, fetal salvage will be impaired.* The Utah experiences are instructive here (Holmgren, 2012). Of the 35 laboring patients with a uterine rupture, the decision-to-delivery time was < 18 minutes in 17, and none of these infants had an adverse neurological outcome. Of the 18 born > 18 minutes from decision time, the three infants with long-term neurological impairments were delivered at 31, 40, and 42 minutes. There were no deaths, thus severe neonatal neurological morbidity developed in 8 percent of these 35 women with uterine rupture.

In a study using the Swedish Birth Registry, Kaczmarczyk and colleagues (2007) found that the risk of neonatal death following uterine rupture was 5 percent—a 60-fold increase in risk compared with pregnancies not complicated by uterine rupture. In the Network study, seven of the 114 uterine ruptures—6 percent—associated with a trial of labor were complicated by the development of neonatal hypoxic ischemic encephalopathy (Spong, 2007).

Maternal deaths from rupture are uncommon. For example, of 2.5 million women who gave birth in Canada between 1991 and 2001, there were 1898 cases of uterine rupture, and four of these—0.2 percent—resulted in maternal death (Wen, 2005). In other regions of the world, however, maternal mortality rates associated with uterine rupture are much higher. In a report from rural India, for example, the maternal mortality rate associated with uterine rupture was 30 percent (Chatterjee, 2007).

### Hysterectomy versus Repair

With complete rupture during a trial of labor, hysterectomy may be required. In the reports by McMahon (1996) and Miller (1997) and their coworkers, 10 to 20 percent of such women required hysterectomy for hemostasis. In selected cases, however, suture repair with uterine preservation may be performed. Sheth (1968) described outcomes from a series of 66 women in whom repair of a uterine rupture was elected rather than hysterectomy. In 25 instances, the repair was accompanied by tubal sterilization. Thirteen of the 41 mothers who did not have tubal sterilization had a total of 21 subsequent pregnancies. Uterine rupture recurred in four of these—
approximately 25 percent. Usta and associates (2007) identified 37 women with a prior complete uterine rupture delivered during a 25-year period in Lebanon. Hysterectomy was performed in 11, and in the remaining 26 women, the rupture was repaired. Twelve of these women had 24 subsequent pregnancies, one third of which were complicated by recurrent uterine rupture. In another study, however, women with a uterine dehiscence were not more likely to have uterine rupture with a subsequent pregnancy (Baron, 2013b).

**COMPLICATIONS WITH MULTIPLE REPEAT CESAREAN DELIVERIES**

Because of the concerns with attempting a trial of labor—even in the woman with excellent criteria that forecast successful VBAC—most women in the United States undergo elective repeat cesarean delivery. This choice is not without several significant maternal complications, and rates of these increase in women who have multiple repeat operations. The incidences of some common complications for women with one prior transverse cesarean delivery who undergo an elective repeat cesarean delivery were shown in Table 31-2. Finally, half of cesarean hysterectomies done at Parkland Hospital are in women with one or more prior cesarean deliveries (Hernandez, 2013).

The Network addressed issues of increased morbidity in a cohort of 30,132 women who had from one to six repeat cesarean deliveries (Silver, 2006). This report addressed a list of morbidities, most of which increased as a trend with increasing number of repeat operations. The rates of some of the more common or serious complications are depicted in Figure 31-5. In addition to the ones shown, rates of bowel or bladder injury, admission to an intensive care unit or ventilator therapy, and maternal mortality, as well as operative and hospitalization length, showed significantly increasing trends. Similar results have been reported by others (Nisenblat, 2006; Usta, 2005). More difficult to quantify are risks for bowel obstructions and pelvic pain from peritoneal adhesive disease, both of which increase with each successive cesarean delivery (Andolf, 2010; Mankuta, 2013).
Cook and colleagues (2013) from the United Kingdom Obstetric Surveillance System (UKOSS) described adverse sequelae of women with multiple cesarean deliveries. Outcomes of those undergoing a fifth or greater operation were compared with those from women having a second through fourth procedure. Those having five or more cesarean deliveries had significantly increased rates of morbidity compared with rates in women having fewer than five procedures. Specifically, the major hemorrhage rate increased 18-fold; visceral damage, 17-fold; critical care admissions, 15-fold; and delivery < 37 weeks, sixfold. Much of this morbidity was in the 18 percent who had placenta previa or accrete syndromes (Chap. 41, p. 799). A percreta may invade the bladder or other adjacent structures. With this, difficult resection carries an inordinately high risk of hysterectomy, massive hemorrhage with transfusion, and maternal mortality.
The “best answer” for a given woman with a prior cesarean delivery is unknown. We agree with Scott (2011) regarding a “common-sense” approach. Thus, the woman—and her partner if she wishes—are encouraged to actively participate with her health-care provider in the final decision after appropriate counseling. For women who wish TOLAC despite a factor that increases their specific risk, additions to the consent form are recommended (American College of Obstetricians and Gynecologists, 2013a). Bonanno and colleagues (2011) have provided such an example.

Brief synopses of professional society guidelines are shown in Table 31-4. Guidelines that tend to be more conservative are shown in Table 31-5.

CD = cesarean delivery; VBAC = vaginal birth after cesarean.

### TABLE 31-5. Conservative Guidelines to Approach a Trial of Labor Following Cesarean Delivery

**Follow ACOG practice guidelines**

**Education and counseling**

- Preconceptionally
  - Provide ACOG patient pamphlet
- Early during prenatal care
Develop preliminary plan
Revisit at least each trimester
Be willing to alter decision
Have facilities availability

**Risk assessment**
Review previous operative note(s)
Review relative and absolute contraindications
Reconsider risks as pregnancy progresses
Tread carefully: > 1 prior transverse CD, unknown incision, twins, macrosomia

**Labor and delivery**
Cautions for induction—unfavorable cervix, high station
  
  Consider AROM
  
  Avoid prostaglandins
  
  Respect oxytocin—know when to quit
Beware of abnormal labor progress
Respect EFM pattern abnormalities
Know when to abandon a trial of labor

ACOG = American College of Obstetricians and Gynecologists; AROM = artificial rupture of membranes; CD = cesarean delivery; EFM = electronic fetal monitoring.

SECTION 9
THE NEWBORN
CHAPTER 32

The Newborn

INITIATION OF AIR BREATHING

CARE IN THE DELIVERY ROOM

EVALUATION OF NEWBORN CONDITION

PREVENTIVE CARE

ROUTINE NEWBORN CARE

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend attendance at delivery of at least one person whose primary responsibility is the neonate and who is capable of initiating resuscitation that includes intubation, vascular access, and medication administration. This usually is a pediatrician, nurse practitioner, anesthesiologist, nurse anesthetist, or specially trained nurse. However, in their absence, the responsibility for neonatal resuscitation falls to the obstetrical attendant. Thus, obstetricians should be well versed in measures for immediate care of the newborn.

INITIATION OF AIR BREATHING

Immediately following birth, the infant must promptly convert to air breathing as the fluid-filled alveoli expand with air and pulmonary perfusion is established. The newborn begins to breathe and cry almost immediately after birth, which indicates establishment of active respiration. Some factors that appear to influence the first breath include:

- Physical stimulation—examples include handling the neonate during delivery.
- Oxygen deprivation and carbon dioxide accumulation—these serve to increase the frequency and magnitude of breathing movements both before and after birth (Dawes, 1974).
- Thoracic compression—this occurs during pelvic descent, following which vaginal birth forces fluid from the respiratory tract in volume equivalent to approximately a fourth of the ultimate functional residual capacity (Saunders, 1978).
- Aeration of the newborn lung does not involve the inflation of a collapsed structure, but instead, the rapid replacement of bronchial and alveolar fluid by air. After delivery, the residual alveolar
fluid is cleared through the pulmonary circulation and to a lesser degree, through the pulmonary lymphatics (Chernick, 1978). Delay in fluid removal from the alveoli probably contributes to the syndrome of transient tachyypnea of the newborn (TTN) (Guglani, 2008). As fluid is replaced by air, compression of the pulmonary vasculature is reduced considerably, and in turn, resistance to blood flow is lowered. With the fall in pulmonary arterial blood pressure, the ductus arteriosus normally closes (Fig. 7-8, p. 136).

High negative intrathoracic pressures are required to bring about the initial entry of air into the fluid-filled alveoli. Normally, from the first breath after birth, progressively more residual air accumulates in the lung, and with each successive breath, lower pulmonary opening pressure is required. In the normal mature newborn, by approximately the fifth breath, pressure-volume changes achieved with each respiration are very similar to those of the adult. Thus, the breathing pattern shifts from the shallow episodic inspirations characteristic of the fetus to regular, deeper inhalations (Chap. 17, p. 337). Surfactant, which is synthesized by type II pneumocytes and already present in the alveoli, lowers alveolar surface tension and thereby prevents lung collapse. Insufficient surfactant, common in preterm infants, leads promptly to respiratory distress syndrome, which is described in Chapter 34 (p. 653).

**CARE IN THE DELIVERY ROOM**

Personnel designated for infant support are responsible for immediate care and for acute resuscitation initiation if needed.

**Immediate Care**

Before and during delivery, careful consideration must be given to several determinants of neonatal well-being including: (1) maternal health status; (2) prenatal complications, including any suspected fetal malformations; (3) gestational age; (4) labor complications; (5) duration of labor and ruptured membranes; (6) type and duration of anesthesia; (7) difficulty with delivery; and (8) medications given during labor and their dosages, administration routes, and timing relative to delivery.

**Newborn Resuscitation**

The International Liaison Committee on Resuscitation (ILCOR) updated its guidelines for neonatal resuscitation that are sanctioned by the American Academy of Pediatrics and the American Heart Association (Biban, 2011; Perlman, 2010). These substantially revised guidelines are incorporated into the following sections.

Approximately 10 percent of newborns require some degree of active resuscitation to stimulate breathing, and 1 percent require extensive resuscitation. It is perhaps not coincidental that there is a two- to threefold risk of death for newborns delivered at home compared with those delivered in hospitals (American College of Obstetricians and Gynecologists, 2013b). When deprived of oxygen, either before or after birth, neonates demonstrate a well-defined sequence of events leading to apnea (Fig. 32-1). With oxygen deprivation, there is a transient period of rapid breathing, and if it persists, breathing stops, which is termed *primary apnea*. This stage is accompanied by a fall in heart rate and loss of neuromuscular tone. Simple stimulation and
Exposure to oxygen will usually reverse primary apnea. If oxygen deprivation and asphyxia persist, however, the newborn will develop deep gasping respirations, followed by secondary apnea. This latter stage is associated with a further decline in heart rate, falling blood pressure, and loss of neuromuscular tone. Neonates in secondary apnea will not respond to stimulation and will not spontaneously resume respiratory efforts. Unless ventilation is assisted, death follows. Clinically, primary and secondary apneas are indistinguishable. Thus, secondary apnea must be assumed and resuscitation of the apneic newborn must be started immediately.

**FIGURE 32-1** Physiological changes associated with primary and secondary apnea in the newborn. bpm = beats per minute; HR = heart rate; MAP = mean arterial pressure. (Adapted from Kattwinkel, 2006.)

---

**Resuscitation Protocol**

The updated algorithm for newborn resuscitation recommended by ILCOR and the International Consensus on Cardiopulmonary Resuscitation is shown in Figure 32-2. Many of its tenets follow below.
Basic Measures

The vigorous newborn is first placed in a warm environment to minimize heat loss, the airway is cleared, and the infant dried. Routine gastric aspiration has been shown to be nonbeneficial and even harmful (Kiremitci, 2011). And although previously recommended, there is no evidence that bulb suctioning for clear or meconium-stained fluid is beneficial, even if the newborn is depressed (Chap. 33, p. 638). With stimulation, the healthy newborn will take a breath within a few seconds of birth and cry within half a minute, after which routine supportive care is provided.

Assessment at 30 Seconds of Life. Apnea, gasping respirations, or heart rate < 100 bpm beyond 30 seconds after delivery should prompt administration of positive-pressure ventilation with room air (Fig. 32-3). Assisted ventilation rates of 30 to 60 breaths per minute are commonly employed, and the percent of oxygen saturation is monitored by pulse oximetry. At this point, supplemental oxygen can be given in graduated increasing percentages to maintain oxygen saturation ($Sp_{O2}$) values within a normal range (Vento, 2011). Adequate ventilation is indicated by improved heart rate.

Assessment at 60 Seconds of Life. If the heart rate remains < 100 bpm, then ventilation is inadequate. The head position should be checked as shown in Figure 32-3, secretions cleared, and if necessary, inflation pressure increased. If the heart rate persists below 100 bpm beyond 60 seconds, tracheal intubation is considered. A number of conditions may be the cause of inadequate response, including the following:
Tracheal Intubation

If bag-and-mask ventilation is ineffective or prolonged, tracheal intubation is then performed. Other indications include the need for chest compressions or tracheal administration of medications, or special circumstances such as extremely low birthweight or a congenital diaphragmatic hernia. A laryngoscope with a straight blade—size 0 for a preterm infant and size 1 for a term neonate—is introduced at the side of the mouth and then directed posteriorly toward the oropharynx as shown in Figure 32-4. The laryngoscope is next moved gently into the vallecula—the space between the base of the tongue and the epiglottis. Gentle elevation of the laryngoscope tip will raise the epiglottis and expose the glottis and the vocal cords. The tube is then introduced through the vocal cords. Gentle cricoid pressure may be useful. Tube sizes vary from 3.5 to 4.0 mm for term infants down to 2.5 mm for those < 28 weeks or < 1000 g.

FIGURE 32-4 Sagittal view of laryngoscope positioning during intubation. The laryngoscope
blade is inserted between the tongue base and epiglottis. Upward tilting of the tongue also lifts the epiglottis. The endotracheal tube is then threaded below the epiglottis and between the vocal cords (inset) to enter the trachea.

Several steps are taken to ensure that the tube is positioned in the trachea and not the esophagus: observation for symmetrical chest wall motion; auscultation for equal breath sounds, especially in the axillae; and auscultation for the absence of breath sounds or gurgling over the stomach. Tracheal suctioning is no longer recommended or discouraged. Using an appropriate ventilation bag attached to the tracheal tube, puffs of air are delivered into the tube at 1- to 2-second intervals with a force adequate to gently lift the chest wall. In term infants, pressures of 30 to 40 cm H₂O typically will expand the alveoli without causing barotrauma. For preterm infants, pressures are 20 to 25 cm H₂O. An increase in heart rate and SpO₂ levels within acceptable ranges reflect a positive response.

Chest Compressions
If the heart rate remains < 60 bpm despite adequate ventilation for 30 seconds, chest compressions are initiated. These are delivered on the lower third of the sternum at a depth sufficient to generate a palpable pulse. A 3:1 compressions-to-ventilation ratio is recommended, with 90 compressions and 30 breaths to achieve approximately 120 events each minute. The heart rate is reassessed every 30 seconds, and chest compressions are continued until the spontaneous heart rate is at least 60 bpm.

Epinephrine and Volume Expansion
Intravenously administered epinephrine is indicated when the heart rate remains < 60 bpm after adequate ventilation and chest compressions. Epinephrine may be given through the endotracheal tube if venous access has not been established. The recommended intravenous dose is 0.01 to 0.03 mg/kg. If given through the tracheal tube, higher doses are employed—0.05 to 0.1 mg/kg.

For infants with blood loss, early volume replacement with crystalloid or packed red cells is indicated if they do not respond to resuscitation.

Discontinuation of Resuscitation
As expected, newborns with cardiopulmonary arrest who do not respond promptly to resuscitation are at great risk for death, and if they survive, for severe morbidity (Haddad, 2000). The International Consensus Committee concluded that discontinuation of resuscitative efforts may be appropriate in a neonate without a heartbeat for 10 minutes of continuous and adequate resuscitative efforts (Perlman, 2010). This committee cites lack of data for more specific recommendations regarding the infant whose heart rate remains < 60 bpm.

EVALUATION OF NEWBORN CONDITION

Apgar Score
The scoring system described in 1953 by Dr. Virginia Apgar remains a useful clinical tool to identify those neonates who require resuscitation and to assess the effectiveness of any resuscitative measures. As shown in Table 32-1, each of the five easily identifiable characteristics
—heart rate, respiratory effort, muscle tone, reflex irritability, and color—is assessed and assigned a value of 0 to 2. The total score, based on the sum of the five components, is determined in all neonates at 1 and 5 minutes after delivery. In depressed infants, the score may be calculated at further 5-minute intervals until a 20-minute Apgar score is assessed.

bpm = beats per minute.

Data from Apgar, 1953.

The 1-minute Apgar score reflects the need for immediate resuscitation. The 5-minute score, and particularly the change in score between 1 and 5 minutes, is a useful index of the effectiveness of resuscitative efforts. The 5-minute Apgar score also has prognostic significance for neonatal survival because survival is related closely to the condition of the neonate in the delivery room (Apgar, 1958). In an analysis of more than 150,000 infants delivered at Parkland Hospital, Casey and associates (2001b) assessed the significance of the 5-minute score for predicting survival during the first 28 days of life. They found that in term neonates, the risk of neonatal death was approximately 1 in 5000 for those with Apgar scores of 7 to 10. This risk compares with a mortality rate of 1 in 4 for term infants with 5-minute scores of 3 or less. Low 5-minute scores were comparably predictive of neonatal death in preterm infants. These investigators concluded that the Apgar scoring system is as relevant for the prediction of neonatal survival today as it was more than 50 years ago.

There have been attempts to use Apgar scores to define asphyxial injury and to predict subsequent neurological outcome—uses for which the Apgar score was never intended. Such associations are difficult to measure with reliability given that both asphyxial injury and low Apgar scores are infrequent outcomes. For example, according to United States birth certificate records for 2010, only 1.8 percent of newborns had a 5-minute score below 7 (Martin, 2012). Similarly, in a population-based study of more than 1 million term infants born in Sweden between 1988 and 1997, the incidence of 5-minute Apgar scores of 3 or less was approximately 2 per 1000 (Thorngren-Jerneck, 2001).

Despite the methodological challenges, erroneous definitions of asphyxia by many groups were established based solely on low Apgar scores. These prompted the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2010) to issue a series of joint opinions with important caveats regarding limitations of use of the Apgar score. One is that because certain elements of the Apgar score are partially dependent on the physiological maturity of the newborn, a healthy preterm infant may receive a low score only because of immaturity (Catlin, 1986). Apgar scores may be influenced by a variety of factors including, but not limited to, fetal malformations, maternal medications, and infection. Therefore, it is inappropriate to use an
Apgar score alone to diagnose asphyxia. A 5-minute Apgar score of 3 correlates poorly with adverse future neurological outcomes, and thus scores are measured also at 10, 15, and 20 minutes when the score remains 3 or less (Freeman, 1988; Nelson, 1981).

Importantly, the Apgar score alone cannot establish hypoxia as the cause of cerebral palsy. As discussed in Chapter 33 (p. 638), a neonate who has had an asphyxial insult proximate to delivery that is severe enough to result in acute neurological injury will demonstrate most of the following: (1) profound acidemia with cord artery blood pH < 7 and acid-base deficit ≥ 12 mmol/L; (2) Apgar score of 0–3 persisting for 10 minutes or longer; (3) neurological manifestations such as seizures, coma, or hypotonia; and (4) multisystem organ dysfunction—cardiovascular, gastrointestinal, hematological, pulmonary, or renal (American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, 2003).

**Umbilical Cord blood Acid–Base Studies**

Blood taken from umbilical vessels may be used for acid-base studies to assess the metabolic status of the neonate. Blood collection is performed following delivery by immediately isolating a 10- to 20-cm segment of cord with two clamps placed near the neonate and another two clamps nearer the placenta. The importance of clamping the cord is underscored by the fact that delays of 20 to 30 seconds can alter both the \( \text{PcO}_2 \) and pH (Valero, 2012; White, 2012). The cord is then cut between the two proximal clamps and then the two distal clamps.

Arterial blood is drawn from the isolated cord segment into a 1- to 2-mL commercially prepared plastic syringe containing lyophilized heparin or a similar syringe that has been flushed with a heparin solution containing 1000 U/mL. Once sampling is completed, the needle is cappeć and the syringe transported, on ice, to the laboratory. Although efforts should be made for prompt transport, neither the pH nor \( \text{PcO}_2 \) values change significantly in blood kept at room temperature for up to 60 minutes (Duerbeck, 1992). Mathematical models have been developed that allow reasonable prediction of birth acid–base status in properly collected cord blood samples analyzed as late as 60 hours after delivery (Chauhan, 1994). Also, Swedish investigators reported significant variances in acid-base measurements with the use of different analyzers (Mokarami, 2012).

**Fetal Acid-Base Physiology**

The fetus produces both carbonic and organic acids. Carbonic acid (\( \text{H}_2\text{CO}_3 \)) is formed by oxidative metabolism of \( \text{CO}_2 \). The fetus usually rapidly clears \( \text{CO}_2 \) through the placental circulation. If \( \text{CO}_2 \) clearance is lowered, then carbonic acid levels rise. When \( \text{H}_2\text{CO}_3 \) accumulates in fetal blood and there is no concurrent increase in organic acids, the result is termed respiratory acidemia. This often follows impaired placental exchange.

In contrast, organic acids primarily include lactic and \( \beta \)-hydroxybutyric acids. Levels of these increase with persistent placental exchange impairment and result from anaerobic glycolysis. These organic acids are cleared slowly from fetal blood, and when they accumulate without a concurrent increase in \( \text{H}_2\text{CO}_3 \), the result is termed metabolic acidemia. With the development of metabolic acidemia, bicarbonate (\( \text{HCO}_3^- \)) decreases because it is used to buffer the organic acid. An increase in \( \text{H}_2\text{CO}_3 \) accompanied by an increase in organic acid reflected by decreased \( \text{HCO}_3^- \) causes mixed respiratory-metabolic acidemia.
In the fetus, respiratory and metabolic acidemia and ultimately tissue acidosis are most likely part of a progressively worsening continuum. This is different from the adult pathophysiology, in which distinct conditions result in either respiratory acidosis—for example, pulmonary disease, or metabolic acidosis—for example, diabetes. In the fetus, the placenta serves as both the lungs and to a certain degree, the kidneys. One principal cause of fetal acidemia is a decrease in uteroplacental perfusion. This results in the retention of CO$_2$, that is, respiratory acidemia, and if protracted and severe enough, a mixed or metabolic acidemia.

Assuming that maternal pH and blood gases are normal, the actual pH of fetal blood is dependent on the proportion of carbonic and organic acids and the amount of bicarbonate, which is the major buffer in blood. This can best be illustrated by the Henderson–Hasselbalch equation:

$$\text{pH} = \text{pK} + \log \frac{[\text{base}]}{[\text{acid}]}$$

For clinical purposes, HCO$_3^-$ represents the metabolic component and is reported in mEq/L. The H$_2$CO$_3$ concentration represents the respiratory component and is reported as the P$_{CO_2}$ in mm Hg. Thus:

$$\text{pH} = \text{pK} + \log \frac{\text{HCO}_3^- \text{ mEq/L}}{\text{P}_{CO_2} \text{ mm Hg}}$$

The result of this equation is a pH value. Because pH is a logarithmic term, it does not give a linear measure of acid accumulation. For example, a change in hydrogen ion concentration associated with a fall in pH from 7.0 to 6.9 is almost twice that which is associated with a fall in pH from 7.3 to 7.2. For this reason, the change in base, termed delta base, offers a more linear measure of the degree of accumulation of metabolic acid (Armstrong, 2007). The delta base is a calculated number used as a measure of the change in buffering capacity of bicarbonate (HCO$_3^-$). The formula for calculating the base excess (BE) is as follows:

$$\text{BE} = 0.02786 \times \text{P}_{CO_2} \times 10^{(\text{pH} - 6.1)} \times 13.77 \times \text{pH} - 124.58$$

Shown in Figure 32-5 is a nomogram developed from which these can be calculated if only two parameters are known. For example, HCO$_3^-$ concentration will be decreased with a metabolic acidemia as it is consumed to maintain a normal pH. A base deficit occurs when HCO$_3^-$ concentration decreases to below normal levels, and a base excess occurs when HCO$_3^-$ values are above normal. Importantly, a mixed respiratory–metabolic acidemia with a large base deficit and a low HCO$_3^-$, for example 12 mmol/L, is more often associated with a depressed neonate than is a mixed acidemia with a minimal base deficit and a more nearly normal HCO$_3^-$ level.
Clinical Significance of Acidemia

Fetal oxygenation and pH generally decline during the course of normal labor. Normal umbilical cord blood pH and blood gas values at delivery in term newborns are summarized in Table 32-2.

FIGURE 32-5 Nomogram for determining the delta base. (Adapted from Siggaard-Andersen, 1963).
Similar values have been reported for preterm infants (Dickinson, 1992; Ramin, 1989; Riley, 1993). The lower limits of normal pH in the newborn have been found to range from 7.04 to 7.10 (Boylan, 1994). Thus, these values should be considered to define neonatal acidemia. Even so, most fetuses will tolerate intrapartum acidemia with a pH as low as 7.00 without incurring neurological impairment (Freeman, 1988; Gilstrap, 1989). However, in a study of newborns with a pH < 7.0 from Parkland Hospital, there were inordinate proportions of neonatal deaths—8 percent, intensive-care admission—39 percent, intubations—14 percent, and seizures—13 percent (Goldaber, 1991). And in a study from Oxford of more than 51,000 term infants, the incidence of neonatal encephalopathy with the pH < 7.0 was 3 percent (Yeh, 2012).

<sup>d</sup>Data shown as range with 2.5 or 97.5 percentile.
<sup>e</sup>Cesarean delivery—labor not stated.

Another important prognostic consideration is the direction of pH change from birth to the immediate neonatal period. For example, the risk of seizures during the first 24 hours of life was reduced fivefold if an umbilical artery cord pH below 7.2 normalized within 2 hours after delivery (Casey, 2001a).

### Respiratory Acidemia

Acute interruption in placental gas exchange is accompanied by subsequent CO₂ retention and respiratory acidemia. The most common antecedent factor is transient umbilical cord compression.
Generally, respiratory acidemia is not harmful to the fetus (Low, 1994).

The degree to which pH is affected by $P_{\text{CO}_2}$—the respiratory component of the acidosis—can be calculated. First, the upper normal neonatal $P_{\text{CO}_2}$ of 49 mm Hg is subtracted from the cord blood gas $P_{\text{CO}_2}$ value. Each additional 10 mm Hg $P_{\text{CO}_2}$ increment will lower the pH by 0.08 units (Eisenberg, 1987). Thus, in a mixed respiratory–metabolic acidemia, the benign respiratory component can be calculated. As an example, acute cord prolapse during labor prompts cesarean delivery of an infant 20 minutes later. The umbilical artery blood gas pH was 6.95 and the $P_{\text{CO}_2}$ was 89 mm Hg. To calculate the degree to which the cord compression and subsequent impairment of CO$_2$ exchange affected the pH, the relationship given earlier is applied: 89 mm Hg minus 49 mm Hg = 40 mm Hg excess CO$_2$. To correct pH: $(40 ÷ 10) × 0.08 = 0.32; 6.95 + 0.32 = 7.27$. Therefore, the pH before cord prolapse was approximately 7.27, well within normal limits, and thus the low pH resulted from respiratory acidosis.

**Metabolic Acidemia**

The fetus begins to develop metabolic acidemia when oxygen deprivation is of sufficient duration and magnitude to require anaerobic metabolism for cellular energy needs. Low and associates (1997) defined fetal acidosis as a base deficit $\geq$ 12 mmol/L and severe fetal acidosis as a base deficit $\geq$ 16 mmol/L. In the Parkland study of more than 150,000 newborns cited earlier, metabolic acidemia was defined using umbilical cord blood gas cutoffs that were 2 standard deviations below the mean (Casey, 2001b). Thus, metabolic acidemia was an umbilical artery blood pH $< 7.00$ accompanied by a $P_{\text{CO}_2}$ of $\leq 76.3$ mm Hg, with higher values indicating a respiratory component; HCO$_3^-$ concentration $\leq 17.7$ mmol/L; and base deficit $\geq 10.3$ mEq/L. From the standpoint of possible cerebral palsy causation, the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2003), in their widely endorsed monograph, defined metabolic acidosis as umbilical arterial pH $< 7.0$ and a base deficit $\geq 12$ mmol/L.

Metabolic acidemia is associated with a high rate of multiorgan dysfunction. In rare cases, such hypoxia-induced metabolic acidemia may be so severe that it causes subsequent neurological impairment—*hypoxic-ischemic encephalopathy* (Chap. 33, p. 639). In fact, a fetus without such acidemia cannot by definition have suffered recent hypoxic-induced injury. That said, severe metabolic acidosis is poorly predictive of subsequent neurological impairment in the term neonate. Although metabolic acidosis was associated with an increase in immediate neonatal complications in a group of infants with depressed 5-minute Apgar scores, there were no differences in umbilical artery blood gas measurements among infants who subsequently developed cerebral palsy compared with those with normal neurological outcomes (Socol, 1994).

In very-low-birthweight infants, that is, those $< 1000$ g, newborn acid-base status may be more closely linked to long-term neurological outcome (Gaudier, 1994; Low, 1995). In the study cited above, Casey and coworkers (2001b) described the association between metabolic acidemia, low Apgar scores, and neonatal death in term and preterm infants. Regarding term neonates, as shown in Figure 32-6, relative to newborns with a 5-minute Apgar score of at least 7, the risk of neonatal death was more than 3200-fold greater in term infants with metabolic acidemia and 5-minute scores of 3 or less.
Recommendations for Cord blood Gas Determinations

A cost-effectiveness analysis for universal cord blood gas measurements has not been conducted. In some centers, such as ours at Parkland Hospital, cord gas analysis is performed in all neonates at birth. The American College of Obstetricians and Gynecologists (2012) recommends that cord blood gas and pH analyses be obtained in the following circumstances:

- Cesarean delivery for fetal compromise
- Low 5-minute Apgar score
- Severe fetal-growth restriction
- Abnormal fetal heart rate tracing
- Maternal thyroid disease
- Intrapartum fever
- Multifetal gestation.

Although umbilical cord acid-base blood determinations are poorly predictive of either immediate or long-term adverse neurological outcome, they provide the most objective evidence of the fetal metabolic status at birth.

PREVENTIVE CARE

Eye Infection Prophylaxis

Gonococcal Infection
Ophthalmia neonatorum is mucopurulent conjunctivitis of newborns. Some form of conjunctivitis affects 1 to 12 percent of all neonates, and gonococcal and chlamydial infections are some of the most common causes (Zuppa, 2011). Blindness was previously common in children who developed *Neisseria gonorrhoeae* infection. However, in 1884, Credé, a German obstetrician, introduced a 1-percent ophthalmic solution of silver nitrate that largely eliminated this. Various other antimicrobial agents have also proven to be effective, and gonococcal prophylaxis is now mandatory for all neonates (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). Recommendations for gonococcal eye prophylaxis include a single application of either 1-percent silver nitrate solution or 0.5-percent erythromycin or 1-percent tetracycline ophthalmic ointment soon after delivery. Treatment of presumptive gonococcal ophthalmia, that is, conjunctivitis in a neonate born to a mother with untreated gonorrhea, is given with single-dose ceftriaxone, 100 mg/kg, either intramuscularly or intravenously. Testing for both gonococcus and chlamydia should be obtained before treatment.

**Chlamydial Infection**

Adequate neonatal prophylaxis against chlamydial conjunctivitis is complex. Ideally, prenatal screening and treatment for *Chlamydia trachomatis* obviates conjunctival infection (Hammerschlag, 2011). Of neonates delivered vaginally of mothers with an active chlamydial infection, from 12 to 25 percent will develop conjunctivitis for up to 20 weeks (Teoh, 2003). Prophylactic topical eye treatments do not reliably reduce the incidence of chlamydial conjunctivitis. In a study from Kenya, 2.5-percent povidone-iodine solution was reported to be superior to either 1-percent silver nitrate solution or 0.5-percent erythromycin ointment in preventing chlamydial conjunctivitis (Isenberg, 1995). In another study from Iran, povidone-iodine eye drops were twice as effective in preventing clinical conjunctivitis as erythromycin drops—9 versus 18 percent failure rate, respectively (Ali, 2007). In an Israeli study, tetracycline ointment was marginally superior to povidone-iodine (David, 2011). For all of these reasons, conjunctivitis in a newborn up to 3 months old should prompt consideration for chlamydial infection. Treatment for chlamydial infection is with oral azithromycin for 5 days or erythromycin for 14 days.

**Hepatitis B Immunization**

Routine immunization of all newborns with thimerosal-free vaccine against hepatitis B before hospital discharge is standard practice (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). This vaccine does not appear to increase the number of febrile episodes, sepsis evaluations, or adverse neurological sequelae (Lewis, 2001). Some advocate treatment of high-risk or even all seropositive women with antiviral nucleoside or nucleotide analogues during pregnancy to minimize transmission to the fetus (Dusheiko, 2012; Tran, 2012). Certainly, if the mother is seropositive for hepatitis B surface antigen, then the neonate should also be passively immunized with hepatitis B immune globulin as discussed in Chapter 55 (p. 1090).

**Vitamin K**

This injection is provided to prevent vitamin K-dependent hemorrhagic disease of the newborn, which is discussed in Chapter 33 (p. 644). A single dose of 0.5- to 1-mg intramuscular vitamin K is given within 1 hour of birth (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012).
Newborn Screening

State-based public-health newborn screening programs were solidified when, in response to calls for a uniform national policy, the Maternal and Child Health Bureau appointed a committee of the American College of Medical Genetics to recommend a panel of tests (Watson, 2006). Technical advances have made a large number of relatively simply performed mass screening tests available for newborn conditions, and many are mandated by various state laws (American College of Obstetricians and Gynecologists, 2011b). Since then, two have been added to the original core panel of 29 congenital conditions, and all are shown in Table 32-3.

<sup>a</sup>Determined by tandem mass spectrometry.

<sup>b</sup>Added after 2006.

From Centers for Disease Control and Prevention, 2012b; Watson, 2006.

According to the Centers for Disease Control and Prevention (2012b), the programs have been successful and cost effective. For example, neonatal screening for hearing loss was shown in a Dutch study to diagnose problems a mean of 6 months earlier and improve long-term outcomes (Durieux-Smith, 2008). A successful screening program for medium chain acyl-CoA dehydrogenase deficiency was described in a Danish study (Anderson, 2012). The use of pulse oximetry to screen for severe congenital heart disease was reviewed by Thangaratinam (2012).

Most states require that all tests in the core panel be performed. Supplemental conditions—secondary targets—are also listed on the Maternal and Child Health Bureau website. Some
states require some of these 24 in addition to their mandated core panel. Each practitioner should be familiar with their individual state requirements, which are available at [http://genes-r-us.uthscsa.edu/resources/consumer/statemap.htm](http://genes-r-us.uthscsa.edu/resources/consumer/statemap.htm) and [http://www.hrsa.gov/advisorycommittee/mchbadvisory/hereditarydisorders/recommendedpanel/index.html](http://www.hrsa.gov/advisorycommittee/mchbadvisory/hereditarydisorders/recommendedpanel/index.html).

### ROUTINE NEWBORN CARE

#### Gestational Age Estimation

Newborn gestational age can be estimated very soon after delivery. The relationship between gestational age and birthweight should be used to identify neonates at risk for complications (McIntire, 1999). For example, neonates who are either small or large for gestational age are at increased risk for hypoglycemia and polycythemia, and measurements of blood glucose and hematocrit are indicated (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012).

#### Care of Skin and Umbilical Cord

All excess vernix, bull- listood, and meconium should be gently wiped off at the time of delivery while keeping the infant warm. Any remaining vernix is readily absorbed and disappears within 24 hours. The first bath should be postponed until the neonate’s temperature has stabilized.

Aseptic precautions should be observed in the immediate care of the cord. The American Academy of Pediatrics and the American College of Obstetrics and Gynecologists (2012) have concluded that keeping the cord dry is sufficient care. The umbilical cord begins to lose water from Wharton jelly shortly after birth. Within 24 hours, the cord stump loses its characteristic bull-lustuish-white, moist appearance and soon becomes dry and black. Within several days to weeks, the stump sloughs and leaves a small, granulating wound, which after healing forms the umbilicus. Separation usually takes place within the first 2 weeks, with a range of 3 to 45 days (Novack, 1988). The umbilical cord dries more quickly and separates more readily when exposed to air. Thus, a dressing is not recommended.

In resource-poor countries, prophylaxis is reasonable. Triple-dye applied to the cord was reported superior to soap and water care in preventing colonization and exudate formation (Janssen, 2003). In a Nepalese study, cleansing the cord stump with 4-percent chlorhexidine reduced severe omphalitis by 75 percent compared with soap and water cleansing (Mullany, 2006). Likewise, 0.1-percent chlorhexidine powder was superior to dry cord care (Kapellen, 2009).

Despite precautions, a serious umbilical infection—omphalitis—is sometimes encountered. In a German study of more than 750 newborns with aseptic cord care, 1.3 percent developed omphalitis (Kapellen, 2009). The most likely offending organisms are *Staphylococcus aureus, Escherichia coli*, and group B streptococcus. Typical signs of cellulitis and stump discharge usually aid diagnosis. However, mild erythema and some bleeding at the stump site with cord detachment is common, and some cases may present no outward signs. Thus, the diagnosis can be elusive.

#### Feeding and Weight Loss
According to the American College of Obstetricians and Gynecologists (2013a), exclusive breastfeeding is preferred until 6 months. In many hospitals, infants begin breast feeding in the delivery room. Most term newborns thrive best when fed 8 to 12 times daily for approximately 15 minutes per episode. Preterm or growth-restricted newborns require feedings at shorter intervals.

One goal of Healthy People 2020 of the United States Department of Health and Human Services (2010) is to increase the proportion of mothers who breast feed their infants. Substantial progress toward this goal has been made. In 2009, 77 percent of infants were initially breast fed, and 47 percent were still breast fed at 6 months and 26 percent at 1 year (Centers for Disease Control and Prevention, 2012a). Breast feeding is discussed further in Chapter 36 (p. 673). Because most neonates actually receive little nutriment for the first 3 or 4 days of life, they progressively lose weight until the flow of maternal milk has been established or other feeding is instituted. Preterm infants lose relatively more weight and regain their birthweight more slowly. Conversely, growth-restricted but otherwise healthy infants regain their initial weight more quickly than those born preterm. With proper nourishment, birthweight of term infants usually is regained by the end of the 10th day.

Stools and Urine
For the first 2 or 3 days after birth, the colon contains soft, brownish-green meconium. This consists of desquamated epithelial cells from the intestinal tract, mucus, epidermal cells, and lanugo (fetal hair) that have been swallowed along with amnionic fluid. The characteristic color results from bile pigments. During fetal life and for a few hours after birth, the intestinal contents are sterile, but bacteria quickly colonize the bowel.

Meconium stooling is seen in 90 percent of newborns within the first 24 hours, and most of the rest within 36 hours. Usually, newborns first void shortly after birth, but may not until the second day. Meconium and urine passage indicates patency of the gastrointestinal and urinary tracts, respectively. Failure of the newborn to stool or urinate after these times suggests a congenital defect, such as imperforate anus or a urethral valve. After the third or fourth day, as a result of milk ingestion, meconium is replaced by light-yellow homogenous feces with a consistency similar to peanut butter.

Icterus Neonatorum
Between the second and fifth day of life approximately one third of all neonates develop so-called physiological jaundice of the newborn. It has special significance considering most hospitals have policies for early discharge. Correspondingly, it has been the subject of several recent reviews and is discussed further in Chapter 33 (p. 644) (Dijk, 2012; Gazzin, 2011; Hansen, 2011; Lauer, 2011).

Newborn Male Circumcision
Neonatal circumcision has been a controversial topic in the United States for at least 25 years. For centuries, newborn male circumcision has been performed as a religious ritual. Even so, scientific evidence supports several medical benefits that include prevention of phimosis, paraphimosis, and balanoposthitis. Circumcision also decreases the incidence of penile cancer and of cervical cancer among their sexual partners. In 1999, the American Academy of Pediatrics concluded that existing evidence was insufficient to recommend routine neonatal circumcision. It seems that this policy
has had only a negligible effect on practices in this country. Specifically, the Centers for Disease Control and Prevention (2011) estimated that the newborn male circumcision rate decreased during a 12-year period from approximately 60 percent in 2009 to only 55 percent in 2010.

Subsequent studies have again endorsed health benefits of circumcision. In two large randomized trials from regions of Africa with a high prevalence of human immunodeficiency virus (HIV), adult male circumcision was found to lower the risk of HIV acquisition by half (Bailey, 2007; Gray, 2007). And adult male circumcision was reported to decrease incidences of HIV, HPV, and herpes infections (Tobian, 2009). These and other studies were considered by the American Academy of Pediatrics Task Force on Circumcision (2012). In its policy statement, the Task Force concluded that health benefits of newborn male circumcision outweigh the risks, and thus, access to the procedure is justified for families who choose it. Benefits cited include prevention of urinary infections, penile cancer, and transmission of some sexually transmitted infections, including HIV infection. The Task Force stopped short of recommending circumcision for all newborns. The American College of Obstetricians and Gynecologists (2011a) endorses these views.

Anesthesia for Circumcision

The American Academy of Pediatrics Task Force (2012) recommends that if circumcision is performed, procedural analgesia should be provided. Various pain relief techniques have been described, including lidocaine-prilocaine topical cream, local analgesia infiltration, dorsal penile nerve block, or ring block. Several studies attest to the efficacy of the dorsal penile nerve block (Arnett, 1990; Stang, 1988). Studies show that the dorsal penile nerve block or the ring block techniques are both superior to topical analgesia (Hardwick-Smith, 1998; Lander, 1997; Taddio, 1997). The use of a pacifier dipped in sucrose is a useful adjunct to these methods (Kaufman, 2002).

After appropriate penile cleansing, the ring block technique consists of placing a wheal of 1-percent lidocaine at the base of the penis and advancing the needle in a 180-degree arc around the base of the penis first to one side and then the other to achieve a circumferential ring of analgesia. The maximum dose of lidocaine is 1.0 mL. No vasoactive compounds such as epinephrine should ever be added to the local analgesic agent.

Surgical Technique

Newborn circumcision should be performed only on a healthy neonate. Other contraindications include any genital abnormalities such as hypospadias and a family history of a bleeding disorder unless excluded in the infant. The most commonly used instruments are shown in Figure 32-7 and include Gomco and Mogen clamps and the Plastibell device. Compared with the Gomco procedure, Kaufman and colleagues (2002) reported that the Mogen technique required less time to perform and was associated with less apparent discomfort for the newborn. Regardless of the method used, the goal is to remove enough shaft skin and inner preputial epithelium so that the glans is exposed sufficiently to prevent phimosis. In all techniques: (1) the amount of external skin to be removed must be accurately estimated, (2) the preputial orifice must be dilated to visualize the glans and ensure that it is normal, (3) the inner preputial epithelium must be freed from the glans epithelium, and (4) the circumcision device must be left in place long enough to produce hemostasis before amputating the prepuce (Lerman, 2001). For a detailed description of surgical techniques, see the second edition of Operative Obstetrics (Mastrobattista, 2002).
FIGURE 32-7 Three different tools used for circumcision. A. Mogen clamp. The arms of the clamp open to a 3-mm maximum width. B. Gomco clamp, assembled. C. Plastibell device.

Circumcision Complications
As with any surgical procedure, there is a risk of bleeding, infection, and hematoma formation. These risks, however, are low (Christakis, 2000). Unusual complications reported as isolated cases include distal glans amputation, acquisition of human immunodeficiency virus-1 (HIV-1) infection or other sexually transmitted diseases, meatal stenosis, penile denudation, penile destruction with electrosurgical coagulation, subsequent epidermal inclusion cyst and urethrocrotaneous fistula, and ischemia following the inappropriate use of lidocaine with epinephrine (Amucole, 2003; Berens, 1990; Gearhart, 1989; Neulander, 1996; Nicoll, 1997; Pippi-Salle, 2013; Upadhyay, 1998).

Rooming-In
This model of maternity care place newborns in their mothers’ rooms instead of central nurseries.
Termed rooming-in, this approach first appeared in United States hospitals in the early 1940s (Temkin, 2002). In part, rooming-in stems from a trend to make all phases of childbearing as natural as possible and to foster early mother-child relationships. By 24 hours, the mother is generally fully ambulatory. Thereafter, with rooming-in, she can usually provide routine care for herself and her newborn. An obvious advantage is her increased ability to assume full care of the infant when she arrives home.

Hospital Discharge

Traditionally, the newborn is discharged with its mother, and in most cases, maternal stay has determined that of the neonate. Safe discharge for late preterm infants has special concerns (Whyte, 2012). From 1970 to the mid-1990s, average maternal postpartum length of stay declined steadily, and many mothers were discharged in under 48 hours. Although it is clear that most newborns can be safely discharged within 48 hours, this is not uniformly true. For example, using data from the Canadian Institute for Health Information, Liu and colleagues (2000) examined readmission rates in more than 2.1 million neonatal discharges. As the length of hospital stay decreased from 4.2 days in 1990 to 2.7 days in 1997, the readmission rate increased from 27 to 38 per 1000 births. Dehydration and jaundice accounted for most of these readmissions, and brain damage from icterus neonatorum is discussed in Chapter 33 (p. 644). Using Washington state neonatal discharge data, Malkin and coworkers (2000) found that the 28-day mortality rate was increased fourfold and the 1-year mortality rate increased twofold in newborns discharged within 30 hours of birth.

Because of the increased scrutiny regarding short hospital stays, federal legislation—The Newborns’ and Mothers’ Health Protection Act of 1996—was enacted to prohibit insurers from restricting hospital stays for mothers and newborns to less than 2 days for vaginal delivery or 4 days for cesarean delivery. As a result, the average length of hospital stay for childbirth increased from 2.1 days in 1995 to 2.5 days in 2000. This increase reflected the reduced number of very short hospital stays following childbirth (Hall, 2002). Although Mosen and associates (2002) found that implementation of the new legislation was associated with a 6-percent increase in cost, readmission rates within 7 days of discharge decreased by nearly half. In an analysis of more than 662,000 births in California, Datar and Sood (2006) found decreased rates of readmission of 9, 12, and 20 percent, respectively, at 1, 2, and 3 years after the legislation was implemented.

RESPIRATORY DISTRESS SYNDROME

NEONATAL ENCEPHALOPATHY AND CEREBRAL PALSY

HEMATOLOGICAL DISORDERS

INJURIES OF THE NEWBORN

Term newborns are susceptible to a wide spectrum of illnesses. In many instances, clinical manifestations of these disorders are extensions of pathological effects already incurred by the fetus. A common example is the newborn who is depressed and acidotic because of intrapartum septicemia. Because many of these disorders are differently manifested, those more common in term newborns are considered here, whereas those more frequent in preterm neonates are discussed in Chapter 34. Specific disorders that are the direct consequence of maternal diseases are discussed in pertinent chapters.

RESPIRATORY DISTRESS SYNDROME

At the time of delivery, the newborn must convert rapidly to air breathing as described in Chapter 7 (p. 142). With inspiration, there is alveolar expansion, fluid clearance, and surfactant secretion by type II pneumocytes to prevent lung collapse. Interference with these functions can create respiratory insufficiency with hypoxemia and compensatory tachypnea, which is generally referred to as neonatal respiratory distress syndrome or simply RDS. In preterm infants, this is caused by lung immaturity and insufficient surfactant, and variants may be seen in severely ill older children and adults (Chap. 47, p. 943). All of these have some element of surfactant deficiency because the inciting agent damages alveolar epithelium. As fetuses approach term, surfactant deficiency as a cause of RDS diminishes. In a report from Beijing that described 125 term infants with RDS, the most frequent causes were perinatal infection with sepsis syndrome in 50 percent, elective cesarean delivery in 27 percent, severe asphyxia in 10 percent, and meconium aspiration in 7 percent (Liu, 2010).

Surfactant Deficiency
Inadequate surfactant secretion that leads to respiratory distress syndrome becomes less frequent with increasing gestational age. That said, even with a low incidence in term infants, RDS from surfactant deficiency is not rare (Berthelot-Ricou, 2012). Male gender and white race are independent risk factors (Anadkat, 2012). Also, mutations of genes that encode for surfactant protein synthesis may augment the deficiency (Garmany, 2008; Wambach, 2012). Regardless of etiology, when surfactant secretion is diminished, the pulmonary pathophysiology, clinical course, and management are similar to that for preterm infants. Treatment includes mechanical ventilation and replacement of surfactant by insufflation (Chap. 34, p. 654). There is no evidence that antenatal maternal corticosteroid treatment will enhance surfactant synthesis in late preterm fetuses (Gyamfi-Bannerman, 2012). The prognosis in term newborns largely depends on the cause, severity, and response to treatment.

Meconium Aspiration Syndrome

The physiology of meconium passage and amnionic fluid contamination is considered in detail in Chapter 24 (p. 493). In some instances, inhalation of meconium-stained fluid at or near delivery causes acute airway obstruction, chemical pneumonitis, surfactant dysfunction or inactivation, and pulmonary hypertension (Swarnam, 2012). If severe, hypoxemia may lead to neonatal death or long-term neurological sequelae in survivors.

Given the high frequency—10 to 20 percent—of meconium-stained amnionic fluid in laboring women at term, it is reasonable to assume that meconium aspiration must be relatively common. Fortunately, severe aspiration leading to overt respiratory failure is much less frequent. And although the exact incidence of meconium aspiration is not known, Singh and associates (2009) reported it to be 1.8 percent for all deliveries. In a French study of nearly 133,000 term newborns, the prevalence of severe aspiration syndrome was 0.07 percent, and this increased progressively from 37 to 43 weeks’ gestation (Fischer, 2012). Mortality rates depend on severity. In an earlier report from Parkland Hospital, for all patients, meconium aspiration caused 1 death per 1000 live births (Nathan, 1994).

Fetal morbidity is more often associated with thicker meconium content. It is presumed that in most cases, amnionic fluid is ample to dilute the meconium to permit prompt clearance by normal fetal physiological mechanisms. Meconium aspiration syndrome occasionally develops with light staining. Many newborns are affected after a normal labor and uncomplicated delivery. However, some associated obstetrical factors include postterm pregnancy and fetal-growth restriction. These fetuses are at highest risk because there frequently is diminished amnionic fluid and labor with cord compression or uteroplacental insufficiency. These may increase the likelihood of meconium passage that is thick and undiluted (Leveno, 1984).

Prevention

It was once widely held that aspiration was stimulated by fetal hypoxic episodes, and fetal heart rate tracing abnormalities were used to identify fetuses at greatest risk during labor. Unfortunately, this was found to be an unreliable predictor (Dooley, 1985). Preliminary studies reported that the incidence and severity of the syndrome could be mitigated by oropharyngeal suctioning after delivery of the fetal head, but before the chest. For a while, this was standard care, but it was abandoned when shown that strict adherence to this protocol did not reduce syndrome incidence or severity (Davis, 1985; Wiswell, 1990). At the same time, reports described that pulmonary hypertension caused by aspirated meconium was characterized by abnormal arterial muscularization beginning well before birth. These findings led some to conclude that only
chronically asphyxiated fetuses developed meconium aspiration syndrome (Katz, 1992). Proof of this never materialized, and Richey (1995) and Bloom (1996) and their colleagues found no correlation between meconium aspiration and markers of acute asphyxia—for example, umbilical artery acidosis. Conversely, others have reported that thick meconium is an independent risk factor for neonatal acidosis (Maisonneuve, 2011).

Conflicted findings regarding suctioning stimulated performance of an 11-center randomized trial designed to compare suctioning with no suctioning (Vain, 2004). There was an identical 4-percent incidence of meconium aspiration syndrome in both groups. Subsequently, a committee that represented the American Heart Association and American Academy of Pediatrics (Perlman, 2010), as well as the American College of Obstetricians and Gynecologists (2013b), has recommended against routine intrapartum oro- and nasopharyngeal suctioning at delivery. Instead, for depressed newborns, management includes intubation and suctioning to remove meconium and other aspirated material from beneath the glottis (Chap. 32, p. 626).

Intrapartum amnioinfusion has been used successfully in laboring women with decreased amniotic fluid volume and frequent variable fetal heart rate decelerations (Chap. 24, p. 494). It has also been studied as a preventive measure in labors complicated by meconium staining (Spong, 1994). Although amnioinfusion apparently posed little or no increased risk, it was found to be of no benefit because fetuses usually inhaled meconium before labor (Bryne, 1987; Wenstrom, 1995). To further settle this issue, a trial was conducted with almost 2000 women at 36 weeks’ gestation or later and in whom labor was complicated by thick meconium (Fraser, 2005). The perinatal death rate with and without amnioinfusion was 0.05 percent in both groups. Rates of moderate or severe meconium aspiration were also not significantly different—4.4 percent with and 3.1 percent without amnioinfusion. Finally, cesarean delivery rates were similar—32 versus 29 percent, respectively. Currently, the American College of Obstetrics and Gynecologists (2012c) does not recommend amnioinfusion to reduce meconium aspiration syndrome.

**Treatment**

Ventilatory support is given as needed. Because some aspects of meconium aspiration syndrome are caused by surfactant deficiency, replacement therapy has been given in some studies. Extracorporeal membrane oxygenation—ECMO—therapy is reserved for neonates who remain poorly oxygenated despite maximal ventilatory assistance. In their Cochrane review of randomized trials, El Shahed and colleagues (2007) found that surfactant replacement significantly decreased need for extracorporeal membrane oxygenation. Although they found that surfactant administration did not lower the mortality rate, a subsequent trial suggested that it was reduced (Dargaville, 2011). The proportion that requires ECMO treatment varies. In the report by Singh and coworker: (2009), 1.4 percent of 7518 term newborns with the syndrome required such treatment, and these had a 5-percent mortality rate. Ramachandrappa and colleagues (2011) reported a higher mortality rate in late-preterm infants compared with term infants. Finally, pulmonary lavage with surfactant is being evaluated (Choi, 2012).

**NEONATAL ENCEPHALOPATHY AND CEREBRAL PALSY**

Few events evoke more fear and apprehension in parents and obstetricians than the specter of “brain damage,” which immediately conjures visions of disabling cerebral palsy and hopeless intellectual disability. Although most brain disorders or injuries are less horrific, history has helped to perpetuate the more dismal outlook. In the first edition of this textbook, J. Whitridge
Williams (1903) limited discussions of brain injury to that sustained from birth trauma. Later editions introduced the concept that *asphyxia neonatorum* was another cause of cerebral palsy, this too was linked to traumatic birth. Even as brain damage caused by traumatic delivery became uncommon during the ensuing decades, the belief—albeit erroneous—was that intrapartum events caused most neurological disability. This was a major reason for the escalating cesarean delivery rate beginning in the 1970s. Unfortunately, because in most cases the genesis of cerebral palsy occurred long before labor, this did little to mitigate risks for cerebral palsy (O’Callaghan, 2013).

These realizations stimulated scientific investigations to determine the etiopathogenesis of fetal brain disorders to include those leading to cerebral palsy. Seminal observations include those of Nelson and Ellenberg (1984, 1985, 1986a), discussed subsequently. These investigators are appropriately credited with proving that these neurological disorders are due to complex multifactorial processes caused by a combination of genetic, physiological, environmental, and obstetrical factors. Importantly, these studies showed that few neurological disorders were associated with peripartum events. Continuing international interest was garnered to codify the potential role of intrapartum events. In 2000, President Frank Miller of the American College of Obstetricians and Gynecologists appointed a task force to study the vicissitudes of neonatal encephalopathy and cerebral palsy. From this, the 2003 Task Force findings were promulgated by the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2003). The multispecialty coalition reviewed contemporaneous data and provided criteria to define various neonatal brain disorders.

In 2010, 10 years later, President Richard Waldman of the American College of Obstetricians and Gynecologists appointed a second task force to update these findings. The 2014 Task Force has now published its findings (American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, 2014). The 2014 Task Force findings are more circumspect in contrast to the earlier ones. Specifically, more limitations are cited in identifying cause(s) of peripartum *hypoxic-ischemic encephalopathy* compared with other etiologies of neonatal encephalopathy. The 2014 Task Force recommends multidimensional assessment of each affected infant. They add the caveat that no one strategy is infallible, and thus, no single strategy will achieve 100-percent certainty in attributing a cause to neonatal encephalopathy.

### Neonatal Encephalopathy

The 2014 Task Force defined neonatal encephalopathy as a syndrome of neurological dysfunction identified in the earliest days of life in neonates born at ≥ 35 weeks’ gestation. It is manifested by subnormal levels of consciousness or seizures and often accompanied by difficulty with initiating and maintaining respiration and by depressed tone and reflexes. The incidence of encephalopathy has been cited to be 0.27 to 1.1 per 1000 term liveborn neonates, and it is much more frequent in preterm infants (Ensing, 2013; Plevani, 2013; Takenouchi, 2012; Wu, 2011). Although the 2014 Task Force concluded that there are many causes of encephalopathy and cerebral palsy, it focused on those termed *hypoxic-ischemic encephalopathy (HIE)* and thought to be incurred intrapartum. To identify affected infants, a thorough evaluation is necessary, including maternal history, obstetrical antecedents, intrapartum factors, placental pathology, and newborn course, along with laboratory and neuroimaging findings.

There are three clinically defined levels. *Mild encephalopathy* is characterized by hyperalertness, irritability, jitteriness, and hypertonia and hypotonia. *Moderate encephalopathy* is manifest by lethargy, severe hypertonia, and occasional seizures. *Severe encephalopathy* is manifest by coma, multiple seizures, and recurrent apnea.
The 2014 Task Force also concluded that of the several forms of cerebral palsy, only the spastic quadriplegic type can result from acute peripartum ischemia. Other forms—hemiparetic or hemiplegic cerebral palsy, spastic diplegia, and ataxia—are unlikely to result from an intrapartum event. Purely dyskinetic or ataxic cerebral palsy, especially when accompanied by a learning disorder, usually has a genetic origin (Nelson, 1998).

Criteria for Hypoxic-Ischemic Encephalopathy

The 2014 Task Force radically revised its 2003 criteria used to define an acute peripartum event that is consistent with a hypoxic-ischemic episode and neonatal encephalopathy. These are outlined in Table 33-1 and are considered with the following caveats.

<table>

HIE = hypoxic ischemic encephalopathy; MRI = magnetic resonance imaging; MRS = magnetic resonance spectroscopy.
From the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, 2014.

Apgar Scores. Low 5- and 10-minute Apgar scores are associated with increased risks for neurological impairment. There are many causes of low Apgar scores, and most of these infants will not develop cerebral palsy. If the 5-minute Apgar is ≥ 7, it is unlikely that peripartum HIE caused cerebral palsy.

Acid-Base Studies. Low pH and base deficit levels increase the likelihood that neonatal encephalopathy was caused by HIE. Decreasing levels form a continuum of increasing risk, but most acidemic neonates will be neurologically normal (Wayock, 2013). A cord artery pH > 7.2 is very unlikely to be associated with HIE.

Neuroimaging Studies. Magnetic resonance (MR) imaging or spectroscopy (MRS) is the best modality with which to visualize findings consistent with HIE. The 2014 Task Force concludes that cranial sonography and computed tomography (CT) lack sensitivity in the term newborn. Normal MR imaging/MRS findings after the first 24 hours of life, however, effectively exclude a hypoxic-ischemic cause of encephalopathy. MR imaging between 24 and 96 hours may be more sensitive for the timing of peripartum cerebral injury, and MR imaging at 7 to 21 days following...
birth is the best technique to delineate the full extent of cerebral injury.

**Multisystem Involvement.** Neonatal manifestations of multisystem injury are consistent with HIE. These include renal, gastrointestinal, hepatic, or cardiac injury; hematological abnormalities; or combinations of these. The severity of neurological injury does not necessarily correlate with injuries to these other systems.

**Contributing Factors**
The 2014 Task Force also found that certain contributing factors may be consistent with an acute peripartum event.

**Sentinel Event.** Adverse obstetrical events that may lead to catastrophic clinical outcomes are designated sentinel events. Examples given by the 2014 Task Force include ruptured uterus, severe placental abruption, cord prolapse, and amniotic-fluid embolism. Martinez-Biarge and associates (2012) studied almost 58,000 deliveries and identified 192 cases with one of these sentinel events. Of these 192 infants, 6 percent died intrapartum or in the early neonatal period, and 10 percent developed neonatal encephalopathy. In a study of 307 cases of cord prolapse, the fetal death rate was 6.8 percent (Hartigan, 2013). Besides these sentinel events, other risk factors for neonatal acidosis include prior cesarean delivery, maternal age ≥ 35 years, thick meconium, chorioamnionitis, and general anesthesia (Johnson, 2014; Maisonneuve, 2011).

**Fetal Heart Rate Patterns.** The 2014 Task Force emphasized the importance of differentiating an abnormal fetal heart rate (FHR) tracing on presentation versus one that develops subsequently. A category 1 or 2 FHR tracing associated with Apgar scores ≥ 7 at 5 minutes, normal cord gases (±1 SD), or both, is not consistent with an acute HIE event (Anderson, 2013). An FHR pattern at the time of presentation with persistently minimal or absent variability and lacking accelerations, with duration ≥ 60 minutes, and even without decelerations is suggestive of an already compromised fetus. The Task Force further recommended that if fetal well-being cannot be established with these findings present, the woman should be evaluated for the method and timing of delivery.

**Application of 2003 Task Force Criteria**
It seemed likely that strict adherence to all of the criteria set forth by the 2003 Task Force would exclude some infants who go on to develop cerebral palsy as a result of neonatal encephalopathy (Strijbis, 2006). To test these criteria, Phelan and coworkers (2011) retrospectively applied the 2003 Task Force criteria to 39 term infants with permanent central nervous system impairment. They found that the Task Force criteria and these 39 cases correlated in varying degrees. Of the essential criteria, pH < 7.0 and base deficit ≥ 12 mmol/L showed a 97- and 100-percent correlation, respectively; moderate to severe encephalopathy—97 percent correlation; spastic quadriplegia or dyskinetic form—92 percent; and no other identifiable cause—100 percent. Of the nonspecific criteria, a sentinel hypoxic event had an 80-percent correlation; fetal heart rate requirements—100 percent; Apgar score ≤ 3 beyond 5 minutes—29 percent; and multisystem involvement—100 percent. As discussed subsequently, a sentinel event alone had only a 10-percent predictive value for newborn encephalopathy (Martinez-Biarge, 2012).

**Prevention**
Most prophylactic measures for neonatal encephalopathy have been evaluated in preterm infants (Chap. 42, p. 854). One of these—hypothermia—may prevent death and mitigate moderate to
severe neurological disability in term infants (Nelson, 2014; Pfister, 2010; Shankaran, 2005, 2012). MR imaging studies have demonstrated a slowing of diffusional abnormalities and fewer infarctions with hypothermia (Bednarek, 2012; Shankaran, 2012). Most randomized trials have shown improved outcomes with hypothermia in infants born at 36 weeks or older (Azzopardi, 2009; Guillet, 2012; Jacobs, 2011). In a metaanalysis of more than 1200 newborns, Tagin and colleagues (2012) concluded that hypothermia improves survival rates and neurodevelopment. More recently, clinical trials to evaluate concomitant erythropoietin therapy for neuroprophylaxis are being conducted (Wu, 2012). Preliminary data from a Dutch multicenter trial of maternal allopurinol therapy indicate some mitigation of cerebral damage from hypoxia and ischemia (Kaandorp, 2013).

Cerebral Palsy

This term refers to a group of nonprogressive disorders of movement or posture caused by abnormal development or damage to brain centers for motor control. Cerebral palsy is further classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—as well as the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia. Together, the major types are spastic quadriplegia—the most common—which has a strong association with mental retardation and seizure disorders; diplegia, which is common in preterm or low-birthweight infants; hemiplegia; choreoathetoid types; and mixed varieties. Although epilepsy and mental retardation frequently accompany cerebral palsy, these two disorders seldom are associated with perinatal asphyxia in the absence of cerebral palsy.

Incidence and Epidemiological Correlates

According to the Centers for Disease Control and Prevention (2011), the prevalence of cerebral palsy is variably reported in the United States. In one multisite surveillance program in 2006, the average prevalence was 2.9 per 1000 8-year-old children. It is crucial to emphasize that this rate is derived from all children—including preterm infants. Because of the remarkably increased survival rates of the latter, the overall rate of cerebral palsy and other developmental disabilities reported in the 1950s has remained essentially unchanged (Boyle, 2011). Long-term follow-up studies of more than 900,000 Norwegian nonanomalous term infants cite an incidence of 1 per 1000 (Moster, 2008). By contrast, the incidence was 91 per 1000 for infants born at 23 to 27 weeks. In absolute numbers, term infants comprise half of cerebral palsy cases because there are proportionately far fewer preterm births. It is again emphasized that most studies have not made distinctions between term and preterm infants.

As noted earlier, Nelson and Ellenberg (1984, 1985, 1986a) made many foundational observations concerning cerebral palsy. Their initial studies emanated from data from the Collaborative Perinatal Project. This included children from almost 54,000 pregnancies who were followed until age 7. They found that the most frequently associated risk factors for cerebral palsy were: (1) evidence of genetic abnormalities such as maternal mental retardation or fetal congenital malformations; (2) birthweight < 2000 g; (3) birth before 32 weeks; and (4) perinatal infection. They also found that obstetrical complications were not strongly predictive, and only a fifth of affected children had markers of perinatal asphyxia. For the first time, there was solid evidence that the cause of most cases of cerebral palsy was unknown, and importantly, only a small proportion was caused by neonatal hypoxic-ischemic encephalopathy. Equally importantly, there was no foreseeable single intervention that would likely prevent a large proportion of cases.

Numerous studies have since confirmed many of these findings and identified an imposing list
of other risk factors that are shown in Table 33-2. As expected, preterm birth continues to be the single most important risk factor (Goepfert, 1996; Thorngren-Jerneck, 2006). Small-for-gestational-age infants are also at increased risk. Stoknes and associates (2012) showed that in more than 90 percent of growth-restricted infants, cerebral palsy was due to antepartum factors. A myriad other placental and neonatal risk factors has been correlated with neurodevelopmental abnormalities (Ahlin, 2013; Avagliano, 2010; Blair, 2011; Redline, 2005, 2008). Some placental factors are discussed further in Chapter 6, and in just one example, there is a substantively increased risk with chorioamnionitis (Gilbert, 2010; Shatrov, 2010). An example of a neonatal cause is arterial ischemic stroke, which may be associated with inherited fetal thrombophilias (Gibson, 2005; Harteman, 2013; Kirton, 2011). Also, neonates with isolated congenital heart lesions have an increased risk for microcephaly, possibly due to chronic fetal hypoxemia (Barbu, 2009). Other miscellaneous causes of cerebral palsy include fetal anemia, twin-twin transfusion syndrome, intrauterine transfusions, and fetal alcohol syndrome (DeJong, 2012; Lindenburg, 2013; O’Leary, 2012; Rossi, 2011; Spruijt, 2012).

Intrapartum Events. The National Collaborative Perinatal Project found that intrapartum hypoxemia was linked to a minority of cerebral palsy cases. However, because the study was carried out in the 1960s, there were inconsistent criteria to accurately assign cause. The contribution of hypoxic-ischemic encephalopathy to subsequent neurological disorders is discussed in detail on page 639. Thus, the 2003 Task Force applied these criteria to more contemporaneous outcomes and determined that only 1.6 cases of cerebral palsy per 10,000 deliveries are attributable solely to intrapartum hypoxia. This finding is supported by a study from Western Australia that spanned from 1975 to 1980 (Stanley, 1991). These latter investigators concluded that intrapartum injury as the cause of cerebral palsy was unlikely in 92 percent of cases; in 3 percent, it was possible; and in only 5 percent was it likely. infants with neurological impairment, 75 percent were classified as nonpreventable (Phelan, 1996). In yet another study of 213 such children, only 2 percent of cases could be attributed to intrapartum hypoxia (Strijbis, 2006).

**Intrapartum Fetal Heart Rate Monitoring**

Despite persistent attempts to validate continuous intrapartum electronic fetal monitoring as effective to prevent adverse perinatal outcomes, evidence does not support its ability to predict or reduce cerebral palsy risk (Clark, 2003; Devoe, 2011; MacDonald, 1985; Thacker, 1995). Importantly, there are no specific fetal heart rate patterns predictive of cerebral palsy, and no relationship has been found between the clinical response to abnormal patterns and neurological outcome (Melone, 1991; Nelson, 1996). Indeed, an abnormal heart rate pattern in fetuses that ultimately develop cerebral palsy may reflect a preexisting neurological abnormality (Phelan, 1994). Because of these studies, the American College of Obstetricians and Gynecologists (2013a) has concluded that electronic fetal monitoring does not reduce the incidence of long-term neurological impairment.

**Apgar Scores**

In general, 1- and 5-minute Apgar scores are poor predictors of long-term neurological impairment. When the 5-minute Apgar score is 3 or less, however, neonatal death or the risk of neurological sequelae is increased substantially (Dijxhoorn, 1986; Nelson, 1984). In a Swedish study, 5 percent of such children subsequently required special schooling (Stuart, 2011). In a Norwegian study, the incidence of these low Apgar scores was 0.1 percent in more than 235,000 newborns. Almost a fourth died, and 10 percent of survivors developed cerebral palsy (Moster, 2001).

Persistence past 5 minutes of these extremely low scores correlates strongly with an increased risk for neurological morbidity and death (Grünebaum, 2013). This of course is not absolute, and the 2003 Task Force cited a 10-percent risk for cerebral palsy for infants with 10-minute scores of 0 to 3. For 15-minute scores ≤ 2, there is a 53-percent mortality rate and a 36-percent cerebral palsy rate, and for 20-minute scores ≤ 2, there is a 60-percent mortality rate and a 57-percent rate of cerebral palsy. Some outcomes in the Norwegian Study of infants with these low 5-minute Apgar scores are shown in Table 33-3. Survivors with Apgar scores of 0 at 10 minutes have even worse outcomes. In a review of 94 such infants, 78 died, and all survivors assessed had long-term disabilities (Harrington, 2007).

Survivors with Apgar scores of 0 at 10 minutes have even worse outcomes. In a review of 94 such infants, 78 died, and all survivors assessed had long-term disabilities (Harrington, 2007).
**Umbilical Cord Blood Gas Studies**

As outlined on page 639, objective evidence for metabolic acidosis—cord arterial blood pH < 7.0 and base deficit ≥ 12 mmol/L—is a risk factor for encephalopathy as well as for cerebral palsy. The risk increases as acidosis worsens. From their review of 51 studies, Malin and coworkers (2010) found that low cord arterial pH correlates with increased risk for neonatal encephalopathy and cerebral palsy. When used alone, however, these determinations are not accurate in predicting long-term neurological sequelae (Dijxhoorn, 1986; Yeh, 2012).

Data from several studies corroborate that a pH < 7.0 is the threshold for clinically significant acidemia (Gilstrap, 1989; Goldaber, 1991). The likelihood of neonatal death increases as the cord artery pH falls to 7.0 or less. Casey and colleagues (2001) reported that when the pH was 6.8 or lower, the neonatal mortality rate was increased 1400-fold. When the cord pH was ≤ 7.0 and the 5-minute Apgar score was 0 to 3, there was a 3200-fold increased risk of neonatal death.

In the study from Oxford, adverse neurological outcomes were 0.36 percent with pH < 7.1 and 3 percent with pH < 7.0 (Yeh, 2012). As mentioned, newborn complications increase coincident with increasing severity of acidemia at birth. According to the American College of Obstetricians and Gynecologists (2012d), encephalopathy develops in 10 percent of newborns whose umbilical arterial base deficit is 12 to 16 mmol/L, and in 40 percent of those whose deficit is > 16 mmol/L. In a Swedish study, researchers observed that cord blood lactate levels may prove to be superior to base deficit for prognostication of neurological disorders (Wiberg, 2010).

**Nucleated Red Blood Cells and Lymphocytes**

Both immature red cells and lymphocytes enter the circulation of term infants in response to hypoxia or hemorrhage. During the past two decades, quantification of these cells has been proposed as a measure of hypoxia, but most studies do not support this premise (Hankins, 2002; Silva, 2006; Walsh, 2011, 2013). The 2003 Task Force concluded that their use was investigational.
Various neuroimaging techniques have provided important insight into the etiology and evolution of perinatal hypoxic-ischemic encephalopathy and later cerebral palsy (p. 639). Importantly, findings are highly dependent on fetal age. The preterm neonatal brain responds quite differently to an ischemic episode compared with that of a term infant. Other factors include insult severity and duration as well as restoration of cerebrovascular hypoperfusion. Thus, precise timing of an injury with neuroimaging studies is not a realistic goal. Reports are of two types—those in which neuroimaging was done during the neonatal period and those done when older children are diagnosed with cerebral palsy.

**Neuroimaging in Neonatal Period**

Regarding early use, the 2014 Task Force concluded that these imaging techniques provide the following information:

1. Sonographic studies are generally normal on the day of birth. Increasing echogenicity in the thalami and basal ganglia is seen beginning at approximately 24 hours. This progresses over 2 to 3 days and persists for 5 to 7 days.
2. Computed tomography scans are usually normal the first day in term infants. Decreased density in the thalami or basal ganglia is seen beginning at about 24 hours and persists for 5 to 7 days.
3. Magnetic resonance imaging will detect some abnormalities on the first day. Within 24 hours, MR imaging may show restricted water diffusion that peaks at about 5 days and disappears within 2 weeks. Acquisitions with T1- and T2-weighted images show variable abnormalities, which have an onset from less than 24 hours to several days. In a study of 175 term infants with acute encephalopathy, it was reported that MR imaging showing basal ganglia lesions accurately predicted motor impairment at 2 years of age (Martinez-Biarge, 2012).

The 2014 Task Force concluded that for term infants, imaging studies are helpful in timing an injury, but they provide only a window in time that is imprecise. Findings in preterm infants are considered in Chapter 34 (p. 656).

**Neuroimaging in Older Children with Cerebral Palsy**

Imaging studies performed in children diagnosed with cerebral palsy frequently show abnormal findings. Wu and associates (2006) used CT or MR imaging to study 273 children who were born after 36 weeks and who were diagnosed later in childhood with cerebral palsy. Although a third of these studies were normal, focal arterial infarction was seen in 22 percent; brain malformations in 14 percent; and periventricular white-matter injuries in 12 percent. In another study of 351 children with cerebral palsy—about half were born near term—MR imaging findings were abnormal in 88 percent (Bax, 2006). Similar findings were reported in an Australian study (Robinson, 2008).

CT and MR imaging techniques have also been used in older children in an attempt to define the timing of fetal or perinatal cerebral injury. Wiklund and coworkers (1991a,b) studied 83 children between ages 5 and 16 years who were born at term and who developed hemiplegic cerebral palsy. Nearly 75 percent had abnormal CT findings, and these investigators concluded that more than half had CT findings that suggested a prenatal injury. Approximately 20 percent was attributed to a perinatal injury. In a similar study, Robinson and colleagues (2008) used MR imaging. They reported pathological findings in 84 percent of children with spastic quadriplegia,
which is the neurological lesion that the 2014 Task Force reported to correlate with neonatal encephalopathy.

### Intellectual Disability and Seizure Disorders

The term **intellectual disability** is the preferred substitute term for the older culturally insensitive term **mental retardation** (Centers for Disease Control and Prevention, 2012). It describes a spectrum of disabilities and seizure disorders that frequently accompany cerebral palsy. But when either of these manifests alone, they are seldom caused by perinatal hypoxia (Nelson, 1984, 1986a,b). Severe mental retardation has a prevalence of 3 per 1000 children, and its most frequent causes are chromosomal, gene mutations, and other congenital malformations. Finally, preterm birth is a common association for these (Moster, 2008).

The major predictors of seizure disorders are fetal malformations—cerebral and noncerebral; family history of seizures; and neonatal seizures (Nelson, 1986b). Neonatal encephalopathy causes a small proportion of seizure disorders. Reports from the Neonatal Research Network and other studies concluded that increasing severity of encephalopathy correlates best with seizures (Glass, 2011; Kwon, 2011).

### Autism Spectrum Disorders

According to the Centers for Disease Control and Prevention (2012), the frequency of autism is almost 0.5 percent, and for attention deficit hyperactivity disorders, it is 6.7 percent. Although these may be associated with maternal metabolic conditions, none has been linked convincingly to peripartum events (Krakowiak, 2012).

### HEMATOLOGICAL DISORDERS

There are a few neonatal disorders of erythrocytes, platelets, and coagulation with which the obstetrician should be familiar. As is the case for most other conditions manifest by the newborn shortly after birth, many of these hematological problems were acquired by the fetus and persist in the newborn.

#### Anemia

After 35 weeks’ gestation, the mean cord hemoglobin concentration is approximately 17 g/dL, and values below 14 g/dL are considered abnormal. A review of nearly 3000 deliveries found that late cord clamping was associated with a mean hemoglobin increase of 2.2 g/dL (McDonald, 2008). Unfortunately, this practice almost doubled the incidence of hyperbilirubinemia requiring phototherapy. The American College of Obstetricians and Gynecologists (2012b) has concluded that optimal timing of cord clamping for term infants is unknown. Conversely, cord blood hemoglobin concentration may be abnormally low, or it may fall after delivery. Fetal anemia results from many causes and is discussed in Chapter 15 (p. 306).

Acute anemia with hypovolemia is seen with deliveries in which the placenta is cut or torn, if a fetal vessel is perforated or lacerated, or if the infant is held well above the level of the placenta for some time before cord clamping. Intracranial or extracranial injury or trauma to fetal intraabdominal organs can also cause hemorrhage with acute anemia (Akin, 2011).
Neonatal polycythemia with hyperviscosity can be associated with chronic hypoxia in utero, twin-twin transfusion syndrome, placental- and fetal-growth restriction, fetal macrosomia from maternal diabetes, and transfusion at delivery. Current recommendations by the International Liaison Committee on Resuscitation (ILCOR) are to delay cord clamping for at least 1 minute after delivery (Davis, 2012). When the hematocrit rises above 65, blood viscosity markedly increases and may cause neonatal plethora, cyanosis, or neurological aberrations. Because of the shorter lifespan of macrocytic fetal erythrocytes, hyperbilirubinemia commonly accompanies polycythemia as subsequently discussed. Other findings include thrombocytopenia, fragmented erythrocytes, and hypoglycemia. Partial exchange transfusion may be necessary in some neonates.

Hyperbilirubinemia

Even in term fetuses, hepatic maturation is not complete, and thus some unconjugated bilirubin—either albumin bound or free—is cleared by placental transfer to be conjugated in the maternal liver (Chap. 7, p. 141). Fetal protection from unconjugated bilirubin is lost after delivery if it is not cleared rapidly. Because clearance is totally dependent on neonatal hepatic function, varying degrees of neonatal hyperbilirubinemia result. Even in the mature newborn, serum bilirubin usually increases for 3 to 4 days to reach levels up to 10 mg/dL. After this, concentrations usually fall rapidly. In one large study, 1 to 2 percent of neonates delivered at 35 weeks’ gestation or later had a maximum serum bilirubin level > 20 mg/dL (Eggert, 2006). In approximately 15 percent of term newborns, bilirubin levels cause clinically visible skin color changes termed physiological jaundice (Burke, 2009). As expected, in preterm infants, the bilirubin increase is greater and more prolonged.

Acute Bilirubin Encephalopathy and Kernicterus

Excessive serum bilirubin levels can be neurotoxic for newborns (Dijk, 2012; Watchako, 2013). The pathogenesis is complex, and toxicity has two forms. Acute bilirubin encephalopathy is encountered in the first days of life and is characterized by hypotonia, poor feeding, lethargy, and abnormal auditory-evoked responses (Kaplan, 2011). Immediate recognition and treatment will usually mitigate progressive neurotoxicity. The chronic form is termed kernicterus—from Greek jaundice of the nuclei. Neurotoxicity follows bilirubin deposition and staining of the basal ganglia and hippocampus and is further characterized by profound neuronal degeneration. Survivors have spasticity, muscular incoordination, and varying degrees of mental retardation. Although there is a positive correlation between kernicterus and unconjugated bilirubin levels above 18 to 20 mg/dL, it can develop at much lower concentrations, especially in very preterm neonates (Sgro, 2011). Continuing hemolysis is a risk factor for kernicterus, and experiences from the Collaborative Perinatal Project were that bilirubin levels ≥ 25 mg/dL correlated with kernicterus only with ongoing Coombs-positive hemolysis (Kuzniewicz, 2009). This was recently verified in a study by Vandborg and associates (2012).

Prevention and Treatment

Various forms of phototherapy are used to prevent as well as treat neonatal hyperbilirubinemia (Hansen, 2011). These “bili-lights” emit a spectrum of 460 to 490 nm, which increases bilirubin oxidation to enhance its renal clearance and lower serum levels. Light that penetrates the skin also
increases peripheral blood flow, which further enhances photo-oxidation. It is problematic that available devices are not standardized (Bhutani, 2011). Another advantage is that exchange transfusions are seldom required with phototherapy. There are studies in both preterm and term newborns that attest to phototherapy efficacy (Watchko, 2013). A Neonatal Research Network study reported that aggressive phototherapy in low-birthweight neonates reduced rates of neurodevelopmental impairment (Newman, 2006).

For term infants, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012b) stress early detection and prompt phototherapy to prevent bilirubin encephalopathy. Despite these measures, bilirubin encephalopathy persists, and this is somewhat related to early hospital discharges (Gazzin, 2011; Kaplan, 2011; Sgro, 2011). According to Burke and coworkers (2009), hospitalizations for kernicterus in term infants were 5.1 per 100,000 in 1988. Since then, however, this rate has decreased to 0.4 to 2.7 cases per 100,000 births (Watchko, 2013).

Hemorrhagic Disease of the Newborn

This disorder is characterized by spontaneous internal or external bleeding beginning any time after birth. Most hemorrhagic disease results from abnormally low levels of the vitamin K-dependent clotting factors—V, VII, IX, X, prothrombin, and proteins C and S (Zipursky, 1999). Infants whose mothers took anticonvulsant drugs are at higher risk because these suppress maternal hepatic synthesis of some of these factors (Chap. 60, p. 1190). Classic hemorrhagic disease is usually apparent 2 to 5 days after birth in infants not given vitamin K prophylaxis at delivery (Busfield, 2013). Delayed hemorrhage may occur at 2 to 12 weeks in exclusively breast-fed infants because breast milk contains little vitamin K. Other causes of neonatal hemorrhage include hemophilia, congenital syphilis, sepsis, thrombocytopenia purpura, erythroblastosis, and intracranial hemorrhage.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommends routine prophylaxis for hemorrhagic disease with a 0.5 to 1 mg dose of vitamin K₁ (phytonadione) given intramuscularly. Oral administration is not effective, and maternal vitamin K administration results in very little transport to the fetus. For treatment of active bleeding, vitamin K is injected intravenously.

Thrombocytopenia

Abnormally low platelet concentrations in term newborns may be due to various etiologies such as immune disorders, infections, drugs, or inherited platelet defects, or they may be part of a congenital syndrome. In many, thrombocytopenia is an extension of a fetal disorder such as infection with B19 parvovirus, cytomegalovirus, toxoplasmosis, and others discussed in Chapters 64 and 65. Term infants admitted to neonatal intensive care units, especially those with sepsis, have accelerated platelet consumption (Eissa, 2013). In these, transfusions are occasionally indicated (Sallmon, 2012).

Immune Thrombocytopenia

In women with an autoimmune disorder such as systemic lupus erythematosus or immunological thrombocytopenia, maternal antiplatelet IgG is transferred to the fetus and can cause accelerated platelet destruction. Most cases are mild, and platelet levels usually reach a nadir at 48 to 72 hours. Maternal corticosteroid therapy generally has no effect on fetal platelets. Fetal blood
sampling for platelet determination is seldom necessary, and platelets are usually adequate to prevent fetal hemorrhage during delivery (Chap. 56, p. 1115).

Alloimmune Thrombocytopenia

Alloimmune thrombocytopenia (AIT) or neonatal alloimmune thrombocytopenia (NAIT) is caused by maternal-fetal platelet antigen disparity. If maternal alloimmunization is stimulated, then transplacental antiplatelet IgG antibodies cause severe fetal thrombocytopenia, which is considered in detail in Chapter 15 (p. 313).

Preeclampsia Syndrome

Maternal platelet function and destruction can be severely affected in women with severe preeclampsia. That said, fetal or neonatal thrombocytopenia is rarely caused by the preeclampsia syndrome even when the mother has severe thrombocytopenia. The large study of mother-infant pairs delivered at Parkland Hospital dispelled earlier reports of an association of neonatal thrombocytopenia with preeclampsia (Pritchard, 1987). Instead, neonatal thrombocytopenia was found to be associated with preterm delivery and its myriad complications (Chap. 34, p. 653).

INJURIES OF THE NEWBORN

Birth injuries can potentially complicate any delivery. Thus, although some are more likely associated with “traumatic” delivery by forceps or vacuum, others are seen with otherwise uncomplicated vaginal or cesarean delivery. In this section, some injuries are discussed in general, but specific injuries are described elsewhere in connection with their associated obstetrical complications, for example, breech delivery in Chapter 28 or multifetal gestation in Chapter 45.

Incidence

In three population studies that included more than 8 million term infants, the overall incidence of birth trauma was 20 to 26 per 1000 deliveries (Baskett, 2007; Linder, 2012; Moczygemba, 2010). Of these studies, data from Nova Scotia are shown in Table 33-4 with an overall trauma risk of 19.5 per 1000 deliveries. Only 1.6 per 1000 were due to major trauma, and these rates were highest with failed instrumented delivery and lowest with cesarean delivery without labor. Thus, most traumatic injuries were minor and had an incidence of 18 per 1000 deliveries.
Injuries associated with cesarean delivery from a Maternal-Fetal Medicine Units Network study were described by Alexander and coworkers (2006). Four hundred injuries were identified from a total of 37,100 operations—a rate of 11 per 1000 cesarean deliveries. Although skin lacerations predominated—7 per 1000—more serious injuries in these 400 infants included 88 cephalohematomas, 11 clavicular fractures, 11 facial nerve palsies, nine brachial plexopathies, and six skull fractures.

<sup>a</sup>Major trauma = depressed skull fracture, intracranial hemorrhage, brachial plexopathy, or combination.

<sup>b</sup>Minor trauma = linear skull fracture, other fractures, facial palsy, cephalohematoma, or combination.

Data from Baskett, 2007.

Injuries associated with cesarean delivery from a Maternal-Fetal Medicine Units Network study were described by Alexander and coworkers (2006). Four hundred injuries were identified from a total of 37,100 operations—a rate of 11 per 1000 cesarean deliveries. Although skin lacerations predominated—7 per 1000—more serious injuries in these 400 infants included 88 cephalohematomas, 11 clavicular fractures, 11 facial nerve palsies, nine brachial plexopathies, and six skull fractures.

### Cranial Injuries

Traumatic head injuries that are associated with labor or delivery can be external and obvious, such as a skull or mandibular fracture; they can be intracranial; and in some, they are covert. The fetal head has considerable plasticity and can undergo appreciable molding. Rarely, severe molding can result in tearing of bridging cortical veins that empty into the sagittal sinus, internal cerebral veins, the vein of Galen, or of the tentorium itself. As a result, intracranial, subdural, and even epidural hemorrhage can be seen after an apparently uneventful vaginal delivery (Scheibl, 2012). Bleeding may also be asymptomatic. Conversely, subgaleal hemorrhages associated with instrumented delivery can be life threatening (Doumouchtsis, 2008; Swanson, 2012). In rare severe head trauma cases, there is embolization of fetal brain tissue to the heart or lungs (Cox, 2009).
Intracranial Hemorrhage

Most aspects of neonatal intracranial hemorrhage are related to gestational age. Specifically, most hemorrhage in preterm neonates results from hypoxia and ischemia, whereas in term newborns, trauma is the most frequent cause. Some varieties are shown in Table 33-5. Importantly, in some infants, a putative cause is not found. In many cases, intracranial hemorrhage is asymptomatic. The reported incidence varies, but it is highest with operative deliveries—both vaginal and cesarean deliveries. In the study by Moczygemba and colleagues (2010), for more than 8 million singleton deliveries, the overall intracranial hemorrhage rate was approximately 0.2 per 1000 births—1 per 5000. In a study from New York City, Werner and associates (2011) cited a combined incidence in more than 120,000 nulliparous singleton operative deliveries of 0.12 percent, or about 1 in 750 procedures. The rates of intracranial hemorrhage were 1:385 with vacuum delivery; 1:515 with forceps, and 1:1210 with cesarean delivery. In another study, its incidence was nearly 1 percent following vacuum-assisted deliveries (Simonson, 2007). According to the American College of Obstetricians and Gynecologists (2012a), the incidence of intracranial hemorrhage from birth trauma has been substantively decreased by elimination of difficult operative vaginal deliveries. This was verified in a recent report of carefully conducted Kielland forceps deliveries (Burke, 2012).

*AVM = arteriovenous malformation; SAH = subarachnoid hemorrhage.*

Data from Volpe, 1995.

The prognosis after hemorrhage depends on its location and extent, as shown in Table 33-5. For example, subdural and subarachnoid hemorrhage seldom results in neurological abnormalities, whereas large hematomas are serious. Any bleeding into the parenchyma from intraventricular or intracerebellar hemorrhage often causes serious permanent damage or death. Periventricular hemorrhage rarely causes the type of sequelae that are common in those born preterm (Chap. 34, p. 656).

Infants who have traumatic subdural or infratentorial hemorrhage tears will have neurological abnormalities from the time of birth (Volpe, 1995). Those most severely affected have stupor or coma, nuchal rigidity, and opisthotonos that worsen over minutes to hours. Some newborns who are born depressed appear to improve until about 12 hours of age, when drowsiness, apathy, feebler cry, pallor, failure to nurse, dyspnea, cyanosis, vomiting, and convulsions become evident.

Spontaneous intracranial hemorrhage has also been documented in healthy term neonates (Huang, 2004; Rutherford, 2012). In a prospective MR imaging study, Whitby and coworkers (2004) found that 6 percent of those delivered spontaneously and 28 percent of those delivered by forceps had a subdural hemorrhage. None of these had clinical findings, and hematomas resolved by 4 weeks in all infants.
Extracranial Hematomas

These blood collections accumulate outside the calvarium and are categorized as a cephalohematoma or subgaleal hemorrhage (Fig. 33-1). From its most superficial inward, the scalp is composed of skin, subcutaneous tissue, galea aponeurotica, subgaleal space, and calvarium periosteum. The galea aponeurotica is dense fibrous tissue, whereas the subgaleal space contains loose, fibroareolar tissue. Traversing across the subgaleal space are large, valveless emissary veins, which connect the dural sinuses inside the skull with the superficial scalp veins. Both the galea aponeurotica and subgaleal space span across the occipital, parietal, and frontal bones. In contrast, periosteum invests each individual skull bone and does not cross suture lines.

Cephalohematomas are cranial subperiosteal hematomas. These develop from shearing forces during labor and delivery that lacerate the emissary or diploic veins. Fortunately, the densely adhered periosteum impedes rapid enlargement and limits final hematoma size. Hemorrhage can be over one or both parietal bones, but palpable edges can be appreciated as the blood reaches the
limits of the periosteum. These hematomas must be differentiated from *caput succedaneum*, also shown in Figure 33-1. A cephalohematoma may not be apparent until hours after delivery, when bleeding sufficient to raise the periosteum has occurred. After it is identified, it often grows larger and persists for weeks or even months, and bleeding may be sufficient to cause anemia. By contrast, with caput succedaneum, swelling of the scalp causes edema that overlies the periosteum. The caput is maximal at birth, rapidly grows smaller, and usually disappears within hours or a few days. Occasionally, it becomes infected, and abscess may form (Kersten, 2008).

Cephalohematomas are common, and in the study from Nova Scotia shown in Table 33-3, these accounted for 80 percent of traumatic injuries with an incidence of 16 per 1000 (Baskett, 2007). They rarely develop in the absence of birth trauma, and an 11-percent incidence was reported in 913 term infants delivered by vacuum extraction (Simonson, 2007). In the Network study of cesarean delivery outcomes cited above, the incidence of cephalohematoma was 2.4 per 1000 operations (Alexander, 2006). Others have reported lower incidences, although cephalohematoma is more common with vacuum compared with forceps deliveries—0.8 versus 2.7 per 1000 operative deliveries (Werner, 2011).

Subgaleal hemorrhage results from laceration of one of the emissary veins, with bleeding between the galea aponeurotica and the skull periosteum. Because of its loose areolar tissue and large surface area, significant blood volumes can collect in this potential space and can extend from the neck to the orbits and laterally to the temporal fascia above the ears. Resulting hypotension can lead to significant morbidity, and cited mortality rates range from 12 to 18 percent (Chang, 2007; Kilani, 2006).

**Skull Fractures**

These are rare but are especially worrisome because of their association with serious intracranial hemorrhages as discussed above. Volpe (1995) considers three types of skull injuries to be fractures—linear and depressed fractures and occipital osteodiastasis. In a French study of nearly 2 million deliveries from 1990 to 2000, the incidence of skull fractures was reported to be 3.7 per 100,000 births, and 75 percent were associated with operative vaginal deliveries (Dupuis, 2005). These are occasionally seen with spontaneous or cesarean delivery such as the depressed skull fracture shown in Figure 33-2. These latter fractures are more common when the head is tightly wedged in the pelvis. In such cases, there are at least three possible causes. A fracture may result from skull compression against the sacral promontory, by hand pressure used to lift the head at cesarean delivery, or from transvaginally applied upward hand pressure by an assistant. Fractures are managed with surgical decompression, although spontaneous resolution can follow (Basaldella, 2011).
FIGURE 33-2 Depressed skull fracture (arrow) evident immediately after cesarean delivery. Labor had progressed, and the head was deep in the pelvis. Dislodgment of the head from the birth canal was performed by an assistant using manual pressure upward through the vagina.

### Spinal Cord Injury

Overstretching of the spinal cord and associated hemorrhage and edema are rare injuries. They are usually caused by excessive longitudinal or lateral traction of the spine or by torsion during delivery. In some cases, there is fracture or dislocation of the vertebrae. Menticoglou and associates (1995) described 15 neonates with this type of high cervical spinal cord injury and found that all of the injuries were associated with forceps rotations. Spinal cord injury also can occur during breech delivery. Ross and coworkers (2006) described C5–6 vertebral dislocation associated with a Zavanelli maneuver done because of shoulder dystocia (Chap. 27, p. 544).

### Peripheral Nerve Injuries

Traumatic injuries to nerves can be serious and distressing, especially if permanent. Injury can involve a single nerve, or it can affect a nerve root, plexus, or trunk (Volpe, 1995).

### Brachial Plexopathy

Injuries to the brachial plexus are relatively common. They are identified in 1 to 3 per 1000 term births (Baskett, 2007; Joyner, 2006; Lindqvist, 2012). In the study of more than 8 million singleton births reported by Moczygemba and colleagues (2010), the incidence of brachial nerve injury was 1.5 per 1000 vaginal deliveries and 0.17 per 1000 cesarean deliveries. Breech delivery and shoulder dystocia are risks for this trauma. However, severe plexopathy may also occur without risk factors or shoulder dystocia (Torki, 2012).
The injury with plexopathy is actually to the nerve roots that supply the brachial plexus—C₅–₈ and T₁. With hemorrhage and edema, axonal function may be temporarily impaired, but the recovery chances are good. However, with avulsion, the prognosis is poor. In 90 percent of cases, there is damage to the C₅–₆ nerve roots causing Erb or Duchenne paralysis (Volpe, 1995). Injuries with breech delivery are normally of this type, whereas the more extensive lesions follow difficult cephalic deliveries (Ubachs, 1995). The C₅–₆ roots join to form the upper trunk of the plexus, and injury leads to paralysis of the deltoid, infraspinatus, and flexor muscles of the forearm. The affected arm is held straight and internally rotated, the elbow is extended, and the wrist and fingers flexed. Finger function usually is retained. Because lateral head traction is frequently employed to effect delivery of the shoulders in normal vertex presentations, most cases of Erb paralysis follow deliveries that do not appear difficult. Damage to the C₈-T₁ roots supplying the lower plexus results in Klumpke paralysis, in which the hand is flaccid. Total involvement of all brachial plexus nerve roots results in flaccidity of the arm and hand, and with severe damage, there may also be Horner syndrome.

Unfortunately, as discussed in Chapter 27 (p. 541), shoulder dystocia cannot be accurately predicted. In most cases, axonal death does not occur and the prognosis is good. Lindqvist and associates (2012) reported complete recovery in 86 percent of children with C₅–₆ trauma, which was the most common injury, and in 38 percent of those with C₅–₇ damage. However, those with global C₅–₈-T₁ injuries always had permanent disability. Surgical exploration and possible repair may improve function if there is persistent paralysis (Malessy, 2009).

Facial Paralysis

Trauma to the facial nerve commonly occurs as it emerges from the stylomastoid foramen, and this can cause facial paralysis (Fig. 33-3). The incidence, which ranges from 0.2 to 7.5 per 1000 term births, is likely influenced by the vigor with which the diagnosis is sought (Al Tawil, 2010; Moczygemba, 2010). Facial paralysis may be apparent at delivery or may develop shortly after birth. It most frequently is associated with uncomplicated vaginal delivery. However, in one series, a fourth of cases followed cesarean delivery (Alexander, 2006; Al Tawil, 2010; Moczygemba, 2010). Facial nerve damage is likely more common with low forceps (Hagadorn-Freathy, 1991; Levine, 1984). It is possible that damage is caused by pressure exerted by the posterior blade when forceps have been placed obliquely on the fetal head. In these cases, forceps marks indicate the cause of injury. Spontaneous recovery within a few days is the rule, however, permanent paralysis has been described (Al Tawil, 2010; Duval, 2009).
Fractures

Most long-bone fractures follow difficult deliveries, however, this is not always the case. At minimum, palpation of the clavicles and long bones is indicated for all newborns after a difficult delivery. Crepititation or unusual irregularity should prompt radiographic examination.

Clavicular fractures are common, unpredictable, and unavoidable complications of normal birth. Their incidence averages 5 to 10 per 1000 live births (Linder, 2012; Moczygemba, 2010). Other than female gender, no specific risk factors—including birthweight and mode of delivery—have been identified.

Humeral fractures are infrequent, and 70 percent follow an uneventful birth (Turpenny, 1993). Others are associated with difficult delivery of the shoulders in cephalic deliveries and of an extended arm in breech deliveries. Radiographically, they are often of the greenstick type, although complete fracture with overriding bones can be seen. Sonography has also been used to confirm diagnosis (Sherr-Lurie, 2011).

Femoral fractures are relatively rare and usually are associated with vaginal breech delivery. They occasionally follow cesarean delivery, and in one report, they were bilateral (Cebesoy, 2009). Because most breech-presenting fetuses now undergo cesarean delivery, most of these fractures are associated with this mode (Alexander, 2006; Cebesoy, 2009).

Mandibular fractures have been reported, are rare, and have been reviewed by Vasconcelos and coworkers (2009). The rare cases of cervical vertebral dislocation in fetuses delivered as breech or after the Zavanelli maneuver are discussed above (Ross, 2006).

Muscle Injuries
Sternocleidomastoid muscle injury was usually seen with vaginal breech delivery (Roemer, 1954). Hematomas of the muscle or the fascial sheath may resolve slowly with cicatrical contraction. With normal neck growth, the less-elastic damaged muscle does not elongate appropriately. As a result, the head is gradually turned toward the side of the injury—torticollis.

**Soft Tissue Injuries**

Conceivably, any fetal organ or part could be injured with either vaginal or cesarean delivery. Some of these include subcapsular hepatic hematomas that presented as inguinal and scrotal hematoma. In such cases, ecchymoses of the inguinal region are termed *Stabler sign*, and those of the scrotum are termed *Bryant sign* (Heyman, 2011; Lee, 2011). Thymic gland traumatic hemorrhage in those with underlying hyperplasia or cyst has been described before, during, and after delivery (Eifinger, 2007; Saksenberg, 2001). Injuries to the sixth cranial nerve with resultant lateral rectus ocular muscle paralysis have also been reported following operative vaginal delivery (Galbraith, 1994).

**Congenital Deformity Injuries**

There are several injuries creating morphological defects that the fetus can sustain long before delivery. One is the amnionic band syndrome caused when a free strip of amnion forms a focal ring around an extremity or digit. Eventually, deformation or amputation may result. Occasionally, the amputated part may be found within the uterus. The genesis of such bands is debated and discussed in Chapter 6 (p. 121). A similar anomaly is a *limb-reduction defect* associated with chorionic villus sampling performed before 9 weeks’ gestation as discussed in Chapter 14 (p. 300).

Various congenital postural anomalies form when a normally developed fetal structure becomes deformed by intrauterine mechanical factors. Examples of the latter include chronic oligohydramnios, restricted fetal movement imposed by an abnormally shaped or small uterine cavity, or by the presence of additional fetuses. Some mechanical deformations include talipes equinovarus (clubfoot), scoliosis, and hip dislocation (Miller, 1981). Talipes and other positional foot abnormalities are associated with membrane rupture from early amniocentesis between 11 and 13 weeks’ gestation (Chap. 14, p. 299). Finally, somewhat related, hypoplastic lungs also can result from oligohydramnios (Chap. 11, p. 237).

The preterm infant is susceptible to various serious medical complications during the newborn period as well as morbidities extending later into life (Table 34-1). These complications are primarily the consequence of immature organs that result from abbreviated gestation. A less commonly cited cause of morbidity and mortality is congenital malformations, which are much more prevalent in preterm births. For example, between 2010 and 2013 at Parkland Hospital, major malformations were diagnosed in 67 per 1000 singleton births < 37 weeks’ gestation. This compared with 15 per 1000 in those ≥ 38 weeks—an almost fivefold excess. The pivotal complication, however, is respiratory distress syndrome (RDS). This results from immature lungs that are unable to sustain necessary oxygenation. Resulting hypoxia is an underlying associated cause of neurological damage such as cerebral palsy. In addition, hyperoxia, a side effect of RDS treatment, causes bronchopulmonary dysplasia and retinopathy of prematurity. These complications of prematurity can be placed in perspective in terms of the human consequences. In 2009, two thirds of all infant deaths in the United States were in the 12 percent of infants who were born < 37 weeks (Mathews, 2013).

**TABLE 34-1. Complications of Prematurity**

Respiratory distress syndrome (RDS, HMD)
Bronchopulmonary dysplasia (BPD)
Pneumothorax
Pneumonia/sepsis
Patent ductus arteriosus (PDA)
RESPIRATORY DISTRESS SYNDROME

To provide blood gas exchange immediately following delivery, the lungs must rapidly fill with air while being cleared of fluid. Concurrently, pulmonary arterial blood flow must increase remarkably. Some of the fluid is expressed as the chest is compressed during vaginal delivery, and the remainder is absorbed through the pulmonary lymphatics. Sufficient surfactant, synthesized by type II pneumocytes, is essential to stabilize the air-expanded alveoli. It lowers surface tension and thereby prevents lung collapse during expiration (Chap. 7, p. 142). If surfactant is inadequate, hyaline membranes form in the distal bronchioles and alveoli, and RDS develops. Although respiratory insufficiency is generally a disease of preterm neonates, it does develop in term newborns, especially with sepsis or meconium aspiration.

Clinical Course

In typical RDS, tachypnea develops, the chest wall retracts, and expiration is accompanied by grunting and nostril flaring. Shunting of blood through nonventilated lung contributes to hypoxemia and metabolic and respiratory acidosis. Poor peripheral circulation and systemic hypotension may be evident. The chest radiograph shows a diffuse reticulogranular infiltrate and an air-filled tracheobronchial tree—air bronchogram.

As discussed further in Chapter 33 (p. 637), respiratory insufficiency can also be caused by sepsis, pneumonia, meconium aspiration, pneumothorax, persistent fetal circulation, heart failure, and malformations involving thoracic structures, such as diaphragmatic hernia. Evidence is also accruing that common mutations in surfactant protein production may cause RDS (Garmany, 2008; Shulenin, 2004).

Pathology

With inadequate surfactant, alveoli are unstable, and low pressures cause collapse at end expiration. Pneumocyte nutrition is compromised by hypoxia and systemic hypotension. Partial persistence of the fetal circulation may lead to pulmonary hypertension and a relative right-to-left shunt. Eventually, alveolar cells undergo ischemic necrosis. When oxygen therapy is initiated, the pulmonary vascular bed dilates, and the shunt reverses. Protein-filled fluid leaks into the alveolar ducts, and the cells lining the ducts slough. Hyaline membranes composed of fibrin-rich protein and cellular debris line the dilated alveoli and terminal bronchioles. The epithelium underlying the membrane becomes necrotic. With hematoxylin-eosin staining, these membranes appear amorphous and eosinophilic, like hyaline cartilage. Because of this, respiratory distress in the newborn is also termed hyaline membrane disease.
Treatment

The most important factor influencing survival is neonatal intensive care. Although hypoxemia prompts supplemental oxygen, excess oxygen can damage the pulmonary epithelium and the retina. However, advances in mechanical ventilation technology have improved neonatal survival rates. For example, *continuous positive airway pressure (CPAP)* prevents the collapse of unstable alveoli. This allows high inspired-oxygen concentrations to be reduced, thereby minimizing its toxicity. Disadvantages include overstretch of the endothelium and epithelium, which results in barotrauma and impaired venous return (Verbrugge, 1999). *High-frequency oscillatory ventilation* may reduce the barotrauma risk by using a constant, low-distending pressure and small oscillations to promote alveolar patency. This technique allows optimal lung volume to be maintained and carbon dioxide to be cleared without damaging alveoli. Although mechanical ventilation has undoubtedly improved survival rates, it is also an important factor in the genesis of chronic lung disease—*bronchopulmonary dysplasia*.

Treatment of the ventilator-dependent neonate with *glucocorticoids* was used previously to prevent chronic lung disease. The American Academy of Pediatrics now recommends against their use because of limited benefits and increased adverse neuropsychological effects (Watterberg, 2010). Yeh and colleagues (2004) described significantly impaired motor and cognitive function and school performance in exposed neonates. A review by Halliday and associates (2009) supports late postnatal corticosteroid treatment only for infants who could not be weaned from mechanical ventilation. In some studies, *inhaled nitric oxide* was shown to be associated with improved outcomes for neonates undergoing mechanical ventilation (Ballard, 2006; Kinsella, 2006; Mestan, 2005). Other studies showed no benefits (van Meurs, 2005). Currently, such treatment is considered investigational (Chock, 2009; Stark, 2006).

Surfactant Prophylaxis

Exogenous surfactant products can prevent RDS. They contain biological or animal surfactants such as bovine—*Survanta*, calf—*Infasurf*, porcine—*Curosurf*, or synthetic—*Exosurf*. Lucinactant—*Surfaxin R*—is a synthetic form that contains simulpeptide KL4 to diminish lung inflammation (Zhu, 2008). In a Cochrane review, Pfister and coworkers (2007) found that animal-derived and synthetic surfactants were comparable.

Surfactant therapy has been credited with the largest drop in infant mortality rates observed in 25 years (Jobe, 1993). It has been used for *prophylaxis* of preterm, at-risk newborns and for *rescue* of those with established disease. Given together, antenatal corticosteroids and surfactant result in an even greater reduction in the overall death rate. In their review, Seger and Soll (2009) found that infants who received prophylactic surfactant had decreased risks of pneumothorax, pulmonary interstitial emphysema, bronchopulmonary dysplasia, and mortality.

Complications

Persistent hyperoxia injures the lung, especially the alveoli and capillaries. High oxygen concentrations given at high pressures can cause *bronchopulmonary dysplasia*. With this, alveolar and bronchiolar epithelial damage leads to hypoxia, hypercarbia, and chronic oxygen dependence from peribronchial and interstitial fibrosis. According to Baraldi and Filippone (2007), most cases are now seen in infants born before 30 weeks’ gestation and represent a developmental disorder secondary to alveolarization injury. Severe disease and death rates are decreasing, however, long-term pulmonary dysfunction is encountered later. *Pulmonary hypertension* is
another frequent complication. If hyperoxemia is sustained, the infant also is at risk of developing retinopathy of prematurity, formerly called retrolental fibroplasia (p. 656). When any of these develop, the likelihood of subsequent neurosensory impairment is substantively increased (Schmidt, 2003).

### Prevention

#### Antenatal Corticosteroids

The National Institutes of Health (1994, 2000) concluded that a single course of antenatal corticosteroid therapy reduced respiratory distress and intraventricular hemorrhage in preterm infants born between 24 and 34 weeks (p. 657). The American College of Obstetricians and Gynecologists and American Academy of Pediatrics (2012) considers all women at risk for preterm birth in this gestational-age range to be potential candidates for therapy. This is discussed further in Chapter 42 (p. 850). After 34 weeks, approximately 4 percent of infants develop respiratory distress syndrome (Consortium on Safe Labor, 2010).

#### Amniocentesis for Fetal Lung Maturity

Delivery for fetal indications is necessary when the risks to the fetus from a hostile intrauterine environment are greater than the risk of severe neonatal problems, even if the fetus is preterm. If this degree of risk is absent and the criteria for elective delivery at term are not met, then amniocentesis and amniotic fluid analysis can be used to confirm fetal lung maturity. To accomplish this, there are several methods to determine the relative concentration of surfactant-active phospholipids in amniotic fluid. Fluid acquisition is similar to that described for second-trimester amniocentesis (Chap. 16, p. 297). With this sampling, complications requiring urgent delivery arise in up to 1 percent of procedures (American College of Obstetricians and Gynecologists, 2008). Following analysis, the probability of respiratory distress developing in a given infant depends on the test used and fetal gestational age. Importantly, administration of corticosteroids to induce pulmonary maturation has variable effects on some of these tests.

#### Lecithin–Sphingomyelin (L/S) Ratio

Although not used nearly as much as in the past, the labor-intensive L/S ratio for many years was the gold-standard test. Dipalmitoylphosphatidylcholine (DPPC), that is, lecithin—along with phosphatidylinositol and especially phosphatidylglycerol (PG)—is an important component of the surface-active layer that prevents alveolar collapse (Chap. 32, p. 624). Before 34 weeks, lecithin and sphingomyelin are present in amniotic fluid in similar concentrations. At 32 to 34 weeks, the concentration of lecithin relative to sphingomyelin begins to rise (Fig. 34-1).
Gluck (1971) reported that the risk of neonatal respiratory distress is slight whenever the concentration of lecithin is at least twice that of sphingomyelin—the L/S ratio. Conversely, there is increased risk of respiratory distress when this ratio is < 2. Because lecithin and sphingomyelin are found in blood and meconium, contamination with these substances may falsely lower a mature L/S ratio.

### Phosphatidylglycerol

Previously, respiratory distress was thought to develop despite an L/S ratio > 2 in infants of women with diabetes. Some recommend that phosphatidylglycerol be documented in amnionic fluid of these women. Based on current evidence, it is unclear if either diabetes, per se, or its level of control causes false-positive phospholipid test results for fetal lung maturity (American College of Obstetricians and Gynecologists, 2008).

### Fluorescence Polarization

This automated assay measures the surfactant-to-albumin ratio in uncentrifuged amnionic fluid and gives results in approximately 30 minutes. A ratio of ≥ 50 with the commercially available *TDx-FLM* test predicted fetal lung maturity in 100 percent of cases (Steinfeld, 1992). Subsequent investigators found the TDx-FLM to be equal or superior to the L/S ratio, foam stability index, or phosphatidylglycerol assessment, including testing in diabetic pregnancies (Eriksen, 1996; Karcher, 2005). The recently modified *TDx-FLM II* is used by many hospitals as their primary test of pulmonary maturity, with a threshold ratio of 55 mg/g.

### Other Tests

The foam stability or shake test depends on the ability of surfactant in amnionic fluid, when mixed appropriately with ethanol, to generate stable foam at the air–liquid interface (Clements, 1972). Problems include errors caused by slight contamination and frequent false-negative test results. Alternatively, the Lumadex-FSI test, fluorescent polarization (microviscometry), and amnionic fluid absorbance at 650-nm wavelength have all been used with variable success. The lamellar body count is a rapid, simple, and accurate method of
assessing fetal lung maturity and is comparable to TDx-FLM and L/S ratio (Karcher, 2005).

NECROTIZING ENTEROCOLITIS

This newborn bowel disorder has clinical findings of abdominal distention, ileus, and bloody stools. There is usually radiological evidence of pneumatosis intestinalis—bowel wall gas derived from invading bacteria. Bowel perforation may prompt resection. Necrotizing enterocolitis is seen primarily in low-birthweight newborns but occasionally is encountered in mature neonates. Various hypothesized causes include perinatal hypotension, hypoxia, sepsis, umbilical catheterization, exchange transfusions, and the feeding of cow milk and hypertonic solutions (Kliegman, 1984). All of these can ultimately lead to intestinal ischemia, and reperfusion injury likely also has a role (Czyrko, 1991). The unifying hypothesis for these pathological processes is the uncontrolled inflammatory response to bacterial colonization of the preterm intestine (Grave, 2007).

Treatment for necrotizing enterocolitis is controversial (van Vliet, 2013). A randomized trial of laparotomy versus peritoneal drainage found no difference in survival rates in preterm infants (Moss, 2006). In an observational study, however, Blakely (2006) found that death rates and neurodevelopmental outcomes assessed at 18 to 22 months were more favorable with laparotomy compared with drainage.

RETINOPATHY OF PREMATURITY

Formerly known as retrolental fibroplasia, by 1950, retinopathy of prematurity had become the largest single cause of blindness in this country. After the discovery that the disease resulted from hyperoxemia, its frequency decreased remarkably. The fetal retina vascularizes centrifugally from the optic nerve starting at approximately the fourth month and continues until shortly after birth. During vascularization, excessive oxygen induces severe retinal vasoconstriction with endothelial damage and vessel obliteration, especially in the temporal portion. Neovascularization results, and the new vessels penetrate the retina and extend into the vitreous. Here, they are prone to leak proteins or burst with subsequent hemorrhage. Adhesions then form, which detach the retina.

Precise levels of hyperoxemia that can be sustained without causing retinopathy are not known. Preterm birth results in a “relative” hyperoxia compared with in utero oxygen content even in infants not exposed to higher FiO₂. To better understand the oxygen saturation threshold necessary to minimize retinopathy without increasing other adverse outcomes, the National Institute of Child Health and Human Development (NICHD) Neonatal Network performed a randomized trial of oxygenation in 1316 infants born between 24 and 27 weeks (SUPPORT Study Group, 2010). The target range of oxygen saturation was 85 to 89 percent in one arm of this trial and 91 to 95 percent in the other arm. Death before discharge occurred significantly more frequently in the lower-oxygen saturation group—20 versus 16 percent. However, severe retinopathy among survivors developed significantly less often in the lower-oxygen saturation group—8.6 versus 17.9 percent. This study generated considerable controversy as to whether the consent process was adequate for a trial with such end points (Drazen, 2013).
Central nervous system injury in preterm infants usually creates different neuroanatomical sequelae compared with that in term infants (Chap. 33, p. 639). In preterm infants, cerebral lesions detected by neuroimaging include intraventricular hemorrhage, periventricular hemorrhagic infarction, cystic periventricular leukomalacia, and diffuse white matter injury. All of these are strongly associated with adverse neurodevelopmental outcome. Locatelli and colleagues (2010) found a significantly increased incidence of neurological damage in preterm infants who had periventricular hemorrhage, periventricular leukomalacia, or both.

Cranial sonography remains the preferred approach for detecting frequently occurring brain abnormalities and acute events. It is readily available and reliable for detecting common abnormalities and monitoring brain growth. Because cystic injuries may take 2 to 5 weeks to evolve, serial scans are obtained during this time. In infants whose findings are transient and resolve in the neonatal period, prognosis is improved compared with those whose lesions remain and evolve. At the same time, however, between 4 and 10 percent of prematurely born children may develop cerebral palsy in the absence of lesions. Put another way, 90 to 96 percent of preterm infants with cerebral palsy have cerebral lesions that are detectable using cranial sonography.

**Intracranial Hemorrhage**

There are four major categories of intracranial hemorrhage in the neonate (Volpe, 1995). *Subdural hemorrhage* is usually the result of trauma. *Subarachnoid hemorrhage* and *intracerebellar hemorrhage* usually result from trauma in term infants and hypoxia in preterm infants. *Periventricular-intraventricular hemorrhage* results from either trauma or asphyxia in half of term infants and has no discernible cause in a fourth. In preterm neonates, the pathogenesis of periventricular hemorrhage is multifactorial and includes hypoxic-ischemic events, anatomical factors, coagulopathy, and many others. The prognosis after hemorrhage depends on its location and extent. For example, subdural and subarachnoid hemorrhage often result in minimal, if any, neurological abnormalities. Bleeding into the parenchyma, however, can cause serious permanent damage.

**Periventricular–Intraventricular Hemorrhage**

When the fragile capillaries in the germinal matrix rupture, there is bleeding into surrounding tissues that may extend into the ventricular system and brain parenchyma. This type of hemorrhage is common in preterm neonates, especially those born before 32 weeks. However, it can also develop at later gestational ages and even in term neonates. Most hemorrhages develop within 72 hours of birth, but they have been observed as late as 24 days (Perlman, 1986). Because intraventricular hemorrhage usually is recognized within 3 days of delivery, its genesis is often erroneously attributed to birth events. It is important to realize that *prelabor* intraventricular hemorrhage also can occur (Achiron, 1993; Nores, 1996).

Almost half of hemorrhages are clinically silent, and most small germinal matrix hemorrhages and those confined to the cerebral ventricles resolve without impairment (Weindling, 1995). Large lesions can result in hydrocephalus or in degenerated cystic areas termed *periventricular leukomalacia* (p. 657). Importantly, the extent of periventricular leukomalacia correlates with cerebral palsy risk.
Pathology. Damage to the germinal matrix capillary network predisposes to subsequent extravasation of blood into the surrounding tissue. In preterm infants, this capillary network is especially fragile for several reasons. First, the subependymal germinal matrix provides poor support for the vessels coursing through it. Second, venous anatomy in this region causes stasis and congestion, which makes vessels susceptible to bursting with increased intravascular pressure. Third, vascular autoregulation is impaired before 32 weeks (Matsuda, 2006; Volpe, 1987). Even if extensive hemorrhage or other complications of preterm birth do not cause death, survivors can have major neurodevelopmental handicaps. DeVries and associates (1985) attribute most long-term sequelae of intraventricular-periventricular hemorrhage to periventricular leukomalacia. These degenerated cystic areas develop most commonly as a result of ischemia and least commonly in direct response to hemorrhage.

Incidence and Severity. The incidence of ventricular hemorrhage depends on gestational age at birth. Approximately half of all neonates born before 34 weeks, but only 4 percent of those born at term, will have some evidence of hemorrhage (Hayden, 1985). Very-low-birthweight infants have the earliest onset of hemorrhage, the greatest likelihood of parenchymal tissue involvement, and thus the highest mortality rate (Perlman, 1986). Preterm black infants are at disparate risk for intraventricular hemorrhage (Reddick, 2008).

The severity of intraventricular hemorrhage can be assessed by neuroimaging studies. Papile and coworkers (1978) devised the most widely used grading scheme to quantify the extent of a lesion and estimate prognosis.

Grade I—hemorrhage limited to the germinal matrix
Grade II—intraventricular hemorrhage
Grade III—hemorrhage with ventricular dilatation
Grade IV—parenchymal extension of hemorrhage

Data from the Neonatal Research Network indicate that 30 percent of infants born weighing 501 to 1500 g develop intracranial hemorrhage, and 12 percent are grade III or IV (Fanaroff, 2007). Jakobi and associates (1992) showed that infants with grade I or II intraventricular hemorrhage had a greater than 90-percent survival rate and a 3-percent rate of handicap—similar to control infants without hemorrhage of the same age. The survival rate for infants with grade III or IV hemorrhage, however, was only 50 percent. Extremely-low-birthweight infants with grade I or II hemorrhage have poorer neurodevelopmental outcomes at 20 months than controls (Patra, 2006).

Contributing Factors. Events that predispose to germinal matrix hemorrhage and subsequent periventricular leukomalacia are multifactorial and complex. As noted, the preterm fetus has fragile intracranial blood vessels that make it particularly susceptible. Moreover, preterm birth is frequently associated with infection, which further predisposes to endothelial activation, platelet adherence, and thrombi (Redline, 2008). RDS and mechanical ventilation are commonly associated factors (Sarkar, 2009).

Prevention with Antenatal Corticosteroids. These agents, given at least 24 hours before delivery, appear to prevent or reduce intraventricular hemorrhage incidence and severity. A Consensus Development Conference of the National Institutes of Health (1994) concluded that such therapy reduced rates of mortality, respiratory distress, and intraventricular hemorrhage in preterm infants born between 24 and 32 weeks and that the benefits were additive with those from surfactant therapy. The consensus panel also concluded that benefits of antenatal corticosteroid...
therapy probably extend to women with preterm premature membrane rupture. A second consensus statement by the National Institutes of Health (2000) recommended that repeated courses of corticosteroids should not be given. They noted that there were insufficient data to prove benefit or to document the safety of multiple courses (Chap. 42, p. 850).

Subsequently, the Maternal-Fetal Medicine Units Network reported that repeated corticosteroid courses were associated with some improved preterm neonatal outcomes, but also with reduced birthweight and increased risk for fetal-growth restriction (Wapner, 2006). Surveillance of this cohort through age 2 to 3 years found that children exposed to repeated—versus single-dose—steroid courses did not differ significantly in physical or neurocognitive measures (Wapner, 2007). It was worrisome, however, that there was a nonsignificant 5.7-fold relative risk of cerebral palsy in infants exposed to multiple steroid courses. At the same time, the 2-year follow-up of the Australasian Collaborative Trial was reported by Crowther (2007). In more than 1100 infants, the incidence of cerebral palsy was almost identical—4.2 versus 4.8 percent—in those given repeated versus single-course steroids, respectively.

Other Preventative Methods. The efficacy of phenobarbital, vitamin K, vitamin E, or indomethacin in diminishing the frequency and severity of intracranial hemorrhage, when administered either to the neonate or to the mother during labor, remains controversial (Chiswick, 1991; Hanigan, 1988; Thorp, 1995). Data from various sources suggest that magnesium sulfate may prevent the sequelae of periventricular hemorrhage, as discussed on page 659.

It is generally agreed that avoiding significant hypoxia both before and after preterm delivery is paramount (Low, 1995). There is presently no convincing evidence, however, that routine cesarean delivery for the preterm fetus presenting cephalic will decrease the incidence of periventricular hemorrhage. Anderson and colleagues (1992) found no significant difference in the overall frequency of hemorrhage in infants whose birthweights were below 1750 g and who were delivered without labor compared with those delivered during latent or active labor. Infants delivered of mothers in active labor, however, tended to have more grade III or IV hemorrhages.

Periventricular Leukomalacia
This pathological description refers to cystic areas deep in brain white matter that develop after hemorrhagic or ischemic infarction. Tissue ischemia leads to regional necrosis. Because brain tissue does not regenerate and the preterm neonate has minimal gliosis, these irreversibly damaged areas appear as echolucent cysts on neuroimaging studies. Generally, they require at least 2 weeks to form but may develop as long as 4 months after the initial insult. Thus, their presence at birth may help to determine the timing of a hemorrhagic event.

Cerebral Palsy
This term refers to a group of conditions that are characterized by chronic movement or posture abnormalities that are cerebral in origin, arise early in life, and are nonprogressive (Nelson, 2003). Epilepsy and mental retardation frequently accompany cerebral palsy. The cause(s) of cerebral palsy are different in preterm and term infants (Chap. 33, p. 640).

Cerebral palsy is commonly classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—as well as the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia. The major types and their frequencies are:

1. Spastic quadriplegia, which has a strong association with mental retardation and seizure
disorders—20 percent
2. Diplegia, which is common in preterm or low-birthweight infants—30 percent
3. Hemiplegia—30 percent
4. Choreaethetoid types—15 percent
5. Mixed varieties (Freeman, 1988; Rosen, 1992).

Incidence and Epidemiological Correlates
According to the Centers for Disease Control and Prevention, the prevalence of cerebral palsy in the United States was 3.1 per 1000 children in 2000 (Bhasin, 2006). Importantly, this rate either has remained essentially unchanged or has increased since the 1950s (Torfs, 1990; Winter, 2002). In some countries, the incidence has risen because advances in the care of very preterm infants have improved their survival, but not their neurological prognosis. For example, Moster and associates (2008) presented long-term follow-up of more than 900,000 births in Norway. Of nonanomalous term infants, the cerebral palsy rate was 0.1 percent compared with 9.1 percent in those born at 23 to 27 weeks. Similarly, O’Callaghan and coworkers (2011) studied the epidemiological associations of cerebral palsy and found preterm birth to be the greatest risk factor.

Intraventricular Hemorrhage
Various clinical and pathological data link severe intraventricular hemorrhage—grade III or IV—and resulting periventricular leukomalacia to cerebral palsy. As described earlier, grade I or II hemorrhages usually resolve without extensive tissue injury. Luthy (1987) reported a 16-fold increased risk of cerebral palsy for low-birthweight infants who had grade III or IV hemorrhage compared with the risk in infants who had either no or grade I or II hemorrhage.

Ischemia
Preterm infants are most susceptible to brain ischemia and periventricular leukomalacia. Before 32 weeks, the vascular anatomy of the brain is composed of two systems. One penetrates into the cortex—the ventriculopedal system. The other reaches down to the ventricles, but then curves to flow outward—the ventriculofugal system (Weindling, 1995). There are no vascular anastomoses connecting these two systems. As a result, the area between these systems, through which the pyramidal tracts pass near the lateral cerebral ventricles, is a watershed area vulnerable to ischemia. Vascular insufficiency before 32 weeks leading to ischemia would affect this watershed area first. Resulting damage of the pyramidal tracts may cause spastic diplegia. After 32 weeks, vascular flow shifts toward the cortex. Thus, hypoxic injury after this time primarily damages the cortical region.

Perinatal Infection
Periventricular leukomalacia is more strongly linked to infection and inflammation than to intraventricular hemorrhage. Zupan and colleagues (1996) studied 753 infants born between 24 and 32 weeks, 9 percent of whom developed periventricular leukomalacia. Those born before 28 weeks, those who had inflammatory events during the last days to weeks before delivery, or those who had both were at highest risk. Perlman and associates (1996) found that periventricular leukomalacia was strongly associated with prolonged membrane rupture, chorioamnionitis, and neonatal hypotension. Bailis and coworkers (2008) reported that chronic—and not acute—placental inflammation was associated with leukomalacia.
Fetal infection may be the key element in the pathway between preterm birth and cerebral palsy (Burd, 2012; Leviton, 2010). In the pathway proposed in Figure 34-2, antenatal reproductive tract infection evokes the production of cytokines such as tumor necrosis factor and interleukins-1, -6, and -8. These in turn stimulate prostaglandin production and preterm labor (Chap. 42, p. 838). Preterm intracranial blood vessels are susceptible to rupture and damage, and the cytokines that stimulate preterm labor also have direct toxic effects on oligodendrocytes and myelin. Vessel rupture, tissue hypoxia, and cytokine-mediated damage result in massive neuronal cell death. Glutamate is released, stimulating membrane receptors to allow excess calcium to enter the neurons. High intracellular calcium levels are toxic to white matter, and glutamate may be directly toxic to oligodendrocytes (Oka, 1993).

FIGURE 34-2 Schematic representation of the hypothesized pathway between maternal or intrauterine infection and preterm birth or periventricular leukomalacia. Both potentially lead to cerebral palsy. LPS = lipopolysaccharide; PG = prostaglandin.

Many studies have shown that infection and cytokines can directly damage the immature brain. Inoculation of rabbit embryos with Escherichia coli causes histological damage in white matter (Yoon, 1997a). Moreover, tumor necrosis factor and interleukin-6 were more frequently found in the brains of infants who died with periventricular leukomalacia (Yoon, 1997b). Cytokines are strongly linked to white matter lesions even when organisms cannot be demonstrated (Yoon, 2000).

Andrews and colleagues (2008) provided data that raise questions regarding an increased
incidence of adverse neurodevelopmental outcomes related to chorioamnionitis. In a cohort of infants born between 23 and 32 weeks, they studied several surrogate indicators and direct markers of in utero inflammation. These included clinical findings, cytokine levels, histological findings, and microbial culture results. Infants undergoing comprehensive psychoneurological testing had similar incidences of intelligence quotient (IQ) scores < 70, cerebral palsy, or both, regardless of these markers. The researchers interpreted their findings to support current practices that delay delivery with preterm pregnancies in the absence of overt intrauterine infection. This does not apply to preterm pregnancy in which clinical chorioamnionitis is diagnosed (Soraisham, 2009). Of 3094 singletons born < 33 weeks, 15 percent had evidence of clinical chorioamnionitis, which included foul-smelling amniotic fluid, maternal fever, uterine tenderness, fetal tachycardia, and maternal leukocytosis. Compared with noninfected infants, cases complicated by chorioamnionitis had significantly increased rates of early-onset sepsis—4.8 versus 0.9 percent—and intraventricular hemorrhage—22 versus 12 percent.

Prevention—Neuroprotection
Because epidemiological evidence suggested that maternal magnesium sulfate therapy had a fetal neuroprotective effect, three large randomized trials have been performed to investigate this hypothesis. These studies are discussed in detail in Chapter 42 (p. 854), as well as other evidence that magnesium sulfate is effective in reducing cerebral palsy in preterm infants.

REFERENCES

Fetal mortality—the intrauterine death of a fetus at any gestational age—is considered a major but often overlooked public health issue. It is estimated that there are more than 1 million fetal losses each year in the United States, and most occur before 20 weeks’ gestation. Fetal mortality data from the National Vital Statistics system are usually presented for fetal deaths at 20 weeks’ gestation or older (MacDorman, 2012). Using this definition, there are nearly as many fetal deaths as infant deaths (Fig. 35-1). As shown in Figure 35-2, fetal deaths rates at 20 weeks or more are gestational-age related, reaching a nadir that plateaus between approximately 27 and 33 weeks. Following this, there is a progressive rate increase.
FIGURE 35-1 Percent distribution of fetal deaths at 20 weeks’ gestation or more, and infant deaths: United States 2006. (From MacDorman, 2012.)

FIGURE 35-2 Fetal mortality rate per 1000 births by single weeks of gestation: United States, 2006. (From MacDorman, 2012.)

DEFINITION OF FETAL MORTALITY
The definition of fetal death adopted by the Centers for Disease Control and Prevention National Center for Health Statistics is based on the definitions recommended by the World Health Organization (MacDorman, 2012). This definition is as follows:

Fetal death means death prior to complete expulsion or extraction from the mother of a product of human conception irrespective of the duration of pregnancy and which is not an induced termination of pregnancy. The death is indicated by the fact that after such expulsion or extraction, the fetus does not breathe or show any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles. Heartbeats are to be distinguished from transient cardiac contractions; respirations are to be distinguished from fleeting respiratory efforts or gasps.

Reporting requirements for fetal deaths are determined by each state, and thus, requirements differ significantly (Chap. 1, p. 2). Most states require reporting of fetal deaths at 20 weeks’ gestation or older or a minimum 350-g birthweight—roughly equivalent to 20 weeks—or some combination of these two. Seven states require fetal deaths before 20 weeks to be reported, and one state sets the threshold at 16 weeks. Three states require reporting of fetal deaths with birthweights 500 g or more—roughly equivalent to 22 weeks. There is substantial evidence that not all fetal deaths for which reporting is required are actually recorded (MacDorman, 2012). This is most likely at the earlier gestations of various state requirements.

The overall fetal mortality rate at 20 weeks or more for the United States has steadily declined since 1985 from 7.8 to 6.1 per 1000 total births in 2006 (MacDorman, 2012). Before this, declines were even more impressive and likely due to elimination of deaths of anomalous fetuses at later gestational ages that were “prevented” by early pregnancy terminations (Fretts, 1992).

Fetal mortality is generally divided into three periods: early, or < 20 completed weeks; intermediate, 20–27 weeks; and late, 28 weeks or more. The fetal death rate after 28 weeks has declined since 1990, whereas deaths from 20 to 27 weeks are largely unchanged (Fig. 35-3).

**FIGURE 35-3** Fetal mortality rates by period of gestation: United States, 1990–2006. (From MacDorman, 2012.)
The Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) created the Stillbirth Collaborative Research Network to ascertain stillbirth causes in racially and geographically diverse population in the United States. From this, the Stillbirth Collaborative Research Writing Group (2011b) ascertained stillbirths at 20 weeks or later between 2006 and 2008 in 59 tertiary care and community hospitals in five states. Standardized evaluations that included autopsy, placental histology, and testing of maternal or fetal blood/tissues—including fetal karyotyping—were performed in 500 women with 512 stillbirths. Of these, 83 percent were before labor and were considered antepartum stillbirths. Causes of stillbirth were divided into eight categories shown in Table 35-1. These categories were then classified as probable, possible, or unknown. As an example, diabetes was considered a probable cause if the fetus had diabetic embryopathy with lethal anomalies or the mother had diabetic ketoacidosis, but it was a possible cause if the mother had poor glycemic control and the fetus had abnormal growth. Overall, a probable or possible source was identified in 76 percent of cases.

Percentages are rounded and total more than 100 percent because some stillbirths had more than one cause. Overall, a cause was identified in 76 percent of stillbirths.

Adapted from the Stillbirth Collaborative Research Network Writing Group, 2011b.

This Network study of stillbirths is unprecedented in the United States for several reasons. It was a population-based cohort of stillbirths, all of which underwent systematic and thorough evaluation. Each cause of fetal death assigned is reasonably straightforward and comprehensible except for “placental abnormalities,” which includes “uteroplacental insufficiency” as well as a few other entities less clearly defined. This aside, the leading reasons for fetal death were obstetrical complications that primarily included abruption, multifetal gestation, and spontaneous labor or ruptured membranes before viability. The major contribution of this study was that systematic evaluation led to a likely cause in approximately three fourths of stillbirths. This rate is considerably higher than most analyses of stillbirth etiologies and serves to emphasize the
importance of careful evaluations.

**RISK FACTORS FOR FETAL DEATH**

Factors that have been associated with an increased risk of antepartum stillbirth include advanced maternal age; African-American race; smoking; illicit drug use; maternal medical diseases—such as overt diabetes or chronic hypertension; assisted reproductive technology; nulliparity; obesity; and previous adverse pregnancy outcomes—such as prior preterm birth or growth-restricted newborn (Reddy, 2010; Varner, 2014). There have been two major recent studies in which the investigators assessed whether it was possible to identify stillbirth risk factors either before or shortly after confirmation of pregnancy. Reddy and colleagues (2010) analyzed data from the NICHD Consortium on Safe Labor. Briefly, the pregnancy outcomes of 206,969 women delivered between 2002 and 2008 at 19 hospitals in the United States were analyzed. Shown in Figure 35-4 is the distribution of stillbirths according to gestational age. Clearly, the tragedy of stillbirth occurs primarily in term pregnancies. Reddy and colleagues (2010) found individual risk factors that included race, parity, advanced maternal age, and obesity performed poorly as predictors of stillbirth at term. They concluded that these results did not support routine antenatal surveillance for any of these demographic risk factors. This is discussed further subsequently.

![Graph showing distribution of live births and still births](image-url)

**FIGURE 35-4** Distribution of livebirths and stillbirths in the National Institute of Child Health and Development Safe Labor Consortium according to gestational age. (From Reddy, 2010.)

The second recent analysis of stillbirth risk factors was included in the Stillbirth Collaborative
Research Network study described earlier. Investigators studied stillbirth prediction based on risks identified in early pregnancy. They found that pregnancy factors known at the start of pregnancy accounted for a small proportion of stillbirth risk. Except for prior stillbirth or pregnancy loss such as preterm birth or fetal-growth restriction, other risks had limited predictive value (Stillbirth Collaborative Research Network Writing Group, 2011a). The importance of prior stillbirth as a risk for recurrence has been emphasized by Sharma and associates (2006). Specifically, stillbirth risk was fivefold higher in women with a prior stillbirth, and this recurrence risk was almost tripled in African-American women. Rasmussen (2009) analyzed 864,531 births in Norway between 1967 and 2005 and reported that prior preterm birth, fetal-growth restriction, preeclampsia, and placental abruption were strongly associated with subsequent stillbirth. Shown in Table 35-2 are estimates of stillbirth risk according to maternal factors including prior loss.

\(^a\)Odds ratio of the factor present compared with the risk factor absent. From Fretts, 2005, with permission.
Determining the cause of fetal death aids maternal psychological adaptation to a significant loss, helps assuage the guilt that is part of grieving, permits more accurate counseling regarding recurrence risk, and may prompt therapy or intervention to prevent a similar outcome in the next pregnancy (American College of Obstetricians and Gynecologists, 2012). Identification of inherited syndromes also provides useful information for other family members.

**Clinical Examination**

Important tests in stillbirth evaluation are neonatal autopsy and karyotyping and examination of the placenta, cord, and membranes (Pinar, 2014). An algorithm provided by the American College of Obstetricians and Gynecologists (2012) is shown in Figure 35-5. A thorough examination of the fetus, placenta, and membranes is recommended at delivery, with careful documentation in the medical record. The details of relevant prenatal events should be provided. Photographs should be taken whenever possible, and a full radiograph of the fetus—a *fetogram*—may be performed. Magnetic resonance (MR) imaging and sonography may be especially important in providing anatomical information if parents decline a full autopsy.
Laboratory Evaluation

If autopsy and chromosomal studies are performed, up to 35 percent of stillborns are discovered to
have major structural anomalies (Faye-Petersen, 1999). Approximately 20 percent have
dysmorphic features or skeletal abnormalities, and 8 percent have chromosomal abnormalities
recommends karyotyping all stillborns. Reddy and coworkers (2012) have recently reported that
microarray analysis is more likely than karyotype analysis to provide a genetic diagnosis,
primarily because of its success with nonviable tissue. In the absence of morphological anomalies,
up to 5 percent of stillborns will have a chromosomal abnormality (Korteweg, 2008).

Appropriate consent must be obtained to take fetal tissue samples, including fluid obtained
postmortem by needle aspiration. A total of 3 mL of fetal blood, obtained from the umbilical cord
or by cardiac puncture, is placed into a sterile, heparinized tube for cytogenetic studies. If blood
cannot be obtained, the American College of Obstetricians and Gynecologists (2012) recommends
at least one of the following samples: (1) a placental block measuring about 1 × 1 cm taken below
the cord insertion site in the unfixed specimen; (2) umbilical cord segment approximately 1.5 cm
long; or (3) internal fetal tissue specimen such as costochondral junction or patella. Importantly,
skin is no longer recommended for a tissue sample. Tissue is washed with sterile saline before
being placed in lactated Ringer solution or sterile cytogenetic medium. Placement in formalin or
alcohol kills remaining viable cells and prevents cytogenetic analysis.

A full karyotype may not be possible in cases with prolonged fetal death. For example,
Korteweg and associates (2008) reported that they successfully performed cytogenetic analysis in
only a third of macerated fetuses. Fluorescence in situ hybridization might be used to exclude
numerical abnormalities or to document certain common deletions such as that causing DiGeorge
syndrome. Maternal blood should be obtained for Kleihauer-Betke staining; for antiphospholipid
antibody and lupus anticoagulant testing if indicated; and for serum glucose measurement to
exclude overt diabetes (Silver, 2013).

### Autopsy

Parents should be offered and encouraged to allow a full autopsy. However, valuable information
can still be obtained from limited studies. Pinar and colleagues (2012) described the autopsy
protocol used by the Stillbirth Collaborative Research Network. In the absence of an autopsy, a
gross external examination combined with photography, radiography, MR imaging, bacterial
cultures, and selective use of chromosomal and histopathological studies often can aid
determination of the cause of death.

A complete autopsy is more likely to yield valuable information. An analysis of 400
consecutive fetal deaths in Wales found that autopsy altered the presumed cause of death in 13
percent and provided new information in another 26 percent (Cartlidge, 1995). Other investigators
have shown that autopsy results changed the recurrence risk estimates and parental counseling in
25 to 50 percent of cases (Faye-Petersen, 1999; Silver, 2007).

According to the survey by Goldenberg and coworkers (2013), most hospitals do not audit
stillbirths. In other centers, however, maternal records and autopsy findings are reviewed on a
monthly basis by a stillbirth committee composed of obstetricians, maternal-fetal medicine
specialists, neonatologists, clinical geneticists, and perinatal pathologists. If possible, the cause of
death is assigned based on available evidence. Most importantly, parents should then be contacted
and offered counseling regarding the reason for death, the recurrence risk if any, and possible
strategies to avoid recurrence in future pregnancies.
Fetal death is psychologically traumatic for the woman and her family. Further stress results from an interval of more than 24 hours between the diagnosis of fetal death and the induction of labor, not seeing her infant for as long as she desires, and having no tokens of remembrance (Radestad, 1996). As discussed in Chapter 61 (p. 1205), the woman experiencing a stillbirth or even an early miscarriage is at increased risk for postpartum depression and should be closely monitored (Nelson, 2013). This and other significant life events increase the risks for another subsequent stillborn (Hogue, 2013).

The American College of Obstetricians and Gynecologists (2012) has provided a management outline for women with prior stillbirth (Table 35-3). Importantly, these recommendations are based primarily on limited or inconsistent scientific evidence or on expert opinions. Unfortunately, few studies address management of such women. Those with modifiable risk factors for stillbirth such as hypertension or diabetes control require specific management strategies. According to Reddy (2007), because almost half of fetal deaths are associated with growth restriction, fetal sonographic anatomical assessment beginning at midpregnancy is recommended. This is followed by serial growth studies beginning at 28 weeks.

**TABLE 35-3. Management of Subsequent Pregnancy after Stillbirth**

**Preconceptional or Initial Prenatal Visit**
- Detailed medical and obstetrical history
- Evaluation and workup of previous stillbirth
- Determination of recurrence risk
- Smoking cessation
- Weight loss in obese women (preconceptional only)
- Genetic counseling if family genetic condition exists
- Diabetes screen
- Thrombophilia workup: antiphospholipid antibodies (only if specifically indicated)
- Support and reassurance

**First Trimester**
- Dating ultrasonography
- First-trimester screen: pregnancy-associated plasma protein A, human chorionic gonadotropin, and nuchal translucency
- Support and reassurance

**Second Trimester**
- Fetal ultrasonographic anatomic survey at 18–20 weeks of gestation
Maternal serum screening (quadruple) or single-marker alpha fetoprotein if first trimester screening

Support and reassurance

**Third Trimester**

Ultrasonographic screening for fetal-growth restriction after 28 weeks

Kick counts starting at 28 weeks

Antepartum fetal surveillance starting at 32 weeks or 1–2 weeks earlier than prior stillbirth

Support and reassurance

**Delivery**

Elective induction at 39 weeks

Delivery before 39 weeks only with documented fetal lung maturity by amniocentesis

---

*Provides risk modification but does not alter management.

Adapted from American College of Obstetricians and Gynecologists, 2012; Reddy, 2007.

---

Weeks and associates (1995) evaluated fetal biophysical testing in 300 women whose only indication was prior stillbirth. There was only one recurrent stillbirth, and only three fetuses had abnormal testing results before 32 weeks. There was no relationship between the gestational age of the previous stillborn and the incidence or timing of abnormal test results or fetal jeopardy in the subsequent pregnancy. These investigators concluded that antepartum surveillance should begin at 32 weeks or later in the otherwise healthy woman with a history of stillbirth. This recommendation is supported by the American College of Obstetricians and Gynecologists (2012) with the caveat that it increases the iatrogenic preterm delivery rate.

Delivery at 39 weeks is recommended by induction or by cesarean delivery for those with a contraindication to induction. This minimizes fetal mortality rates, although the degree of risk reduction may be greater for older women (Page, 2013).

---

**REFERENCES**

SECTION 10
THE PUERPERIUM
The word puerperium is derived from Latin—puer, child + parus, bringing forth. Currently, it defines the time following delivery during which pregnancy-induced maternal anatomical and physiological changes return to the nonpregnant state. Its duration is understandably inexact, but is considered to be between 4 and 6 weeks. Although much less complex compared with pregnancy, the puerperium has appreciable changes, some of which may be either bothersome or worrisome for the new mother. Importantly, several complications can develop, and some are serious.

The puerperium may be a time of intense anxiety for many women. Some mothers have feelings of abandonment following delivery because of a newly aimed focus on the infant. Kanotra and colleagues (2007) analyzed challenges that women faced from 2 to 9 months following delivery. A third of these new mothers felt the need for social support, and 25 percent had concerns with breast feeding (Table 36-1).

### TABLE 36-1. Pregnancy Risk Assessment Surveillance System—PRAMS. a Concerns Raised by Women in the First 2–9 Months Postpartum
Birth Canal

Return to the nonpregnant state begins soon after delivery. The vagina and its outlet gradually diminish in size but rarely regain their nulliparous dimensions. Rugae begin to reappear by the third week but are less prominent than before. The hymen is represented by several small tags of tissue, which scar to form the myrtiform caruncles. Vaginal epithelium begins to proliferate by 4 to 6 weeks, usually coincidental with resumed ovarian estrogen production. Lacerations or stretching of the perineum during delivery may result in vaginal outlet relaxation. Some damage to the pelvic floor may be inevitable, and parturition predisposes to urinary incontinence and pelvic organ prolapse. This is discussed in detail in Chapter 27 (p. 536).

Uterus

The massively increased uterine blood flow necessary to maintain pregnancy is made possible by significant hypertrophy and remodeling of pelvic vessels. After delivery, their caliber gradually diminishes to approximately that of the prepregnant state. Within the puerperal uterus, larger blood vessels become obliterated by hyaline changes, are gradually resorbed, and are replaced by smaller ones. Minor vestiges of the larger vessels, however, may persist for years.

During labor, the margin of the dilated cervix, which corresponds to the external os, may be lacerated. The cervical opening contracts slowly and for a few days immediately after labor, readily admits two fingers. By the end of the first week, this opening narrows, the cervix thickens, and the endocervical canal reforms. The external os does not completely resume its pregravid appearance. It remains somewhat wider, and typically, ectocervical depressions at the site of lacerations become permanent. These changes are characteristic of a parous cervix (Fig. 36-1). The markedly attenuated lower uterine segment contracts and retracts, but not as forcefully as the uterine corpus. During the next few weeks, the lower segment is converted from a clearly distinct substructure large enough to accommodate the fetal head to a barely discernible uterine isthmus located between the corpus and internal os.
Cervical epithelium also undergoes considerable remodeling, and this actually may be salutary. Ahdoot and associates (1998) found that approximately half of women showed regression of high-grade dysplasia following vaginal delivery. Kaneshiro and coworkers (2005) found similar regression—about 60 percent overall—regardless of delivery mode.

Postpartum, the fundus of the contracted uterus lies slightly below the umbilicus. It consists mostly of myometrium covered by serosa and internally lined by basal decidua. The anterior and posterior walls, which lie in close apposition, are each 4 to 5 cm thick (Buhimschi, 2003). At this time, the uterus weighs approximately 1000 g. Because blood vessels are compressed by the contracted myometrium, the uterus on section appears ischemic compared with the reddish-purple hyperemic pregnant organ.

Myometrial involution is a truly remarkable tour de force of destruction or deconstruction that begins as soon as 2 days after delivery as shown in Figure 36-2. As emphasized by Hytten (1995), studies that describe the degree of decreasing uterine weight postpartum are poor quality. Best estimates are that by 1 week, the uterus weighs approximately 500 g; by 2 weeks, about 300 g; and at 4 weeks, involution is complete and the uterus weighs approximately 100 g. After each successive delivery, the uterus is usually slightly larger than before the most recent pregnancy. The total number of myocytes does not decrease appreciably—rather, their size decreases markedly.
FIGURE 36-2 Cross sections of uteri made at the level of the involuting placental site at varying times after delivery. p.p. = postpartum. (Redrawn from Williams, 1931.)

Sonographic Findings

Uterine size dissipates rapidly in the first week (Fig. 36-3). And the uterus and endometrium return to pregravid size by 8 weeks after delivery (Belachew, 2012; Steinkeler, 2012). In a study of 42 normal women postpartum, Tekay and Jouppila (1993) identified fluid in the endometrial cavity in 78 percent at 2 weeks, 52 percent at 3 weeks, 30 percent at 4 weeks, and 10 percent at 5 weeks. Demonstrable uterine cavity contents are seen for up to 2 months following delivery. Belachew and colleagues (2012) used 3-dimensional sonography and visualized intracavitary tissue matter in a third on day 1, 95 percent on day 7, 87 percent on day 14, and 28 percent on day 28. By day 56, the small cavity was empty. Sohn and associates (1988) described Doppler ultrasound results showing continuously increasing uterine artery vascular resistance during the first 5 days postpartum.
Decidua and Endometrial Regeneration

Because separation of the placenta and membranes involves the spongy layer, the decidua basalis is not sloughed. The remaining decidua has striking variations in thickness, it has an irregular jagged appearance, and it is infiltrated with blood, especially at the placental site (see Fig. 36-2).

Within 2 or 3 days after delivery, the remaining decidua becomes differentiated into two layers. The superficial layer becomes necrotic and is sloughed in the lochia. The basal layer adjacent to the myometrium remains intact and is the source of new endometrium. This arises from proliferation of the endometrial glandular remnants and the stroma of the interglandular connective tissue.

Endometrial regeneration is rapid, except at the placental site. Within a week or so, the free surface becomes covered by epithelium, and Sharman (1953) identified fully restored endometrium in all biopsy specimens obtained from the 16th day onward. Histological endometritis is part of the normal reparative process. Moreover, microscopic inflammatory changes characteristic of acute salpingitis are seen in almost half of women between 5 and 15 days, but these findings do not reflect infection (Andrews, 1951).

Clinical Aspects

Afterpains. In primiparous women, the uterus tends to remain tonically contracted following delivery. In multiparas, however, it often contracts vigorously at intervals and gives rise to afterpains, which are similar to but milder than labor contractions. These are more pronounced as parity increases and worsen when the infant suckles, likely because of oxytocin release (Holdcroft, 2003). Usually, afterpains decrease in intensity and become mild by the third day. We have encountered unusually severe and persistent afterpains in women with postpartum uterine infections.

Lochia. Early in the puerperium, sloughing of decidual tissue results in a vaginal discharge of
variable quantity. The discharge is termed *lochia* and contains erythrocytes, shredded decidua, epithelial cells, and bacteria. For the first few days after delivery, there is blood sufficient to color it red—*lochia rubra*. After 3 or 4 days, lochia becomes progressively pale in color—*lochia serosa*. After approximately the 10th day, because of an admixture of leukocytes and reduced fluid content, lochia assumes a white or yellow-white color—*lochia alba*. The average duration of lochial discharge ranges from 24 to 36 days (Fletcher, 2012).

### Placental Site Involution

Complete extrusion of the placental site takes up to 6 weeks (Williams, 1931). Immediately after delivery, the placental site is approximately palm-sized. Within hours of delivery, it normally consists of many thrombosed vessels that ultimately undergo organization (see Fig. 36-2). By the end of the second week, it is 3 to 4 cm in diameter.

Placental site involution is an exfoliation process, which is prompted in great part by undermining of the implantation site by new endometrial proliferation (Williams, 1931). Thus, involution is not simply absorption in situ. Exfoliation consists of both extension and “downgrowth” of endometrium from the margins of the placental site, as well as development of endometrial tissue from the glands and stroma left deep in the decidua basalis after placental separation. Anderson and Davis (1968) concluded that placental site exfoliation results from sloughing of infarcted and necrotic superficial tissues followed by a remodeling process.

### Subinvolution

In some cases, uterine involution is hindered because of infection, retained placental fragments, or other causes. Such subinvolution is accompanied by varied intervals of prolonged lochia as well as irregular or excessive uterine bleeding. On bimanual examination, the uterus is larger and softer than would be expected. Ergonovine (Ergotrate) or methylergonovine (Methergine), 0.2 mg orally every 3 to 4 hours for 24 to 48 hours, is recommended by many, but its efficacy is questionable. Of these, only methylergonovine is currently available in the United States. If there is infection, antimicrobial therapy usually leads to a good response. In an earlier study, Wager and coworkers (1980) reported that a third of these late cases of postpartum metritis are caused by *Chlamydia trachomatis*. Empirical therapy with azithromycin or doxycycline usually prompts resolution regardless of bacterial etiology.

Another cause of subinvolution is incompletely remodeled uteroplacental arteries (Andrew, 1989; Kavalar, 2012). These noninvoluted vessels are filled with thromboses and lack an endothelial lining. Perivascular trophoblasts are also identified in the vessel walls, suggesting an aberrant interaction between uterine cells and trophoblasts.

### Late Postpartum Hemorrhage

The American College of Obstetricians and Gynecologists (2013b) defines secondary postpartum hemorrhage as bleeding 24 hours to 12 weeks after delivery. Clinically worrisome uterine hemorrhage develops within 1 to 2 weeks in perhaps 1 percent of women. Such bleeding most often is the result of abnormal involution of the placental site. It occasionally is caused by retention of a placental fragment or by a uterine artery pseudoaneurysm. Usually, retained products undergo necrosis with fibrin deposition and may eventually form a so-called placental polyp. As the eschar of the polyp detaches from the myometrium, hemorrhage may be brisk. As discussed in Chapter 56 (p. 1118), delayed postpartum hemorrhage may also be caused by von Willebrand disease or other inherited coagulopathies (Lipe, 2011).
In our experiences, few women with delayed hemorrhage are found to have retained placental fragments. Thus, we and others do not routinely perform curettage (Lee, 1981). Another concern is that curettage may worsen bleeding by avulsing part of the implantation site. Thus, in a stable patient, if sonographic examination shows an empty cavity, then oxytocin, methylergonovine, or a prostaglandin analogue is given. Antimicrobials are added if uterine infection is suspected. If large clots are seen in the uterine cavity with sonography, then gentle suction curettage is considered. Otherwise curettage is carried out only if appreciable bleeding persists or recurs after medical management.

**URINARY TRACT**

Normal pregnancy-induced glomerular hyperfiltration persists on the first postpartum day but returns to prepregnancy baseline by 2 weeks (Hladunewich, 2004). Also, dilated ureters and renal pelves return to their prepregnant state during the course of 2 to 8 weeks postpartum. Because of this dilated collecting system, coupled with residual urine and bacteriuria in a traumatized bladder, urinary tract infection is a concern in the puerperium.

Bladder trauma is associated most closely with labor length and thus to some degree is a normal accompaniment of vaginal delivery. Funnell and colleagues (1954) used cystoscopy immediately postpartum and described varying degrees of submucosal hemorrhage and edema. Postpartum, the bladder has an increased capacity and a relative insensitivity to intravesical pressure. Thus, overdistention, incomplete emptying, and excessive residual urine are common. Their management is discussed on page 676.

It is unusual for urinary incontinence to manifest during the puerperium. That said, much attention has been given to the potential for subsequent development of urinary incontinence and other pelvic floor disorders in the years following delivery. A fuller discussion is found in Chapter 30 (p. 588).

**PERITONEUM AND ABDOMINAL WALL**

The broad and round ligaments require considerable time to recover from stretching and loosening during pregnancy. As a result of ruptured elastic fibers in the skin and prolonged distention by the pregnant uterus, the abdominal wall remains soft and flaccid. If the abdomen is unusually flabby or pendulous, an ordinary girdle is often satisfactory. An abdominal binder is at best a temporary measure. Several weeks are required for these structures to return to normal, and recovery is aided by exercise. These may be started anytime following vaginal delivery and as soon as abdominal soreness diminishes after cesarean delivery. Silvery abdominal striae commonly develop as striae gravidarum (Chap. 4, p. 51). Except for these, the abdominal wall usually resumes its prepregnancy appearance. When muscles remain atonic, however, the abdominal wall also remains lax. Marked separation of the rectus abdominis muscles—diastasis recti—may result.

**HEMATOLOGICAL PARAMETERS AND PREGNANCY HYPERVOLEMIA**
Hematological and Coagulation Changes

Marked leukocytosis and thrombocytosis may occur during and after labor. The white blood cell count sometimes reaches 30,000/μL, with the increase predominantly due to granulocytes. There is a relative lymphopenia and an absolute eosinopenia. Normally, during the first few postpartum days, hemoglobin concentration and hematocrit fluctuate moderately. If they fall much below the levels present just before labor, a considerable amount of blood has been lost (Chap. 41, p. 781).

By the end of pregnancy, there are many changes in laboratory findings that assess coagulation (Kenny, 2014). These are discussed in Chapter 4 (p. 57) and listed in the Appendix (p. 1288). Many persist in the puerperium. One example is that the markedly increased levels of plasma fibrinogen are maintained at least through the first week, and hence, so is the increase in sedimentation rate.

Pregnancy-Induced Hypervolemia

When the amount of blood attained by normal pregnancy hypervolemia is lost as postpartum hemorrhage, the woman almost immediately regains her nonpregnant blood volume (Chap. 41, p. 781). If less has been lost at delivery, it appears that in most women, blood volume has nearly returned to its nonpregnant level by 1 week after delivery. Cardiac output usually remains elevated for 24 to 48 hours postpartum and declines to nonpregnant values by 10 days (Robson, 1987). Heart rate changes follow this pattern. Systemic vascular resistance and blood pressure rise (Fig. 36-4). Systemic vascular resistance remains in the lower range characteristic of pregnancy for 2 days postpartum and then begins to steadily increase to normal nonpregnant values (Hibbard, 2014).

![FIGURE 36-4](image)

**FIGURE 36-4** During the early puerperium, blood pressure normally rises toward nonpregnant values. MAP = mean arterial pressure.

Normal pregnancy is associated with an appreciable increase in extracellular sodium and water, and postpartum diuresis is a physiological reversal of this process. Chesley and coworkers (1959) demonstrated a decrease in sodium space of approximately 2 L during the first week.
postpartum. This also corresponds with loss of residual pregnancy hypervolemia. In preeclampsia, pathological retention of fluid antepartum and its diuresis postpartum may be prodigious (Chap. 40, p. 768).

Postpartum diuresis results in relatively rapid weight loss of 2 to 3 kg, which is added to the 5 to 6 kg incurred by delivery and normal blood loss. Weight loss from pregnancy itself is likely to be maximal by the end of the second week postpartum. It follows that any residual increased weight compared with prepregnancy values probably represents fat stores that will persist. According to Schauberger and associates (1992), women approach their self-reported prepregnancy weight 6 months after delivery but still retain an average surplus of 1.4 kg (3 lb).

BREASTS AND LACTATION

Breast Anatomy and Products
Each mature mammary gland or breast is composed of 15 to 25 lobes. They are arranged radially and are separated from one another by varying amounts of fat. Each lobe consists of several lobules, which in turn are composed of numerous alveoli. Each alveolus is provided with a small duct that joins others to form a single larger duct for each lobe as shown in Figure 36-5. These lactiferous ducts open separately on the nipple, where they may be distinguished as minute but distinct orifices. The alveolar secretory epithelium synthesizes the various milk constituents, described next.
FIGURE 36-5 Schematic of the alveolar and ductal system during lactation. Note the myoepithelial fibers (M) that surround the outside of the uppermost alveolus. The secretions from the glandular elements are extruded into the lumen of the alveoli (A) and ejected by the myoepithelial cells into the ductal system (D), which empties through the nipple. Arterial blood supply to the alveolus is identified by the upper right arrow and venous drainage by the arrow beneath.

After delivery, the breasts begin to secrete colostrum, which is a deep lemon-yellow liquid. It usually can be expressed from the nipples by the second postpartum day. Compared with mature milk, colostrum is rich in immunological components and contains more minerals and amino acids (Ballard, 2013). It also has more protein, much of which is globulin, but less sugar and fat. Secretion persists for 5 days to 2 weeks, with gradual conversion to mature milk by 4 to 6 weeks.
The colostrum content of immunoglobulin A (IgA) offers the newborn protection against enteric pathogens. Other host resistance factors found in colostrum and milk include complement, macrophages, lymphocytes, lactoferrin, lactoperoxidase, and lysozymes.

Mature milk is a complex and dynamic biological fluid that includes fat, proteins, carbohydrates, bioactive factors, minerals, vitamins, hormones, and many cellular products. The concentrations and contents of human milk change even during a single feed and are influenced by maternal diet, as well as infant age, health, and needs. A nursing mother easily produces 600 mL of milk daily, and maternal gestational weight gain has little impact on its quantity or quality (Institute of Medicine, 1990). Milk is isotonic with plasma, and lactose accounts for half of the osmotic pressure. Essential amino acids are derived from blood, and nonessential amino acids are derived in part from blood or synthesized in the mammary gland. Most milk proteins are unique and include α-lactalbumin, β-lactoglobulin, and casein. Fatty acids are synthesized in the alveoli from glucose and are secreted by an apocrine-like process. Most vitamins are found in human milk, but in variable amounts. Vitamin K is virtually absent, and thus, an intramuscular dose is given to the newborn (Chap. 33, p. 644). Vitamin D content is low—22 IU/mL. Thus, newborn supplementation is also recommended by the American Academy of Pediatrics (Wagner, 2008).

Whey is milk serum and has been shown to contain large amounts of interleukin-6 (Saito, 1991). Human milk has a whey-to-casein ratio of 60:40, considered ideal for absorption. Prolactin appears to be actively secreted into breast milk (Yuen, 1988). Epidermal growth factor (EGF) has been identified in human milk. And because it is not destroyed by gastric proteolytic enzymes, it may be absorbed to promote growth and maturation of newborn intestinal mucosa (McCleary, 1991). Other critical components in human milk include lactoferrin, melatonin, oligosaccharides, and essential fatty acids.

**Endocrinology of Lactation**

The precise humoral and neural mechanisms involved in lactation are complex. Progesterone, estrogen, and placental lactogen, as well as prolactin, cortisol, and insulin, appear to act in concert to stimulate the growth and development of the milk-secreting apparatus (Porter, 1974). With delivery, there is an abrupt and profound decrease in the levels of progesterone and estrogen. This decrease removes the inhibitory influence of progesterone on α-lactalbumin production and stimulates lactose synthase to increase milk lactose. Progesterone withdrawal also allows prolactin to act unopposed in its stimulation of α-lactalbumin production. Serotonin is produced in mammary epithelial cells and has a role in maintaining milk production. This may explain the decreased milk production in women taking selective serotonin-reuptake inhibitors—SSRIs (Collier, 2012).

The intensity and duration of subsequent lactation are controlled, in large part, by the repetitive stimulus of nursing and emptying of milk from the breast. Prolactin is essential for lactation, and women with extensive pituitary necrosis—Sheehan syndrome—do not lactate (Chap. 58, p. 1163). Although plasma prolactin levels fall after delivery to levels lower than during pregnancy, each act of suckling triggers a rise in levels (McNeilly, 1983). Presumably a stimulus from the breast curtails the release of dopamine, also known as prolactin-inhibiting factor, from the hypothalamus. This in turn transiently induces increased prolactin secretion.

The posterior pituitary secretes oxytocin in pulsatile fashion. This stimulates milk expression from a lactating breast by causing contraction of myoepithelial cells in the alveoli and small milk ducts (see Fig. 36-4). Milk ejection, or letting down, is a reflex initiated especially by suckling, which stimulates the posterior pituitary to liberate oxytocin. The reflex may even be provoked by
Immunological Consequences of Breast Feeding

Human milk contains several protective immunological substances, including secretory IgA and growth factors. The antibodies in human milk are specifically directed against maternal environmental antigens such as against *Escherichia coli* (Iyengar, 2012). As a result, breast-fed infants are less prone to enteric infections than bottle-fed ones (Cravioto, 1991). Human milk also provides protection against rotavirus infections, a major cause of infant gastroenteritis (Newburg, 1998). Moreover, the risks of atopic dermatitis and respiratory infections are reduced (Ip, 2009). Bartick and Reinhold (2010) calculated that significant economic burdens from pediatric disease could be lessened by improved breast-feeding rates.

Much attention has been directed to the role of maternal breast-milk lymphocytes in neonatal immunological processes. Milk contains both T and B lymphocytes, but the T lymphocytes appear to differ from those found in blood. Specifically, milk T lymphocytes are almost exclusively composed of cells that exhibit specific membrane antigens. These memory T cells appear to be an avenue for the neonate to benefit from the maternal immunological experience (Bertotto, 1990).

Nursing

Human milk is ideal food for neonates. It provides age-specific nutrients as well as immunological factors and antibacterial substances (American College of Obstetricians and Gynecologists 2013a). Milk also contains factors that act as biological signals for promoting cellular growth and differentiation. The American Academy of Pediatrics (2012) has provided a list of dose-response benefits of nursing (Table 36-2). For both mother and infant, the benefits of breast feeding are long-term. For example, women who breast feed have a lower risk of breast and reproductive cancer, and their children have increased adult intelligence independent of a wide range of possible confounding factors (Jong, 2012; Kramer, 2008). Breast feeding is associated with decreased postpartum weight retention (Baker, 2008). In addition, rates of sudden-infant-death syndrome are significantly lower among breast-fed infants. Last, in the Nurses’ Health Study, women who reported breast feeding for at least 2 cumulative years had a 23-percent lower risk of coronary heart disease (Stuebe, 2009). For all these reasons, the American Academy of Pediatrics (2012) supports the World Health Organization (2011) recommendations of exclusive breast feeding for up to 6 months, with avoidance of exposure to cow milk proteins.

Decrease risks for acute and chronic diseases

The Surgeon General of the U.S. Department of Health and Human Services (2011) lists some barriers for breast feeding and suggests practical means of overcoming them. Educational initiatives that include father and peer counseling may improve these rates (Pisacane, 2005; Wolfberg, 2004). The Baby Friendly Hospital Initiative is an international program to increase rates of exclusive breast feeding and to extend its duration. It is based on the World Health Organization (1989) Ten Steps to Successful Breastfeeding (Table 36-3). Worldwide, almost 20,000 hospitals are designated as “baby-friendly.” Forrester-Knauss and coworkers (2013) described successful trends toward exclusive breast feeding in Switzerland during 9 years in which a Baby-Friendly Hospital Initiative was implemented. However, in 2011 in the United States, fewer than 10 percent of births in 43 states and the District of Columbia occurred in “baby friendly” hospitals (Centers for Disease Control and Prevention, 2012a). In a large population-based study, fewer than two thirds of term neonates were exclusively breast fed at the time of discharge (McDonald, 2012).

**TABLE 36-3. Ten Steps to Successful Breast Feeding**

1. Have a written breast-feeding policy that is regularly communicated to all health-care staff
2. Train all staff in skills necessary to implement this policy
3. Inform all pregnant women about the benefits and management of breast feeding
4. Help mothers initiate breast feeding within an hour of birth
5. Show mothers how to breast feed and how to sustain lactation, even if they should be separated from their infants
6. Feed newborn infants nothing but breast milk, unless medically indicated, and under no circumstances provide breast milk substitutes, feeding bottles, or pacifiers free of charge or at low cost
7. Practice rooming-in, which allows mothers and infants to remain together 24 hours a day
8. Encourage breast feeding on demand
9. Give no artificial pacifiers to breast-feeding infants
10. Help start breast-feeding support groups and refer mothers to them

Adapted from the World Health Organization, 1989.

There are a variety of individual resources available for breast-feeding mothers that include online information from the American Academy of Pediatrics (http://www.aap.org) and La Leche League International (http://www.lalecheleague.org).

**Care of Breasts**

The nipples require little attention other than cleanliness and attention to skin fissures. Fissured nipples render nursing painful, and they may have a deleterious influence on milk production.
These cracks also provide a portal of entry for pyogenic bacteria. Because dried milk is likely to accumulate and irritate the nipples, washing the areola with water and mild soap is helpful before and after nursing. When the nipples are irritated or fissured, it may be necessary to use topical lanolin and a nipple shield for 24 hours or longer. If fissuring is severe, the infant should not be permitted to nurse on the affected side. Instead, the breast should be emptied regularly with a pump until the lesions are healed. Poor latching of the neonate to the breast can create such fissures. Proper technique for positioning the mother and infant during latch-on and nursing has been reviewed by the American College of Obstetricians and Gynecologists (2013a).

### Contraindications to Breast Feeding

Nursing is contraindicated in women who take street drugs or do not control their alcohol use; have an infant with galactosemia; have human immunodeficiency virus (HIV) infection; have active, untreated tuberculosis; take certain medications; or are undergoing breast cancer treatment (American Academy of Pediatrics and American College of Obstetricians and Gynecologists 2012; Faupel-Badger, 2013). Breast feeding has been recognized for some time as a mode of HIV transmission and is proscribed in developed countries in which adequate nutrition is otherwise available (Chap. 65, p. 1282). Other viral infections do not contraindicate breast feeding. For example, with maternal cytomegalovirus infection, both virus and antibodies are present in breast milk. And although hepatitis B virus is excreted in milk, breast feeding is not contraindicated if hepatitis B immune globulin is given to the newborns of affected mothers. Maternal hepatitis C infection is not a contraindication because breast feeding has not been shown to transmit infection. Women with active herpes simplex virus may suckle their infants if there are no breast lesions and if particular care is directed to hand washing before nursing.

### Drugs Secreted in Milk

Most drugs given to the mother are secreted in breast milk, although the amount ingested by the infant typically is small. Many factors influence drug excretion and include plasma concentration, degree of protein binding, plasma and milk pH, degree of ionization, lipid solubility, and molecular weight (Rowe, 2013). The ratio of drug concentration in breast milk to that in maternal plasma is the milk-to-plasma drug-concentration ratio. Most drugs have a ratio of ≤ 1, approximately 25 percent have a ratio > 1, and about 15 percent have a ratio > 2 (Ito, 2000). Ideally, to minimize infant exposure, medication selection should favor drugs with a shorter half-life, poorer oral absorption, and lower lipid solubility. If multiple daily drug doses are required, then each is taken by the mother after the closest feed. Single daily-dosed drugs may be taken just before the longest infant sleep interval—usually at bedtime (Spencer, 2002).

There are only a few drugs that are absolutely contraindicated while breast feeding (Berlin, 2013; Bertino, 2012). Cytotoxic drugs may interfere with cellular metabolism and potentially cause immune suppression or neutropenia, affect growth, and, at least theoretically, increase the risk of childhood cancer. Examples include cyclophosphamide, cyclosporine, doxorubicin, methotrexate, and mycophenolate. If a medication presents a concern, then the importance of therapy should be ascertained. It should be determined whether there is a safer alternative or whether neonatal exposure can be minimized if the medication dose is taken immediately after each breast feeding (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Data on individual drugs are available through the National Institutes of Health website, LactMed, which can be found at: toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT.
Radioactive isotopes of copper, gallium, indium, iodine, sodium, and technetium rapidly appear in breast milk. Consultation with a nuclear medicine specialist is recommended before performing a diagnostic study with these isotopes (Chap. 46, p. 934). The goal is to use a radionuclide with the shortest excretion time in breast milk. The mother should pump her breasts before the study and store enough milk in a freezer for feeding the infant. After the study, she should pump her breasts to maintain milk production but discard all milk produced during the time that radioactivity is present. This ranges from 15 hours up to 2 weeks, depending on the isotope used. Importantly, radioactive iodine concentrates and persists in the thyroid. Its special considerations are discussed in Chapter 63 (p. 1231).

Breast Engorgement

This is common in women who do not breast feed and is typified by milk leakage and breast pain. These peak 3 to 5 days after delivery (Spitz, 1998). Up to half of affected women require analgesia for breast-pain relief, and as many as 10 percent report severe pain for up to 14 days.

Evidence is insufficient to firmly support any specific treatment (Mangesi, 2010). That said, breasts can be supported with a well-fitting brassiere, breast binder, or “sports bra.” Cool packs and oral analgesics for 12 to 24 hours aid discomfort. Pharmacological or hormonal agents are not recommended to suppress lactation.

Fever caused by breast engorgement was common before the renaissance of breast feeding. In one study, Almeida and Kitay (1986) reported that 13 percent of postpartum women had fever from engorgement that ranged from 37.8 to 39°C. Fever seldom persists for longer than 4 to 16 hours. The incidence and severity of engorgement, and fever associated with it, are much lower if women breast feed. Other causes of fever, especially those due to infection, must be excluded. Of these, mastitis is infection of the mammary parenchyma. It is relatively common in lactating women and is discussed in Chapter 37 (p. 691).

Other Issues with Lactation

With inverted nipples, lactiferous ducts open directly into a depression at the center of the areola. With these depressed nipples, nursing is difficult. If the depression is not deep, milk sometimes can be made available by use of a breast pump. If instead the nipple is greatly inverted, daily attempts should be made during the last few months of pregnancy to draw or “tease” the nipple out with the fingers.

Extra breasts—polymastia, or extra nipples—polythelia, may develop along the former embryonic mammary ridge. Also termed the milk line, this line extends from the axilla to the groin bilaterally. In some women, there may be vulvar breast tissue (Wagner, 2013). The incidence of accessory breast tissue ranges from 0.22 to 6 percent in the general population (Loukas, 2007). These breasts may be so small as to be mistaken for pigmented moles, or if without a nipple, for lymphadenopathy or lipoma. Polymastia has no obstetrical significance, although occasionally enlargement of these accessory breasts during pregnancy or engorgement postpartum may result in discomfort and anxiety.

Galactocele is a milk duct that becomes obstructed by inspissated secretions. The amount is ordinarily limited, but an excess may form a fluctuant mass—a galactocele—that may cause pressure symptoms and have the appearance of an abscess. It may resolve spontaneously or require aspiration.

There are marked individual variations in the amount of milk secreted. Many of these are
dependent not on general maternal health but on breast glandular development. Rarely, there is complete lack of mammary secretion—agalactia. Occasionally, mammary secretion is excessive—polygalactia.

**MATERNAL CARE DURING THE PUERPERIUM**

**Hospital Care**

For 2 hours after delivery, blood pressure and pulse should be taken every 15 minutes, or more frequently if indicated. Temperature is assessed every 4 hours for the first 8 hours and then at least every 8 hours subsequently (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). The amount of vaginal bleeding is monitored, and the fundus palpated to ensure that it is well contracted. If relaxation is detected, the uterus should be massaged through the abdominal wall until it remains contracted. Uterotonics are also sometimes required. Blood may accumulate within the uterus without external bleeding. This may be detected early by uterine enlargement during fundal palpation in the first postdelivery hours. Because the likelihood of significant hemorrhage is greatest immediately postpartum, even in normal births, the uterus is closely monitored for at least 1 hour after delivery. Postpartum hemorrhage is discussed in Chapter 41 (p. 783). If regional analgesia or general anesthesia was used for labor or delivery, the mother should be observed in an appropriately equipped and staffed recovery area.

Women are out of bed within a few hours after delivery. An attendant should be present for at least the first time, in case the woman becomes syncopal. The many confirmed advantages of early ambulation include fewer bladder complications, less frequent constipation, and reduced rates of puerperal venous thromboembolism. Almost half of thromboembolic events associated with pregnancy develop in the puerperium. Jacobsen and colleagues (2008) reported that pulmonary embolism is most common in the first 6 weeks postpartum. In a recent audit of puerperal women at Parkland Hospital, the frequency of venous thromboembolism was found to be 0.008 percent after a vaginal birth and 0.04 percent following cesarean delivery. We attribute this low incidence to early ambulation. Risk factors and other measures to diminish the frequency of thromboembolism are discussed in Chapter 52 (p. 1029).

There are no dietary restrictions for women who have been delivered vaginally. Two hours after normal vaginal delivery, if there are no complications, a woman should be allowed to eat. With breast feeding, the level of calories and protein consumed during pregnancy should be increased slightly as recommended by the Food and Nutrition Board of the National Research Council (Chap. 9, p. 178). If the mother does not breast feed, dietary requirements are the same as for a nonpregnant woman. It is standard practice in our hospital to continue oral iron supplementation for at least 3 months after delivery and to check the hematocrit at a first postpartum visit.

**Perineal Care**

The woman is instructed to cleanse the vulva from anterior to posterior—the vulva toward the anus. A cool pack applied to the perineum may help reduce edema and discomfort during the first 24 hours if there is a laceration or an episiotomy. Most women also appear to obtain a measure of relief from the periodic application of a local anesthetic spray. Severe discomfort usually indicates a problem, such as a hematoma within the first day or so and infection after the third or
fourth day (Chap. 37, p. 689 and Chap. 41, p. 790). Severe perineal, vaginal, or rectal pain always warrants careful inspection and palpation. Beginning approximately 24 hours after delivery, moist heat as provided by warm sitz baths can be used to reduce local discomfort. Tub bathing after uncomplicated delivery is allowed. The episiotomy incision normally is firmly healed and nearly asymptomatic by the third week.

Rarely, the cervix, and occasionally a portion of the uterine body, may protrude from the vulva following delivery. This is accompanied by variable degrees of anterior and posterior vaginal wall prolapse. Symptoms include a palpable mass at or past the introitus, voiding difficulties, or pressure. Puerperal procidentia typically improves with time as the weight of the uterus lessens with involution. As a temporizing measure in those with pronounced prolapse, the uterus can be replaced and held in position with a suitable pessary.

### Bladder Function

In most delivery units, intravenous fluids are infused during labor and for an hour or so after delivery. Oxytocin, in doses that have an antidiuretic effect, is typically infused postpartum, and rapid bladder filling is common. Moreover, both bladder sensation and capability to empty spontaneously may be diminished by local or conduction analgesia, by trauma to the bladder, by episiotomy or lacerations, or by operative vaginal delivery. Thus, urinary retention and bladder overdistention is common in the early puerperium. Ching-Chung and associates (2002) reported retention in 4 percent of women delivered vaginally. Musselwhite and coworkers (2007) reported retention in 4.7 percent of women who had labor epidural analgesia. Risk factors that increased likelihood of retention were primiparity, perineal lacerations, oxytocin-induced or -augmented labor, operative vaginal delivery, catheterization during labor, and labor duration > 10 hours.

Prevention of bladder overdistention demands observation after delivery to ensure that the bladder does not overfill and that it empties adequately with each voiding. The enlarged bladder can be palpated suprapubically, or it is evident abdominally indirectly as it elevates the fundus above the umbilicus. Van Os and Van der Linden (2006) have investigated the use of an automated sonography system to detect high bladder volumes and thus postpartum urinary retention.

If a woman has not voided within 4 hours after delivery, it is likely that she cannot. If she has trouble voiding initially, she also is likely to have further trouble. An examination for perineal and genital-tract hematomas is made. With an overdistended bladder, an indwelling catheter should be left in place until the factors causing retention have abated. Even without a demonstrable cause, it usually is best to leave the catheter in place for at least 24 hours. This prevents recurrence and allows recovery of normal bladder tone and sensation.

When the catheter is removed, it is necessary subsequently to demonstrate ability to void appropriately. If a woman cannot void after 4 hours, she should be catheterized and the urine volume measured. If more than 200 mL, the bladder is not functioning appropriately, and the catheter is left for another 24 hours. If less than 200 mL of urine is obtained, the catheter can be removed and the bladder rechecked subsequently as just described. Harris and coworkers (1977) reported that 40 percent of such women develop bacteriuria, and thus a single dose or short course of antimicrobial therapy is reasonable after the catheter is removed.

### Pain, Mood, and Cognition

Discomfort and its causes following cesarean delivery are considered in Chapter 30 (p. 605). During the first few days after vaginal delivery, the mother may be uncomfortable because of
afterpains, episiotomy and lacerations, breast engorgement, and at times, postdural puncture headache. Mild analgesics containing codeine, aspirin, or acetaminophen, preferably in combinations, are given as frequently as every 3 hours during the first few days.

It is fairly common for a mother to exhibit some degree of depressed mood a few days after delivery. Termed *postpartum blues*, this likely is the consequence of several factors that include emotional letdown that follows the excitement and fears experienced during pregnancy and delivery, discomforts of the early puerperium, fatigue from sleep deprivation, anxiety over the ability to provide appropriate infant care, and body image concerns. In most women, effective treatment includes anticipation, recognition, and reassurance. This disorder is usually mild and self-limited to 2 to 3 days, although it sometimes lasts for up to 10 days. Should these moods persist or worsen, an evaluation for symptoms of major depression is done (Chap. 61, p. 1205). Suicidal or infanticidal ideation is dealt with emergently. Because major postpartum depression recurs in at least a fourth of women in subsequent pregnancies, some recommend pharmacological prophylaxis beginning in late pregnancy or immediately postpartum.

Last, postpartum hormonal changes in some women may affect brain function. Bannbers and colleagues (2013) compared a measure of executive function in postpartum women and controls and observed a decrease in postpartum subjects.

### Neuromusculoskeletal Problems

#### Obstetrical Neuropathies

Pressure on branches of the lumbosacral nerve plexus during labor may manifest as complaints of intense neuralgia or cramplike pains extending down one or both legs as soon as the head descends into the pelvis. If the nerve is injured, pain may continue after delivery, and there also may be variable degrees of sensory loss or muscle paralysis. In some cases, there is footdrop, which can be secondary to injury at the level of the lumbosacral plexus, sciatic nerve, or common fibular (peroneal) nerve. Components of the lumbosacral plexus cross the pelvic brim and can be compressed by the fetal head or by forceps. The common fibular nerves may be externally compressed when the legs are positioned in stirrups, especially during prolonged second-stage labor.

Obstetrical neuropathy is relatively infrequent. Wong and associates (2003) evaluated more than 6000 delivered women and found that approximately 1 percent had a confirmed nerve injury. Lateral femoral cutaneous neuropathies were the most common (24), followed by femoral neuropathies (14). A motor deficit accompanied a third of injuries. Nulliparity, prolonged second-stage labor, and pushing for a long duration in the semi-Fowler position were risk factors. The median duration of symptoms was 2 months, and the range was 2 weeks to 18 months.

Nerve injuries with cesarean delivery include the iliohypogastric and ilioinguinal nerves (Rahn, 2010). These are discussed further in Chapter 2 (p. 17).

#### Musculoskeletal Injuries

Pain in the pelvic girdle, hips, or lower extremities may follow stretching or tearing injuries sustained at normal or difficult delivery. Magnetic resonance (MR) imaging is often informative. One example is the piriformis muscle hematoma shown in Figure 36-6. Most injuries resolve with antiinflammatory agents and physical therapy. Rarely, there may be septic pyomyositis such as with iliopsoas muscle abscess (Nelson, 2010; Young, 2010).
FIGURE 36-6 Magnetic resonance image of a piriformis hematoma. A large inhomogeneous mass of the right piriformis muscle consistent with a hematoma (yellow cursor measurements) is compared with the normal-appearing left piriformis muscle (yellow arrow).

Separation of the symphysis pubis or one of the sacroiliac synchondroses during labor leads to pain and marked interference with locomotion. Estimates of the frequency of this event vary widely from 1 in 600 to 1 in 30,000 deliveries (Reis, 1932; Taylor, 1986). In our experiences, symptomatic separations are uncommon. Their onset of pain is often acute during delivery, but symptoms may manifest either antepartum or up to 48 hours postpartum (Snow, 1997). Treatment is generally conservative, with rest in a lateral decubitus position and an appropriately fitted pelvic binder. Surgery is occasionally necessary in some symphyseal separations of more than 4 cm (Kharrazi, 1997). The recurrence risk is > 50 percent in subsequent pregnancy, and Culligan and associates (2002) recommend consideration for cesarean delivery. In rare cases, fractures of the sacrum or pubic ramus are caused by even uncomplicated deliveries (Alonso-Burgos, 2007). As discussed in Chapter 58 (p. 1159), the latter are more likely with osteoporosis associated with heparin or corticosteroid therapy (Cunningham, 2005). In rare but serious cases, bacterial osteomyelitis—osteitis pubis—can be devastating (Fig. 36-7). Lawford and coworkers (2010) reported such a case that caused massive vulvar edema.
Bacterial osteitis pubis–osteomyelitis caused by *Streptococcus milleri* in a woman with symptomatic symphyseal separation.

### Immunizations

The D-negative woman who is not isoimmunized and whose infant is D-positive is given 300 μg of anti-D immune globulin shortly after delivery (Chap. 15, p. 311). Women who are not already immune to rubella or rubeola measles are excellent candidates for combined measles-mumps-rubella vaccination before discharge (Chap. 9, p. 184). Unless contraindicated, at Parkland Hospital a diphtheria-tetanus toxoid booster injection is also given to postpartum women.

### Hospital Discharge

Following uncomplicated vaginal delivery, hospitalization is seldom warranted for more than 48 hours. A woman should receive instructions concerning anticipated normal physiological puerperal changes, including lochia patterns, weight loss from diuresis, and milk let-down. She also should receive instructions concerning fever, excessive vaginal bleeding, or leg pain, swelling, or tenderness. Persistent headaches, shortness of breath, or chest pain warrant immediate concern.

Hospital stay length following labor and delivery is now regulated by federal law (Chap. 32, p. 634). Currently, the norms are hospital stays up to 48 hours following uncomplicated vaginal delivery and up to 96 hours following uncomplicated cesarean delivery (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Earlier hospital discharge is acceptable for appropriately selected women if they desire it.

### Contraception
During the hospital stay, a concerted effort should be made to provide family planning education. Various forms of contraception are discussed throughout Chapter 38 and sterilization procedures in Chapter 39.

Women not breast feeding have return of menses usually within 6 to 8 weeks. At times, however, it is difficult clinically to assign a specific date to the first menstrual period after delivery. A minority of women bleed small to moderate amounts intermittently, starting soon after delivery. Ovulation occurs at a mean of 7 weeks, but ranges from 5 to 11 weeks (Perez, 1972). That said, ovulation before 28 days has been described (Hytten, 1995). Thus, conception is possible during the artificially defined 6-week puerperium. Women who become sexually active during the puerperium, and who do not desire to conceive, should initiate contraception. Kelly and associates (2005) reported that by the third month postpartum, 58 percent of adolescents had resumed sexual intercourse, but only 80 percent of these were using contraception. Because of this, many recommend long-acting reversible contraceptives—LARC (Baldwin, 2013).

Women who breast feed ovulate much less frequently compared with those who do not, but there are great variations. Timing of ovulation depends on individual biological variation as well as the intensity of breast feeding. Lactating women may first menstruate as early as the second or as late as the 18th month after delivery. Campbell and Gray (1993) analyzed daily urine specimens to determine the time of ovulation in 92 lactating women. As shown in Figure 36-8, breast feeding in general delays resumption of ovulation, although as already emphasized, it does not invariably forestall it. Other findings in their study included the following:

1. Resumption of ovulation was frequently marked by return of normal menstrual bleeding.
2. Breast-feeding episodes lasting 15 minutes seven times daily delayed ovulation resumption.
3. Ovulation can occur without bleeding.
4. Bleeding can be anovulatory.
5. The risk of pregnancy in breast-feeding women was approximately 4 percent per year.
For the breast-feeding woman, progestin-only contraceptives—mini-pills, depot medroxyprogesterone, or progestin implants—do not affect the quality or quantity of milk. These may be initiated any time during the puerperium. Estrogen-progestin contraceptives likely reduce the quantity of breast milk, but under the proper circumstances, they too can be used by breast-feeding women. However, these are withheld until after the first 4 weeks because of their higher thromboembolic risk in puerperal patients. These hormonal methods are summarized in Table 36-4 and are discussed in Chapter 38 (p. 695).

**HOME CARE**

**Coitus**

There are no evidence-based data concerning resumption of coitus after delivery. It seems best to use common sense (Minig, 2009). After 2 weeks, coitus may be resumed based on desire and comfort. Barrett and colleagues (2000) reported that almost 90 percent of 484 primiparous women resumed sexual activity by 6 months. And although 65 percent of these reported problems, only 15 percent discussed them with a health-care provider.

Intercourse too soon may be unpleasant, if not frankly painful, due to incomplete healing of the episiotomy or lacerations. Moreover, the vaginal epithelium is thin, and very little lubrication follows sexual stimulation. This is due to the hypoestrogenic state following delivery, which lasts until ovulation resumes. It may be particularly problematic in breast-feeding women who are hypoestrogenic for many months postpartum (Palmer, 2003; Wisniewski, 1991). For treatment, small amounts of topical estrogen cream can be applied daily for several weeks to vulvar tissues. Additionally, vaginal lubricants may be used with coitus.

**Late Maternal Morbidity**

Taken together, major and minor maternal morbidity are surprisingly common in the months following childbirth (MacArthur, 1991). In a survey of 1249 British mothers followed for up to 18 months, 3 percent required hospital readmission within 8 weeks (Glazener, 1995; Thompson, 2002). Milder health problems during the first 8 weeks were reported by 87 percent (Table 36-5).
Moreover, almost three fourths continued to have various problems for up to 18 months. Practitioners should be aware of these potential issues in their patients convalescing from birthing.

Follow-Up Care

By discharge, women who had an uncomplicated course can resume most activities, including bathing, driving, and household functions. Jimenez and Newton (1979) tabulated cross-cultural information on 202 societies from various international geographical regions. Following childbirth, most societies did not restrict work activity, and approximately half expected a return to full duties within 2 weeks. Wallace and coworkers (2013) reported that 80 percent of women who worked during pregnancy resume work by 1 year after delivery. Despite this, Tulman and Fawcett (1988) reported that only half of mothers regained their usual level of energy by 6 weeks. Women who delivered vaginally were twice as likely to have normal energy levels at this time compared with those with a cesarean delivery. Ideally, the care and nurturing of the infant should be provided by the mother with ample help from the father.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend a postpartum visit between 4 and 6 weeks. This has proved quite satisfactory to identify abnormalities beyond the immediate puerperium and to initiate contraceptive practices.

REFERENCES

American College of Obstetricians and Gynecologists: Postpartum hemorrhage. Practice Bulletin No. 76, October 2006, Reaffirmed 2013b

Puerperal complications include many of those encountered during pregnancy, but there are some that are more common at this time. Typical of these is puerperal pelvic infection—a well-known killer of postpartum women. Other infections include mastitis and breast abscesses. Thromboembolism during the short 6-week puerperium is as frequent as during all 40 antepartum weeks.

Traditionally, the term \textit{puerperal infection} describes any bacterial infection of the genital tract after delivery. These infections as well as preeclampsia and obstetrical hemorrhage form the lethal triad of maternal death causes before and during the 20th century. Fortunately, because of effective antimicrobials, maternal mortality from infection has become uncommon. Berg and associates (2010) reported results from the Pregnancy Mortality Surveillance System, which contained 4692 pregnancy-related maternal deaths in the United States from 1998 through 2005. Infection caused 10.7 percent of pregnancy-related deaths and was the fifth leading cause. In a similar analysis of the North Carolina population from 1991 through 1999, Berg and colleagues (2005) reported that 40 percent of infection-related maternal deaths were preventable.
Puerperal Fever

A number of factors can cause fever—a temperature of 38.0°C (100.4°F) or higher—in the puerperium. Most persistent fevers after childbirth are caused by genital tract infection. Using this conservative definition of fever, Filker and Monif (1979) reported that only about 20 percent of women febrile within the first 24 hours after giving birth vaginally were subsequently diagnosed with pelvic infection. This was in contrast to 70 percent of those undergoing cesarean delivery. It must be emphasized that spiking fevers of 39°C or higher that develop within the first 24 hours postpartum may be associated with virulent pelvic infection caused by group A streptococcus and is discussed on page 683.

Other causes of puerperal fever include breast engorgement, urinary infections, episiotomy and abdominal incisions, perineal lacerations, and respiratory complications after cesarean delivery (Maharaj, 2007). Approximately 15 percent of women who do not breast feed develop postpartum fever from breast engorgement. As discussed in Chapter 36 (p. 675), the incidence of fever is lower in breast-feeding women. “Breast fever” rarely exceeds 39°C in the first few postpartum days and usually lasts < 24 hours. Urinary infections are uncommon postpartum because of the normal diuresis encountered then. That said, acute pyelonephritis has a variable clinical picture. The first sign of renal infection may be fever, followed later by costovertebral angle tenderness, nausea, and vomiting. Atelectasis following abdominal delivery is caused by hypoventilation and is best prevented by coughing and deep breathing on a fixed schedule following surgery. Fever associated with atelectasis is thought to follow infection by normal flora that proliferate distal to obstructing mucus plugs.

Uterine Infection

Postpartum uterine infection or puerperal sepsis has been called variously endometritis, endomyometritis, and endoparametritis. Because infection involves not only the decidua but also the myometrium and parametrial tissues, we prefer the inclusive term metritis with pelvic cellulitis.

Predisposing Factors

The route of delivery is the single most significant risk factor for the development of uterine infection (Burrows, 2004; Conroy, 2012; Koroukian, 2004). In the French Confidential Enquiry of Maternal Deaths, Deneux-Tharaux and coworkers (2006) cited a nearly 25-fold increased infection-related mortality rate with cesarean versus vaginal delivery. Rehospitalization rates for wound complications and endometritis were increased significantly in women undergoing a planned primary cesarean delivery compared with those having a planned vaginal birth (Declercq, 2007).

Vaginal Delivery. Compared with cesarean delivery, metritis following vaginal delivery is relatively infrequent. Women delivered vaginally at Parkland Hospital have a 1- to 2-percent incidence of metritis. Women at high risk for infection because of membrane rupture, prolonged labor, and multiple cervical examinations have a 5-to 6-percent frequency of metritis after vaginal delivery. If there is intrapartum chorioamnionitis, the risk of persistent uterine infection increases to 13 percent (Maberry, 1991). Finally, in one study, manual removal of the placenta, discussed in Chapter 41 (p. 784), increased the puerperal metritis rate threefold (Baksu, 2005).

Cesarean Delivery. Single-dose perioperative antimicrobial prophylaxis is recommended for all
women undergoing cesarean delivery (American College of Obstetricians and Gynecologists, 2011). Such single-dose antimicrobial prophylaxis has done more to decrease the incidence and severity of postcesarean delivery infections than any other intervention in the past 30 years. Such practices decrease the puerperal pelvic infection risk by 65 to 75 percent (Smaill, 2010).

The magnitude of the risk is exemplified from reports that predate antimicrobial prophylaxis. Cunningham and associates (1978) described an overall incidence of 50 percent in women undergoing cesarean delivery at Parkland Hospital. Important risk factors for infection following surgery included prolonged labor, membrane rupture, multiple cervical examinations, and internal fetal monitoring. Women with all these factors who were not given perioperative prophylaxis had a 90-percent serious postcesarean delivery pelvic infection rate (DePalma, 1982).

Other Risk Factors. It is generally accepted that pelvic infection is more frequent in women of lower socioeconomic status (Maharaj, 2007). Except in extreme cases usually not seen in this country, it is unlikely that anemia or poor nutrition predispose to infection. Bacterial colonization of the lower genital tract with certain microorganisms—for example, group B streptococcus, Chlamydia trachomatis, Mycoplasma hominis, Ureaplasma urealyticum, and Gardnerella vaginalis—has been associated with an increased postpartum infection risk (Andrews, 1995; Jacobsson, 2002; Watts, 1990). Other factors associated with an increased infection risk include general anesthesia, cesarean delivery for multifetal gestation, young maternal age and nulliparity, prolonged labor induction, obesity, and meconium-stained amniotic fluid (Acosta, 2012; Jazayeri, 2002; Kabiru, 2004; Leth, 2011; Siriwachirachai, 2010; Tsai, 2011).

Microbiology
Most female pelvic infections are caused by bacteria indigenous to the genital tract. Over the past 20 years, there have been reports of group A β-hemolytic streptococcus causing toxic shock-like syndrome and life-threatening infection (Aronoff, 2008; Castagnola, 2008; Nathan, 1994; Palep-Singh, 2007). Prematurely ruptured membranes are a prominent risk factor in these infections (Anteby, 1999). In reviews by Crum (2002) and Udagawa (1999) and their colleagues, women in whom group A streptococcal infection was manifested before, during, or within 12 hours of delivery had a maternal mortality rate of almost 90 percent and fetal mortality rate > 50 percent. In the past 10 years, skin and soft-tissue infections due to community-acquired methicillin-resistant Staphylococcus aureus—CA-MRSA—have become common (Chap. 64, p. 1251). Although this variant is not a frequent cause of puerperal metritis, it is commonly implicated in abdominal incisional infections (Anderson, 2007; Patel, 2007). Rotas and coworkers (2007) reported a woman with episiotomy cellulitis from CA-MRSA and hematogenously spread necrotizing pneumonia.

Common Pathogens. Bacteria commonly responsible for female genital tract infections are listed in Table 37-1. Generally, infections are polymicrobial, which enhances bacterial synergy. Other factors that promote virulence are hematomas and devitalized tissue. Although the cervix and vagina routinely harbor such bacteria, the uterine cavity is usually sterile before rupture of the amnionic sac. As the consequence of labor and delivery and associated manipulations, the amnionic fluid and uterus become contaminated with anaerobic and aerobic bacteria (Fig. 37-1). Intraamnionic cytokines and C-reactive protein are also markers of infection (Combs, 2013; Marchocki, 2013). In studies done before the use of antimicrobial prophylaxis, Gilstrap and Cunningham (1979) cultured amnionic fluid obtained at cesarean delivery in women in labor with membranes ruptured more than 6 hours. All had bacterial growth, and an average of 2.5 organisms
was identified from each specimen. Anaerobic and aerobic organisms were identified in 63 percent, anaerobes alone in 30 percent, and aerobes alone in only 7 percent. Anaerobes included *Peptostreptococcus* and *Peptococcus* species in 45 percent, *Bacteroides* species in 9 percent, and *Clostridium* species in 3 percent. Aerobes included *Enterococcus* in 14 percent, group B streptococcus in 8 percent, and *Escherichia coli* in 9 percent of isolates. Sherman and coworkers (1999) later showed that bacterial isolates at cesarean delivery correlated with those taken from women with metritis at 3 days postpartum.

</table>
The role of other organisms in the etiology of these infections is unclear. Chlamydial infections have been implicated in late-onset, indolent metritis (Ismail, 1985). Observations of Chaim and colleagues (2003) suggest that when cervical colonization of \textit{U. urealyticum} is heavy, it may contribute to the development of metritis. Finally, Jacobsson and associates (2002) reported a threefold risk of puerperal infection in a group of Swedish women in whom bacterial vaginosis was identified in early pregnancy (Chap. 65, p. 1276).

\textbf{Bacterial Cultures.} Routine pretreatment genital tract cultures are of little clinical use and add significant costs. Similarly, routine blood cultures seldom modify care. In two earlier studies done before perioperative prophylaxis was used, blood cultures were positive in 13 percent of women with postcesarean metritis at Parkland Hospital and 24 percent in those at Los Angeles County Hospital (Cunningham, 1978; DiZerega, 1979). In a later Finnish study, Kankuri and associates (2003) confirmed bacteremia in only 5 percent of almost 800 women with puerperal sepsis.
Puerperal infection following vaginal delivery primarily involves the placental implantation site, decidua and adjacent myometrium, or cervicovaginal lacerations. The pathogenesis of uterine infection following cesarean delivery is that of an infected surgical incision (see Fig. 37-1). Bacteria that colonize the cervix and vagina gain access to amnionic fluid during labor. Postpartum, they invade devitalized uterine tissue. Parametrial cellulitis next follows with infection of the pelvic retroperitoneal fibroareolar connective tissue. With early treatment, infection is contained within the parametrial and paravaginal tissue, but it may extend deeply into the pelvis.

Fever is the most important criterion for the diagnosis of postpartum metritis. Intuitively, the degree of fever is believed proportional to the extent of infection and sepsis syndrome. Temperatures commonly are 38 to 39°C. Chills that accompany fever suggest bacteremia or endotoxemia. Women usually complain of abdominal pain, and parametrial tenderness is elicited on abdominal and bimanual examination. Leukocytosis may range from 15,000 to 30,000 cells/μL, but recall that cesarean delivery itself increases the leukocyte count (Hartmann, 2000). Although an offensive odor may develop, many women have foul-smelling lochia without evidence for infection, and vice versa. Some other infections, notably those caused by group A β-hemolytic streptococci, may be associated with scant, odorless lochia.

**Treatment**

If nonsevere metritis develops following vaginal delivery, then treatment with an oral antimicrobial agent is usually sufficient. For moderate to severe infections, however, intravenous therapy with a broad-spectrum antimicrobial regimen is indicated. Improvement follows in 48 to 72 hours in nearly 90 percent of women treated with one of several regimens. Persistent fever after this interval mandates a careful search for causes of refractory pelvic infection. These include a parametrial phlegmon—an area of intense cellulitis; an abdominal incisional or pelvic abscess or infected hematoma; and septic pelvic thrombophlebitis. In our experience, persistent fever is seldom due to antimicrobial-resistant bacteria or due to drug side effects. The woman may be discharged home after she has been afebrile for at least 24 hours, and further oral antimicrobial therapy is not needed (Dinsmoor, 1991; French, 2004).

**Choice of Antimicrobials.** Although therapy is empirical, initial treatment following cesarean delivery is directed against elements of the mixed flora shown in Table 37-1. For infections following vaginal delivery, as many as 90 percent of women respond to regimens such as ampicillin plus gentamicin. In contrast, anaerobic coverage is included for infections following cesarean delivery (Table 37-2).

---

**TABLE 37-2. Antimicrobial Regimens for Intravenous Treatment of Pelvic Infection Following Cesarean Delivery**
In 1979, DiZerega and colleagues compared the effectiveness of clindamycin plus gentamicin with that of penicillin G plus gentamicin for treatment of pelvic infections following cesarean delivery. Women given the clindamycin-gentamicin regimen had a 95-percent response rate, and this regimen is still considered by most to be the standard by which others are measured (French, 2004). Because enterococcal cultures may be persistently positive despite this standard therapy, some add ampicillin to the clindamycin-gentamicin regimen, either initially or if there is no response by 48 to 72 hours (Brumfield, 2000).

Many authorities recommend that serum gentamicin levels be periodically monitored. At Parkland Hospital, we do not routinely do so if the woman has normal renal function. Once-daily dosing versus multiple-dosing with gentamicin provides adequate serum levels, and either method has similar cure rates (Livingston, 2003).

Because of potential nephrotoxicity and ototoxicity with gentamicin in the event of diminished glomerular filtration, some have recommended a combination of clindamycin and a second-generation cephalosporin to treat such women. Others recommend a combination of clindamycin and aztreonam, which is a monobactam compound with activity similar to the aminoglycosides.

The spectra of β-lactam antimicrobials include activity against many anaerobic pathogens. Some examples include cephalosporins such as cefoxitin, cefotetan, cefotaxime, and ceftriaxone, as well as extended-spectrum penicillins such as piperacillin, ticarcillin, and mezlocillin. β-Lactam antimicrobials are inherently safe and except for allergic reactions, are free of major toxicity. The β-lactamase inhibitors, clavulanic acid, sulbactam, and tazobactam, have been combined with ampicillin, amoxicillin, ticarcillin, and piperacillin to extend their spectra. Metronidazole has superior in vitro activity against most anaerobes. This agent given with ampicillin and an aminoglycoside provides coverage against most organisms encountered in serious pelvic infections. It is also used to treat Clostridium difficile colitis.

Imipenem and similar antimicrobials are in the carbapenem family. These offer broad-spectrum coverage against most organisms associated with metritis. Imipenem is used in combination with cilastatin, which inhibits its renal metabolism. Preliminary findings with ertapenem indicated suboptimal outcomes (Brown, 2012). It seems reasonable from both a medical and an economic perspective to consider the use of carbapenems in the absence of severe renal insufficiency.
Vancomycin is a glycopeptide antimicrobial active against gram-positive bacteria. It is used in lieu of β-lactam therapy for a patient with a type 1 allergic reaction and given for suspected infections due to *Staphylococcus aureus* and to treat *C. difficile* colitis (Chap. 54, p. 1074).

**Perioperative Prophylaxis**

As discussed, administration of antimicrobial prophylaxis at the time of cesarean delivery has remarkably reduced the postoperative pelvic and wound infection rates. Numerous studies have shown that prophylactic antimicrobials reduce the pelvic infection rate by 70 to 80 percent (Chelmow, 2001; Dinsmoor, 2009; Smaill, 2010; Witt, 2011). The observed benefit applies to both elective and nonelective cesarean delivery and also includes a reduction in abdominal incisional infection rates.

Single-dose prophylaxis with ampicillin or a first-generation cephalosporin is ideal, and both are as effective as broad-spectrum agents or a multiple-dose regimen (American College of Obstetricians and Gynecologists, 2011). Extended-spectrum prophylaxis with azithromycin added to standard single-dose prophylaxis has shown a further reduction in postcesarean metritis rates (Tita, 2008). These findings need to be verified. Women known to be colonized with methicillin-resistant *Staphylococcus aureus*—MRSA—are given vancomycin in addition to a cephalosporin (Chap. 64, p. 1251). Finally, it is controversial whether the infection rate is lowered more if the selected antimicrobial is given before the skin incision compared with after umbilical cord clamping (Baaqeel, 2012; Macones, 2012; Sun, 2013). The American College of Obstetricians and Gynecologists (2011) has concluded that the evidence favors predelivery administration. There may be additive salutary effects of preoperative vaginal cleansing with povidone-iodine rinse or application of metronidazole gel (Haas, 2013; Reid, 2011; Yildirim, 2012).

**Other Methods of Prophylaxis.** Several studies have evaluated the value of prenatal cervicovaginal cultures. These are obtained in the hope of identifying pathogens that might be eradicated to decrease incidences of preterm labor, chorioamnionitis, and puerperal infections. Unfortunately, treatment of asymptomatic vaginal infections has not been shown to prevent these complications. Carey and coworkers (2000) reported no beneficial effects for women treated for asymptomatic bacterial vaginosis. Klebanoff and colleagues (2001) reported a similar postpartum infection rate in women treated for second-trimester asymptomatic *Trichomonas vaginalis* infection compared with that of placebo-treated women.

Technical maneuvers done to alter the postpartum infection rate have been studied with cesarean delivery. For example, allowing the placenta to separate spontaneously compared with removing it manually lowers the infection risk. However, changing gloves by the surgical team after placental delivery does not (Atkinson, 1996). Exteriorizing the uterus to close the hysterotomy may decrease febrile morbidity (Jacobs-Jokhan, 2004). Postdelivery mechanical lower segment and cervical dilatation have not been shown to be effective (Liabsuetrakul, 2011). No differences were found in postoperative infection rates when single- versus two-layer uterine closure was compared (Hauth, 1992). Similarly, infection rates are not appreciately affected by closure versus nonclosure of the peritoneum (Bamigboye, 2003; Tulandi, 2003). Importantly, although closure of subcutaneous tissue in obese women does not lower the wound infection rate, it does decrease the wound separation incidence (Chelmow, 2004; Magann, 2002; Naumann, 1995). Similarly, skin closure with staples versus suture has a higher incidence of noninfectious skin separation (Mackeen, 2012; Tuuli, 2011).
Complications of Uterine and Pelvic Infections

In more than 90 percent of women, metritis responds to treatment within 48 to 72 hours. In some of the remainder, any of several complications may arise. These include wound infections, complex pelvic infections such as phlegmons or abscesses, and septic pelvic thrombophlebitis (Jaiyeoba, 2012). As with other aspects of puerperal infections, the incidence and severity of these complications are remarkably decreased by perioperative antimicrobial prophylaxis.

### Abdominal Incisional Infections

Wound infection is a common cause of persistent fever in women treated for metritis. Other wound infection risk factors include obesity, diabetes, corticosteroid therapy, immunosuppression, anemia, hypertension, and inadequate hemostasis with hematoma formation. If prophylactic antimicrobials are given as described above, the incidence of abdominal wound infection following cesarean delivery ranges from 2 to 10 percent depending on risk factors (Andrews, 2003; Chaim, 2000).

Incisional abscesses that develop following cesarean delivery usually cause persistent fever or fever beginning about the fourth day. In many cases, antimicrobials had been given to treat pelvic infection, yet fever persisted. There is wound erythema and drainage. Although organisms that cause wound infections are generally the same as those isolated from amnionic fluid at cesarean delivery, hospital-acquired pathogens may also be causative (Emmons, 1988; Owen, 1994). Treatment includes antimicrobials, surgical drainage, and debridement of devitalized tissue. The fascia is carefully inspected to document integrity.

Local wound care is typically completed twice daily. Before each dressing change, procedural analgesia is tailored to wound size and location, and oral, intramuscular, or intravenous dosage routes are suitable. Topical lidocaine may also be added. Necrotic tissue is removed, and the wound is repacked with moist gauze. At 4 to 6 days, healthy granulation tissue is typically present, and secondary en bloc closure of the open layers can usually be accomplished (Wechter, 2005). With this closure, a polypropylene or nylon suture of appropriate gauge enters 3 cm from one wound edge. It crosses the wound to incorporate the full wound thickness and emerges 3 cm from the other wound edge. These are placed in series to close the opening. In most cases, sutures may be removed on postprocedural day 10. Wound vacuum device use is gaining popularity. However, its efficacy remains unproven in randomized trials.

### Wound Dehiscence

Wound disruption or dehiscence refers to separation of the fascial layer. This is a serious complication and requires secondary closure of the incision in the operating room. McNeeley and associates (1998) reported a fascial dehiscence rate of approximately 1 per 300 operations in almost 9000 women undergoing cesarean delivery. Most disruptions manifested on about the fifth postoperative day and were accompanied by a serosanguineous discharge. Two thirds of 27 fascial dehiscences identified in this study were associated with concurrent fascial infection and tissue necrosis.

### Necrotizing Fasciitis

This uncommon, severe wound infection is associated with high mortality rates. In obstetrics, necrotizing fasciitis may involve abdominal incisions, or it may complicate episiotomy or other perineal lacerations. As the name implies, there is significant tissue necrosis. Of the risk factors
for fasciitis summarized by Owen and Andrews (1994), three of these—diabetes, obesity, and hypertension—are relatively common in pregnant women. Like pelvic infections, these wound complications usually are polymicrobial and are caused by organisms that make up the normal vaginal flora. In some cases, however, infection is caused by a single virulent bacterial species such as group A β-hemolytic streptococcus. Occasionally, necrotizing infections are caused by rarely encountered pathogens (Swartz, 2004).

Goepfert and coworkers (1997) reviewed their experiences with necrotizing fasciitis at the University of Alabama Birmingham Hospital. Nine cases complicated more than 5000 cesarean deliveries—frequency of 1.8 per 1000. In two women, the infection was fatal. In a report from Brigham and Women’s and Massachusetts General Hospitals, Schorge and colleagues (1998) described five women with fasciitis following cesarean delivery. None of these women had predisposing risk factors, and none died.

Infection may involve skin, superficial and deep subcutaneous tissues, and any of the abdominopelvic fascial layers (Fig. 37-2). In some cases, muscle is also involved—myofasciitis. Although some virulent infections, for example, from group A β-hemolytic streptococci, develop early postpartum, most of these necrotizing infections do not cause symptoms until 3 to 5 days after delivery. Clinical findings vary, and it is frequently difficult to differentiate more innocuous superficial wound infections from an ominous deep fascial one. A high index of suspicion, with surgical exploration if the diagnosis is uncertain, may be lifesaving. We aggressively pursue early exploration. Certainly, if myofasciitis progresses, the woman may become ill from septicemia. Profound hemoconcentration from capillary leakage with circulatory failure commonly occurs, and death may soon follow as described in Chapter 47 (p. 947).

FIGURE 37-2 Necrotizing fasciitis involving the abdominal wall and Pfannenstiel incision. The skin rapidly became dusky and gangrenous, and pus is seen exuding from the left angle of the incision. Extensive debridement and supportive therapy were lifesaving.
Early diagnosis, surgical debridement, antimicrobials, and intensive care are paramount to successfully treat necrotizing soft-tissue infections (Gallup, 2004; Urschel, 1999). Surgery includes extensive debridement of all infected tissue, leaving wide margins of healthy bleeding tissue. This may include extensive abdominal or vulvar debridement with unroofing and excision of abdominal, thigh, or buttock fascia. Death is virtually universal without surgical treatment, and rates approach 50 percent even if extensive debridement is performed. With extensive resection, synthetic mesh may ultimately be required later to close the fascial incision (Gallup, 2004; McNeeley, 1998).

### Adnexal Abscesses and Peritonitis

An *ovarian abscess* rarely develops in the puerperium. These are presumably caused by bacterial invasion through a rent in the ovarian capsule (Wetchler, 1985). The abscess is usually unilateral, and women typically present 1 to 2 weeks after delivery. Rupture is common, and peritonitis may be severe.

Peritonitis is infrequent following cesarean delivery. It is almost invariably preceded by metritis. It most often is caused by uterine incisional necrosis and dehiscence, but it may be due to a ruptured adnexal abscess or an inadvertent bowel injury at cesarean delivery. Peritonitis is rarely encountered after vaginal delivery, and many such cases are due to virulent strains of group A β-hemocyte streptococci or similar organisms.

*Importantly in postpartum women, abdominal rigidity may not be prominent with puerperal peritonitis because of abdominal wall laxity from pregnancy.* Pain may be severe, but frequently, the first symptoms of peritonitis are those of *adynamic ileus*. Marked bowel distention may develop, and these findings are unusual after uncomplicated cesarean delivery. If the infection begins in an intact uterus and extends into the peritoneum, antimicrobial treatment alone usually suffices. Conversely, peritonitis caused by uterine incisional necrosis as discussed subsequently, or from bowel perforation, must be treated promptly with surgical intervention.

### Parametrial Phlegmon

For some women in whom metritis develops following cesarean delivery, parametrial cellulitis is intensive and forms an area of induration—a *phlegmon*—within the leaves of the broad ligament ([Fig. 37-3](#)). These infections should be considered when fever persists longer than 72 hours despite intravenous antimicrobial therapy (Brown, 1999; DePalma, 1982).
Right-sided parametrial phlegmon: cellulitis causes induration in the parametrium adjacent to the hysterotomy incision. Induration extends to the pelvis sidewall and on bimanual pelvic examination, a phlegmon is palpable as a firm, three-dimensional mass.

Phlegmons are usually unilateral, and they frequently are limited to the parametrium at the base of the broad ligament. If the inflammatory reaction is more intense, cellulitis extends along natural lines of cleavage. The most common form of extension is laterally along the broad ligament, with a tendency to extend to the pelvic sidewall. Occasionally, posterior extension may involve the rectovaginal septum, producing a firm mass posterior to the cervix. In most women with a phlegmon, clinical improvement follows continued treatment with a broad-spectrum antimicrobial regimen. Typically, fever resolves in 5 to 7 days, but in some cases, it persists longer. Absorption of the induration may require several days to weeks.

In some women, severe cellulitis of the uterine incision may lead to necrosis and separation (Treszezamsky, 2011). Extrusion of purulent material as shown in Figure 37-4 leads to intraabdominal abscess formation and peritonitis as described above. Surgery is reserved for women in whom uterine incisional necrosis is suspected because of ileus and peritonitis. For most, hysterectomy and surgical debridement are needed and are predictably difficult because the cervix and lower uterine segment are involved with an intense inflammatory process that extends to the pelvic sidewall. The adnexa are seldom involved, and one or both ovaries can usually be conserved. There is often appreciable blood loss, and transfusion may be necessary.
Imaging Studies

Persistent puerperal infections can be evaluated using computed tomography (CT) or magnetic resonance (MR) imaging. Brown and associates (1991) used CT imaging in 74 women in whom pelvic infection was refractory to 5 days of antimicrobial therapy. They found at least one abnormal radiological finding in 75 percent of these women, and in most, these were nonsurgical. Maldjian and coworkers (1999) used MR imaging in 50 women with persistent fever and found a bladder flap hematoma in two thirds. In three women, parametrial edema was seen, and another two had a pelvic hematoma. In most cases, imaging can be used to dissuade surgical exploration.

Uterine incisional dehiscence such as shown in Figure 37-4 is sometimes suspected based on CT scanning images. Another example is shown in Figure 37-5. These findings must be interpreted within the clinical context because apparent uterine incisional defects thought to represent edema can be seen even after uncomplicated cesarean delivery (Twickler, 1991).
Occasionally, a parametrial phlegmon suppurates, forming a fluctuant broad ligament mass that may point above the inguinal ligament. These abscesses may dissect anteriorly as shown in Figure 37-5 and be amenable to CT-directed needle drainage. Occasionally they dissect posteriorly to the rectovaginal septum, where surgical drainage is easily effected by colpotomy incision. A psoas abscess is rare, and despite antimicrobial therapy, percutaneous drainage may be required (Shahabi, 2002; Swanson, 2008).

**Septic Pelvic Thrombophlebitis**

This was a frequent complication in the preantibiotic era. Collins and colleagues (1951) described suppurative thrombophlebitis in 70 women cared for from 1937 through 1946 at Charity Hospital in New Orleans. Septic embolization was common and caused a third of maternal deaths during that period. With the advent of antimicrobial therapy, the mortality rate and need for surgical therapy for these infections diminished.

Septic phlebitis arises as an extension along venous routes and may cause thrombosis as shown in Figure 37-6. Lymphangitis often coexists. The ovarian veins may then become involved because they drain the upper uterus and therefore the placental implantation site. The experiences of Witlin and Sibai (1995) and Brown and coworkers (1999) suggest that puerperal septic thrombophlebitis is likely to involve one or both ovarian venous plexuses (Fig. 37-7). In a fourth of women, the clot extends into the inferior vena cava and occasionally to the renal vein.
FIGURE 37-6 Septic pelvic thrombophlebitis: uterine and parametrial infection may extend to any pelvic vessel as well as the inferior vena cava. The clot in the right common iliac vein extends from the uterine and internal iliac veins and into the inferior vena cava. The ovarian vein septic thrombosis extends halfway to the vena cava.
FIGURE 37-7 Ovarian vein thrombosis. Pelvic computed tomography scan shows enlargement of the right ovarian venous plexus with low density of the various lumens (arrows). The clotted vessels were easily palpable in this thin woman who had delivered vaginally 3 days earlier and was being treated with antimicrobials for metritis.

The incidence of septic phlebitis has varied in several reports. In a 5-year survey of 45,000 women who were delivered at Parkland Hospital, Brown and associates (1999) found an incidence of septic pelvic thrombophlebitis of 1 per 9000 following vaginal delivery and 1 per 800 with cesarean delivery. The overall incidence of 1 per 3000 deliveries was similar to the 1 per 2000 reported by Dunnihoo and colleagues (1991). In a cohort of 16,650 women undergoing primary cesarean delivery, Rouse and coworkers (2004) reported an incidence of 1 per 400 cesarean deliveries. Incidences approximated 1 per 175 surgeries if there was antecedent chorioamnionitis but only 1 per 500 if there was no intrapartum infection.

Women with septic thrombophlebitis usually have symptomatic improvement with antimicrobial treatment, however, they continue to have fever. Although there occasionally is pain in one or both lower quadrants, patients are usually asymptomatic except for chills. Diagnosis can be confirmed by either pelvic CT or MR imaging (Klima, 2008; Sheffield, 2001). Using either Brown and colleagues (1999) found that 20 percent of 69 women with metritis who had fever despite ≥ 5 days of appropriate antimicrobial therapy had septic pelvic thrombophlebitis.

It has been disproven that intravenous heparin causes fever to dissipate with septic phlebitis (Brown, 1986; Witlin, 1995). And although Garcia and coworkers (2006) and Klima and Snyder (2008) advocate heparin therapy, we do not recommend anticoagulation. In a randomized study of 14 women by Brown and associates (1999), the addition of heparin to antimicrobial therapy for septic pelvic thrombophlebitis did not hasten recovery or improve outcome. Certainly, there is no evidence for long-term anticoagulation as given for non-infection-related venous thromboembolism.

Perineal Infections
Episiotomy infections are not common because the operation is performed much less frequently now than in the past (American College of Obstetricians and Gynecologists, 2013). Reasons for this are discussed further in Chapter 27 (p. 550). In an older study, Owen and Hauth (1990) described only 10 episiotomy infections in 20,000 women delivered at the University of Alabama at Birmingham. With infection, dehiscence is a concern. Ramin and colleagues (1992) reported an episiotomy dehiscence rate of 0.5 percent at Parkland Hospital—80 percent of these were infected. In a more recent study, Uygur and associates (2004) reported a 1-percent dehiscence rate and attributed two thirds to infection. There are no data to suggest that dehiscence is related to faulty repair.

Infection of a fourth-degree laceration can be more serious. Goldaber and coworkers (1993) described 390 women with a fourth-degree laceration, of whom 5.4 percent had morbidity. In these women, 2.8 percent had infection and dehiscence, 1.8 percent had only dehiscence, and 0.8 percent only infection. Stock and associates (2013) reported wound complications in 7.3 percent of women with anal sphincter injuries. They further observed that intrapartum antimicrobials were protective against infection. Although life-threatening septic shock is rare, it may still occur as a result of an infected episiotomy (Soltesz, 1999). Occasionally also, necrotizing fasciitis develops as discussed on page 686.

Pathogenesis and Clinical Course

Episiotomy dehiscence is most commonly associated with infection as discussed above. Other factors include coagulation disorders, smoking, and human papillomavirus infection (Ramin, 1994). Local pain and dysuria, with or without urinary retention, are common symptoms. Ramin and colleagues (1992), evaluating a series of 34 women with episiotomy dehiscence, reported that the most common findings were pain in 65 percent, purulent discharge in 65 percent, and fever in 44 percent. In extreme cases, the entire vulva may become edematous, ulcerated, and covered with exudate.

Vaginal lacerations may become infected directly or by extension from the perineum. The mucosa becomes red and swollen and may then become necrotic and slough. Parametrial extension may result in lymphangitis.

Cervical lacerations are common but seldom are noticeably infected, which may manifest as metritis. Deep lacerations which extend directly into the tissue at the base of the broad ligament may become infected and cause lymphangitis, parametritis, and bacteremia.

Treatment

Infected episiotomies are managed like other infected surgical wounds. Drainage is established, and in many cases, sutures are removed and the infected wound debrided. In women with obvious cellulitis but no purulence, close observation and broad-spectrum antimicrobial therapy alone may be appropriate. With dehiscence, local wound care is continued along with intravenous antimicrobials. Hauth and colleagues (1986) were the first to advocate early repair after infection subsided, and other studies have confirmed the efficacy of this approach. Hankins and coworkers (1990) described early repair of episiotomy dehiscence in 31 women with an average duration of 6 days from dehiscence to episiotomy repair. All but two had a successful repair. Each of the two women with failures developed a pinpoint rectovaginal fistula that was treated successfully with a small rectal flap. With episiotomy dehiscence due to infection, Ramin and coworkers (1992) reported successful early repair in 32 of 34 women (94 percent), and Uygur and colleagues (2004) noted a similarly high percentage. Rarely, intestinal diversion may be required to allow healing.
Early Repair of Infected Episiotomy

Before performing early repair, diligent preparation is essential as outlined in Table 37-3. The surgical wound must be properly cleaned and cleared of infection. Once the surface of the episiotomy wound is free of infection and exudate and covered by pink granulation tissue, secondary repair can be accomplished. The tissue must be adequately mobilized, with special attention to identify and mobilize the anal sphincter muscle. Secondary closure of the episiotomy is accomplished in layers, as described for primary episiotomy closure (Chap. 27, p. 551). Postoperative care includes local wound care, low-residue diet, stool softeners, and nothing per vagina or rectum until healed.

Toxic Shock Syndrome

This acute febrile illness with severe multisystem derangement has a case-fatality rate of 10 to 15 percent. There is usually fever, headache, mental confusion, diffuse macular erythematous rash, subcutaneous edema, nausea, vomiting, watery diarrhea, and marked hemoconcentration. Renal failure followed by hepatic failure, disseminated intravascular coagulation, and circulatory collapse may follow in rapid sequence. During recovery, the rash-covered areas undergo desquamation. For some time, *Staphylococcus aureus* was recovered from almost all afflicted persons. Specifically, a staphylococcal exotoxin, termed toxic shock syndrome toxin-1 (TSST-1) was found to cause the clinical manifestations by provoking profound endothelial injury. A very small amount of TSST-1 has been shown to activate 5 to 30 percent of T cells to create a “cytokine storm” as described by Que (2005) and Heying (2007) and their coworkers.

During the 1990s, sporadic reports of virulent group A β-hemolytic streptococcal infection began to appear. Heavy colonization or infection is complicated in some cases by streptococcal toxic shock syndrome, which is produced when pyrogenic exotoxin is elaborated. Serotypes M1 and M3 are particularly virulent (Beres, 2004; Okumura, 2004). Finally almost identical findings of toxic shock were reported by Robbie and associates (2000) in women with *Clostridium sordellii* colonization.

Thus, in some cases of toxic shock syndrome, infection is not apparent and colonization of a mucosal surface is the presumed source. Ten to 20 percent of pregnant women have vaginal colonization with *S. aureus*. Thus, it is not surprising that the disease develops in postpartum...
women when there is luxuriant bacterial growth vaginally (Chen, 2006; Guerinot, 1982).

Delayed diagnosis and treatment may be associated with maternal mortality (Schummer, 2002). Crum and colleagues (2002) described a neonatal death following antenatal toxic shock syndrome. Principal therapy is supportive, while allowing reversal of capillary endothelial injury (Chap. 47, p. 947). Antimicrobial therapy that includes staphylococcal and streptococcal coverage is given. With evidence of pelvic infection, antimicrobial therapy must also include agents used for polymicrobial infections. Women with these infections may require extensive wound debridement and possibly hysterectomy. Because the toxin is so potent, the mortality rate is correspondingly high (Hotchkiss, 2003).

**BREAST INFECTIONS**

Parenchymal infection of the mammary glands is a rare antepartum complication but is estimated to develop in up to a third of breast-feeding women (Barbosa-Cesnik, 2003). Excluding breast engorgement, in our experiences, as well as that of Lee and associates (2010), the incidence of mastitis is much lower and probably approximates 1 percent. There is no evidence that any of several prophylactic measures prevent breast infection (Crepinsek, 2012). Risk factors include difficulties in nursing and mothers with outside employment (Branch-Elliman, 2012). Symptoms of suppurative mastitis seldom appear before the end of the first week postpartum and as a rule, not until the third or fourth week. Infection almost invariably is unilateral, and marked engorgement usually precedes inflammation. Symptoms include chills or actual rigors, which are soon followed by fever and tachycardia. There is severe pain, and the breast(s) becomes hard and red (Fig. 37-8). Approximately 10 percent of women with mastitis develop an abscess. Detection of fluctuation may be difficult, and sonography is usually diagnostic as also shown in Figure 37-8.
FIGURE 37-8 Puerperal mastitis with breast abscess. A. Photograph shows indurated, erythematous skin overlying area of right-sided breast infection. B. Sonographic picture of this 5-cm abscess. (Images contributed by Dr. Emily Adhikari.)

Etiology
Staphylococcus aureus, especially its methicillin-resistant strain, is the most commonly isolated organism. Matheson and coworkers (1988) reported it in 40 percent of women with mastitis. Other commonly isolated organisms are coagulase-negative staphylococci and viridans streptococci. The immediate source of organisms that cause mastitis is almost always the infant’s nose and throat. Bacteria enter the breast through the nipple at the site of a fissure or small abrasion. The infecting organism can usually be cultured from milk. Toxic shock syndrome from mastitis caused by S. aureus has been reported (Demey, 1989; Fujiwara, 2001).

At times, suppurative mastitis reaches epidemic levels among nursing mothers. Such outbreaks most often coincide with the appearance of a new strain of antibiotic-resistant staphylococcus. A contemporaneous example is community-acquired methicillin-resistant S. aureus (CA-MRSA) which has rapidly become the most commonly isolated staphylococcal species in some areas (Klevens, 2007; Pallin, 2008). At Parkland Hospital from 2000 to 2004, Laibl and associates (2005) reported that a fourth of CA-MRSA isolates were from pregnant or postpartum women with puerperal mastitis. Hospital-acquired MRSA may cause mastitis when the infant becomes colonized after contact with nursery personnel who are colonized (Centers for Disease Control and Prevention, 2006). Stafford and colleagues (2008) found a higher incidence of subsequent abscess in those with CA-MRSA-associated mastitis. In one study of puerperal breast abscesses 63 percent were due to methicillin-resistant strains (Berens, 2010).

### Management

Provided that appropriate therapy for mastitis is started before suppuration begins, the infection usually resolves within 48 hours. As discussed, abscess formation is more common with S. aureus infection (Matheson, 1988). Most recommend that milk be expressed from the affected breast onto a swab and cultured before therapy is begun. Bacterial identification and antimicrobial sensitivities provide information mandatory for a successful program of nosocomial infection surveillance (Lee, 2010).

The initial antimicrobial choice is influenced by the current experience with staphylococcal infections at the institution. Although most are community-acquired organisms, as discussed above, these frequently include CA-MRSA. Dicloxacillin, 500 mg orally four times daily, may be started empirically. Erythromycin is given to women who are penicillin sensitive. If the infection is caused by resistant, penicillinase-producing staphylococci or if resistant organisms are suspected while awaiting the culture results, then vancomycin or another anti-MRSA antimicrobial should be given. Even though clinical response may be prompt, treatment should be continued for 10 to 14 days.

Marshall and coworkers (1975) demonstrated the importance of continued breast feeding. They reported that of 65 women with mastitis, the only three who developed abscesses were among the 15 women who quit breast feeding. Vigorous milk expression may be sufficient treatment alone (Thomsen, 1984). Sometimes the infant will not nurse on the inflamed breast. This probably is not related to any changes in the milk taste but is secondary to engorgement and edema, which can make the areola harder to grip. Pumping can alleviate this. When nursing bilaterally, it is best to begin suckling on the uninvolved breast. This allows let-down to commence before moving to the tender breast.

In resource-poor countries, breast feeding in women infected with the human immunodeficiency virus (HIV) is not contraindicated. In the setting of mastitis or breast abscess, it is recommended to stop feeding from the infected breast. This is because HIV RNA levels increase in affected breast milk. These levels return to baseline after symptoms resolve (Semrau, 2013).
Breast Abscess

In a population-based study of nearly 1.5 million Swedish women, the incidence of breast abscess was 0.1 percent (Kvist, 2005). An abscess should be suspected when defervescence does not follow within 48 to 72 hours of mastitis treatment or when a mass is palpable. Again, sonographic imaging is valuable (see Fig. 37-8). Breast abscesses can be quite large, and in one case report, 2 liters of pus was drained (Martic, 2012). Traditional therapy is surgical drainage, which usually requires general anesthesia. The incision should be made corresponding to Langer skin lines for a cosmetic result (Stehman, 1990). In early cases, a single incision over the most dependent portion of fluctuation is usually sufficient. Multiple abscesses, however, require several incisions and disruption of loculations. The resulting cavity is loosely packed with gauze, which should be replaced at the end of 24 hours by a smaller pack.

A more recently used technique that is less invasive is sonographically guided needle aspiration using local analgesia. This has an 80- to 90-percent success rate (O’Hara, 1996; Schwarz, 2001). In a randomized trial, Naeem and colleagues (2012) compared surgical drainage and aspiration. They found aspiration resulted in quicker healing at 8 weeks, 77 versus 93 percent, respectively.

Half of all pregnancies each year in the United States are unintended (Finer, 2011). These may follow contraceptive method failure or stem from lack of contraceptive use. Specifically, 10 percent of sexually active American women not pursuing pregnancy did not use any birth control method (Jones, 2012). And, for sexually active fertile women not using contraception, pregnancy rates approach 90 percent at 1 year.

For those seeking contraception, various effective contraceptive methods are available. Preferences of United States women are shown in Table 38-1. With these methods, wide variations are seen between estimated failure rates of perfect and typical use during the first year. Similarly, the World Health Organization (WHO) has grouped methods according to effectiveness tiers that reflect these failure rates (Table 38-2). Implants and intrauterine devices are found in the top tier. They are effective in lowering unintended pregnancy rates and are considered long-acting reversible contraception (LARC) (Winner, 2012). The American College of Obstetricians and Gynecologists (2013c) recognizes these efficacy tiers and the high unintended pregnancy rate. Thus, the College recommends that clinicians provide counseling on all options and encourages highly effective LARC for all appropriate candidates.

</table>
Unfortunately, no contraceptive method is completely without side effects. That said, an important tenet is that contraception usually poses less risk than pregnancy. During appropriate method selection, underlying patient health conditions should be known. Some disorders or the medications used for their treatment can increase the risk of some contraceptives. The WHO (2010) has provided evidence-based guidelines, termed Medical Eligibility Criteria, for the use of all highly effective reversible contraceptive methods by women with various health conditions. Individual countries have subsequently modified these. The United States Medical Eligibility Criteria (US MEC) was published in the United States by the Centers for Disease Control and Prevention (CDC) (2010b), and its use is encouraged by the American College of Obstetricians and Gynecologists (2011b). Shown on page 698, the CDC (2011, 2012) has since added updates to reflect changes for women at high risk for human immunodeficiency virus (HIV) infection and for women in the puerperium. The US MEC guidelines and these updates, as well as a free smartphone application of the guidelines, are available at the CDC website: http://www.cdc.gov/reproductivehealth/UnintendedPregnancy/USMEC.htm.

In the US MEC, reversible contraceptive methods are organized into six groups by their similarity: combination hormonal contraceptives (CHCs), progestin-only pills (POPs), depot medroxyprogesterone acetate (DMPA), implants, levonorgestrel-releasing intrauterine system (LNG-IUS), and copper intrauterine devices (Cu-IUDs). For a given health condition, each method is categorized 1 through 4. The score describes a method’s safety profile for a typical woman with that condition: (1) no restriction of method use, (2) method advantages outweigh risks, (3) method risks outweigh advantages, and (4) method poses an unacceptably high health risk.

Alternatively, depending on the underlying disorder or patient desire, male or female sterilization may be a preferred or recommended permanent contraceptive method. These options are fully discussed in Chapter 39 (p. 720).

Methods organized according to tiers of efficacy by World Health Organization (WHO), Johns Hopkins Bloomberg School of Public Health, 2007. DMPA = depot medroxyprogesterone acetate. Data from Trussell, 2011a.
INTRAUTERINE DEVICES

These are the most commonly used method of reversible contraception worldwide, and in the United States, nearly 4 percent of women select this method (d’Arcanques, 2007; Jones, 2012). Fortunately, contraindications to IUD use are few.

Intrauterine devices (IUDs) that are chemically inert are composed of nonabsorbable materials. The three IUDs currently approved for use in the United States are chemically active and have continuous elution of copper or a progestin. Of these, there are two different levonorgestrel-releasing intrauterine systems—Mirena and Skyla (Fig. 38-1). Each releases the progestin into the uterus at a relatively constant rate, which reduces systemic effects. Their T-shaped radiopaque frames have a stem wrapped with a cylinder reservoir that contains the levonorgestrel. There are two trailing brown strings attached to the stem (Bayer Healthcare Pharmaceuticals, 2013a,b). Mirena is currently approved for 5 years of use following insertion, however, some evidence supports its efficacy for 7 years (Thonneau, 2008). Skyla is approved for 3 years of use. It has slightly smaller overall dimensions than its counterpart and was sized to more appropriately fit a nulliparous uterus (Gemzell-Danielsson, 2012). It can also be differentiated from Mirena visually and sonographically by a silver ring near the junction of the device’s stem and arms.

![FIGURE 38-1 Intrauterine devices (IUDs). A. ParaGard T 380A copper IUD. B. Mirena levonorgestrel-releasing intrauterine system.](image)

The third device is the T 380A IUD, named ParaGard. It has a polyethylene and barium sulfate T-shaped frame wound with copper, and two strings extend from the stem base. Originally blue, the strings are now white. It is currently approved for 10 years of use following insertion (Teva Women’s Health, 2011).

In addition to these three currently marketed, women may retain discontinued brands of IUD. A Lippes Loop has two “S” shapes stacked one on the other. The Dalkon Shield has a crab form, whereas a Copper 7 mirrors that number. Progestasert is an early T-shaped progestin-releasing IUD. Last, various metal-eluting ring-shaped devices are common in Asia.
Contraceptive Action

All these IUDs are effective. Failure rates are well below 1 percent and similar overall to those of tubal sterilization (American College of Obstetricians and Gynecologists, 2013a; Thonneau, 2008; Trussell, 2011b). Their mechanisms have not been precisely defined, but prevention of fertilization is now favored. Within the uterus, an intense local endometrial inflammatory response is induced, especially by copper-containing devices. Cellular and humoral components of this inflammation are expressed in endometrial tissue and in fluid filling the uterine cavity and fallopian tubes. These lead to decreased sperm and egg viability (Ortiz, 2007). Also, in the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst. The endometrium is transformed into a hostile site for implantation. With the copper IUD specifically, copper levels increase in the cervical mucus of users and decrease sperm motility and viability (Jecht, 1973). With the LNG-IUS, in addition to an inflammatory reaction, long-term progestin release leads to endometrial atrophy, which hinders normal implantation. Moreover, progestins create scant viscous cervical mucus that obstructs sperm motility. The LNG-IUS may also inconsistently release sufficient progestin to inhibit ovulation, although this is a lesser effect than its local actions.

Method-Specific Adverse Effects

Several method-specific complications may follow IUD insertion and include uterine perforation, device expulsion, menstrual changes, infection, and miscarriage if pregnancy occurs. Also, in the past, IUDs were perceived to increase the risk of ectopic pregnancy. However, this has been clarified. Specifically, IUDs are so effective as contraceptives that they lower the absolute number of ectopic pregnancies by half compared with the rate in noncontracepting women (World Health Organization, 1985, 1987). But, the IUD mechanisms of action are more effective in preventing intrauterine implantation. Thus, if an IUD fails, a higher proportion of pregnancies are likely to be ectopic (Backman, 2004; Furlong, 2002).

Perforation

During uterine sounding or IUD insertion, the uterus may be perforated, which is identified by the tool traveling further than the expected uterine length based on initial bimanual examination. Rates approximate 1 per 1000 insertions, and risks include puerperal insertion, lactation, provider inexperience, and extremes of uterine flexion (Harrison-Woolrych, 2003). Although devices may migrate spontaneously into and through the uterine wall, most perforations occur, or at least begin, at the time of insertion.

With the more common fundal perforation, bleeding typically is minimal due to myometrial contraction around the site. If no brisk or persistent bleeding is noted from the os following instrument removal, then patient observation alone is reasonable. Rarely, lateral perforations may lead to uterine artery laceration and brisk bleeding, which may prompt laparoscopy or laparotomy for control. Following any perforation, although this is not firmly evidence-based, a single dose of broad-spectrum antibiotic may mitigate infection.

Lost Device

Expulsion of an IUD from the uterus is most common during the first month. Thus, women should be examined approximately 1 month following IUD insertion, usually after menses, to identify the tails trailing from the cervix. Following this, a woman should be instructed to palpate the strings
each month after menses. If the tail of an IUD cannot be visualized, the device may have been expelled, may have perforated the uterus, or may be malpositioned. Some have found that IUD perforation, rotation, or embedding may cause pain or bleeding (Benacerraf, 2009; Moschos, 2011). Alternatively, the device may be normally positioned with its tail folded within the endocervical canal or uterine cavity. To investigate, after excluding pregnancy, a cytological brush can be twirled within the endocervical canal to entangle the strings and bring them gently into the vagina. If unsuccessful, the uterine cavity is probed gently with a Randall stone clamp or with a specialized rod with a terminal hook to retrieve the strings.

It should never be assumed that the device has been expelled unless it was seen. Thus, if tails are not visible and the device is not felt by gentle probing of the uterine cavity, transvaginal sonography can be used to ascertain if the device is within the uterus. Although traditional sonography will document IUD position adequately in most cases, three-dimensional sonography offers improved visualization, especially with the levonorgestrel-releasing IUD (Moschos, 2011). If sonography is inconclusive or if no device is seen, then a plain radiograph of the abdominopelvis is taken. Computed tomography (CT) scanning or less commonly, magnetic resonance (MR) imaging is an alternative (Boortz, 2012). It is safe to perform MR imaging at 1.5 and 3 Tesla (T) with an IUD in place (Pasquale, 1997; Zieman, 2007).

A device may penetrate the muscular uterine wall to varying degrees. Those with a predominantly intrauterine location are typically managed by hysteroscopic IUD removal. In contrast, devices that have nearly or completely perforated through the uterine wall are more easily removed laparoscopically. Chemically inert devices usually are removed easily from the peritoneal cavity. An extrauterine copper-bearing device, however, frequently induces an intense local inflammatory reaction and adhesions. Thus, copper IUDs may be more firmly adhered. Laparotomy may be necessary, and bowel preparation is considered. Perforations of large and small bowel and bladder and bowel fistulas have been reported remote from insertion (Lyon, 2012; Mascarenhas, 2012; Zeino, 2011).

**Menstrual Changes**

Women who choose the copper IUD should be informed that dysmenorrhea and menorrhagia may develop. These are often treated with nonsteroidal antiinflammatory drugs (NSAIDs) (Grimes, 2006). Heavy bleeding may cause iron deficiency anemia, for which oral iron salts are given (Hassan, 1999).

With the LNG-IUS, women are counseled to expect irregular spotting for up to 6 months after placement, and thereafter to expect monthly menses to be lighter or even absent (Bayer HealthCare Pharmaceuticals, 2013a). Specifically, the Mirena device is associated with progressive amenorrhea, which is reported by 30 percent of women after 2 years and by 60 percent after 12 years (Ronnedag, 1999). This is often associated with improved dysmenorrhea.

**Infection**

The device-related infection risk is increased only during the first 20 days following insertion (Farley, 1992). Of those who develop an infection during this time, most usually have an unrecognized coexistent cervical infection. Accordingly, women at risk for sexually transmitted diseases (STDs) should be screened either before or at the time of IUD insertion (Centers for Disease Control and Prevention, 2010a; Sufrin, 2012). That said, device insertion need not be delayed while awaiting *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or PAP screening.
results in asymptomatic women. If these bacteria are found and the patient is without symptoms, then the IUD may remain and treatment prescribed as detailed in Chapter 65 (p. 1269). Importantly, routine antimicrobial prophylaxis before insertion is not recommended (Grimes, 2001; Walsh, 1998). Moreover, the American Heart Association does not recommend infective endocarditis prophylaxis with insertion (Wilson, 2007).

After these first 3 weeks, infection risk is not increased in IUD users who would otherwise be at low risk of STDs. Correspondingly, IUDs appear to cause little, if any, increase in the risk of infertility in these low-risk patients (Hubacher, 2001). For these reasons, the American College of Obstetricians and Gynecologists (2011a, 2012a) recommends that women at low risk for STDs including adolescents, are good candidates for IUDs (Table 38-3). The IUD is also safe and effective in HIV-infected women and may be used in others who are immunosuppressed (Centers for Disease Control and Prevention, 2012).

*Combination hormone contraception (CHC) group includes pills, vaginal ring, and patch.

*Associated risks that increase category score include: age ≥ 35, transfusion at delivery, BMI ≥ 30, postpartum hemorrhage, cesarean delivery, smoking, preeclampsia.
If infection does develop, it may take several forms and typically requires broad-spectrum antimicrobials. Septic abortion mandates immediate uterine evacuation in addition to antimicrobials. Pelvic inflammatory disease (PID) without abscess is treated with systemic antibiotics. There are theoretical concerns that a coexistent IUD might worsen the infection or delay resolution. Although a provider may choose to remove an IUD in this setting, some evidence also supports allowing a device to remain during treatment in those hospitalized with mild or moderate PID (Centers for Disease Control and Prevention, 2010b; Tepper, 2013). Last tuboovarian abscess may develop with PID and is treated aggressively with intravenous broad-spectrum antibiotics and IUD removal.

In addition to these infections, *Actinomyces israelii* is a gram-positive, slow-growing, anaerobic indigenous vaginal bacterium that rarely causes infection with abscess formation (Persson, 1984). Some have found it more frequently in the vaginal flora or on the Pap smears of IUD users (Curtis, 1981; Fiorino, 1996). Current recommendations advise that an asymptomatic woman may retain her IUD and does not require antibiotic treatment (American College of Obstetricians and Gynecologists, 2013c; Lippes, 1999; Westhoff, 2007a). However, if signs or symptoms of infection develop in women who harbor *Actinomyces* species, then the device should be removed and antimicrobial therapy instituted. Early findings with infection include fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge. *Actinomyces* species are sensitive to antimicrobials with gram-positive coverage, notably the penicillins.

**Pregnancy with an IUD**

For women who become pregnant while using an IUD, ectopic pregnancy should be excluded (Chap. 19, p. 379). With intrauterine pregnancy, until approximately 14 weeks’ gestation, the tail may be visible through the cervix, and if seen, it should be grasped and the IUD removed by gentle outward traction. This action reduces complications such as subsequent abortion, chorioamnionitis, and preterm birth (Brahmi, 2012; Kim, 2010). Tatum and coworkers (1976) reported an abortion rate of 54 percent with the device left in place compared with a rate of 25 percent if it was promptly removed.

If the tail is not visible, attempts to locate and remove the device may result in abortion. However, some practitioners have successfully used sonography to assist in device removal in cases without visible strings (Schiesser, 2004). After fetal viability is reached, it is unclear...
whether it is better to remove an IUD whose string is visible and accessible or to leave it in place. There is no evidence that fetal malformations are increased with a device in place (Tatum, 1976).

Second-trimester miscarriage with an IUD in place is more likely to be infected (Vessey, 1974). Sepsis may be fulminant and fatal. Pregnant women with a device in utero who demonstrate any evidence of pelvic infection are treated with intensive antimicrobial therapy and prompt uterine evacuation. Because of these risks, a woman should be given the option of early pregnancy termination if the device cannot be removed early in pregnancy. Last, in women who give birth with a device in place, appropriate steps should be taken at delivery to identify and remove the IUD.

### Insertion

#### Timing

Immediately following miscarriage, surgical abortion, or delivery, an IUD may be inserted in the absence of infection. Also, Shimoni and colleagues (2011) describe “immediate” insertion 1 week after medical abortion. The risk of IUD expulsion is slightly higher if it is placed immediately following any of these recent pregnancies. That said, the advantages of preventing future unplanned pregnancies appear to outweigh this (Bednarek, 2011; Chen, 2010; Grimes, 2010a; Steenland, 2011).

Insertion techniques depend on uterine size. After first-trimester evacuation, the IUD can be placed using the manufacturer’s standard instructions. If the uterine cavity is larger, the IUD can be placed using ring forceps with sonographic guidance (Stuart, 2012). Immediately following vaginal or cesarean delivery, an IUD can be placed by hand or with an instrument (Grimes, 2010b). To reduce expulsion rates and to minimize the perforation risk, some may choose to wait for complete involution—at least 6 weeks after delivery. Women delivered at Parkland Hospital are seen 3 weeks postpartum, and IUDs are inserted 6 weeks postpartum or sooner if involution is complete.

For placement not related to pregnancy, insertion near the end of normal menstruation, when the cervix is usually softer and somewhat more dilated, may be easier and at the same time may exclude early pregnancy. But, insertion is not limited to this time. For the woman who is sure she is not pregnant and does not want to be pregnant, insertion is done at any time.

#### Technique

Before insertion, several procedural steps are carried out. Any contraindications are identified. If there are none, the woman is counseled and written consent obtained. An oral NSAID, with or without codeine, can be used to allay cramps (Karabayirli, 2012). Strong evidence does not support an advantage to supplemental misoprostol, intrauterine or cervical canal instillation of lidocaine, or paracervical blockade to lessen insertional pain (McNicholas, 2012; Nelson, 2013; Swenson, 2012). Bimanual pelvic examination is performed to identify uterine position and size. Abnormalities are evaluated, as they may contraindicate insertion. Mucopurulent cervicitis or significant vaginitis should be appropriately treated and resolved before IUD insertion.

The cervical surface is cleansed with an antiseptic solution, and sterile instruments and a sterile IUD should be used. A tenaculum is placed on the cervical lip, and the canal and uterine cavity are straightened by applying gentle traction. The uterus is then sounded to identify the direction and depth of the uterine cavity. Specific steps of ParaGard and Mirena insertion are shown in Figures 38-2 and 38-3 and outlined in their respective package inserts.
A

- IUD
- Inserter tube
- Flange
- Slider
- Handle
- Strings in cleft

B

- Arms released
- Flange 1.5 cm from cervix
- Slider moved back to first mark
FIGURE 38-2 Insertion of the Mirena intrauterine system. Initially, threads from behind the slider are first released to hang freely. The slider found on the handle should be positioned at the top of the handle nearest the device. The IUD arms are oriented horizontally. A flange on the outside of the inserter tube is positioned from the IUD tip to reflect the depth found with uterine sounding. A. As both free threads are pulled, the Mirena IUD is drawn into the inserter tube. The threads are then tightly fixed from below into the handle’s cleft. In these depictions, the inserter tube has been foreshortened. The inserter tube is gently inserted into the uterus until the flange lies 1.5 to 2 cm from the external cervical os to allow the arms to open. B. While holding the inserter steady, the IUD arms are released by pulling the slider back to reach the raised horizontal mark on the handle, but no further. C. The inserter is then gently guided into the uterine cavity until its flange touches the cervix. D. The device is released by holding the inserter firmly in position and pulling the slider down all the way. The threads will be released automatically from the cleft. The inserter may then be removed, and IUD strings trimmed.
FIGURE 38-3 Insertion of ParaGard T 380A. The uterus is sounded, and the IUD is loaded into its inserter tube not more than 5 minutes before insertion. A blue plastic flange on the outside of the inserter tube is positioned from the IUD tip to reflect uterine depth. The IUD arms should lie in the same plane as the flat portion of the oblong blue flange. A. The inserter tube, with the IUD loaded, is passed into the endometrial cavity. A long, solid, white inserter rod abuts the base of the IUD. When the blue flange contacts the cervix, insertion stops. B. To release the IUD arms, the solid white rod within the inserter tube is held steady, while the inserter tube is withdrawn no more than 1 cm. C. The inserter tube, not the inserter rod, is then carefully moved upward toward the top of the uterus until slight resistance is felt. At no time during insertion is the inserter rod advanced forward. D. First, the solid white rod and then the inserter tube are withdrawn individually. At completion, only the threads should be visible protruding from the cervix. These are trimmed to allow 3 to 4 cm to extend into the vagina.

Following insertion, only the threads should be visible trailing from the cervix. These are trimmed to allow 3 to 4 cm to protrude into the vagina, and their length is recorded. If there is suspicion that the device is not positioned correctly, then placement should be confirmed, using sonography if necessary. If the IUD is not positioned completely within the uterus, it is removed and replaced with a new device. An expelled or partially expelled device should not be
LONG-ACTING REVERSIBLE CONTRACEPTION: PROGESTIN IMPLANTS

Etonogestrel Implant

Contraception can be provided by thin, pliable progestin-containing cylinders that are implanted subdermally and release hormone over many years. One of these, Implanon is a single-rod implant with 68 mg of etonogestrel covered by an ethylene vinyl acetate copolymer cover. The implant is placed subdermally on the medial surface of the upper arm 8 to 10 cm from the elbow in the biceps groove and is aligned with the long axis of the arm. It may be used as contraception for 3 years and then replaced at the same site or in the opposite arm (Merck, 2012a).

Implanon is not radiopaque, and a misplaced implant may be identified with sonography using a 10- to 15-MHz linear array transducer (Shulman, 2006). In some cases, MR imaging may be required if supplemental information is needed despite sonography (Correia, 2012). To improve radiologic detection, the manufacturer developed Nexplanon, which is similarly shaped and pharmacologically identical to Implanon but is radiopaque. Additionally, the Nexplanon inserter device is designed to assist with subdermal placement and avert deeper insertions. Both implants are highly effective, and the mechanism of action for progestin-only products is described on page 704 (Croxatto, 1998; Mommers, 2012). Although still approved by the Food and Drug Administration (FDA), Implanon is no longer distributed by the manufacturer.

Levonorgestrel Implants

The first progestin implants contained levonorgestrel, and systems are still available outside the United States. Jadelle, originally named Norplant-2, provides levonorgestrel and contraception for 5 years through two subdermally implanted Silastic rods. After this time, rods may be removed and if desired, new rods inserted at the same site (Bayer Schering Pharma Oy, 2010). Jadelle is approved by the FDA, however, it is not marketed or distributed in the United States (Population Council, 2013). Sino-implant II is a two-rod implant with the same amount (150 mg) of levonorgestrel and same mechanism of action as Jadelle but provides 4 years of contraception (Shanghai Dahua Pharmaceutical, 2012). Sino-implant II is manufactured in China and approved for use by several countries in Asia and Africa.

Both implant systems are highly effective, and the mechanism of action for progestin-only products is described on page 704. Like the etonogestrel implant, these systems are placed subdermally on the inner arm approximately 8 cm from the elbow and have similar removal steps. Implants vary regarding their insertion technique, and manufacturer instructions should be consulted.

The forerunner of these implants was the Norplant System, which provided levonorgestrel in six Silastic rods implanted subdermally. The manufacturer stopped distributing the system in 2002.

Method-Specific Adverse Effects

Risks that are specific to implants stem mainly from malpositioning. First, branches of the medial
The antebrachial cutaneous nerve can be injured if the implant or insertion needle is placed too deeply or if exploration for a lost implant is aggressive. Clinically, numbness and paresthesia over the anteromedial aspect of the forearm are noted (Brown, 2012; Wechselberger, 2006). Second, nonpalpable devices are not uncommon and may require radiological imaging for localization as described earlier. If imaging fails to locate an Implanon or Nexplanon implant, etonogestrel blood level determination can be used to verify that the implant is in situ.

### Insertion

#### Timing

For those not currently using hormonal contraception, the etonogestrel implant is ideally inserted within 5 days of menses onset. If inserted later in the cycle, alternative contraception is recommended for 7 days following placement. With levonorgestrel-releasing implants, contraception is established within 24 hours if inserted within the first 7 days of the menstrual cycle (Sivin, 1997; Steiner, 2010). For transitioning methods, an implant is placed on the day of the first placebo COC pill; on the day that the next DMPA injection would be due; or within 24 hours of taking the last POP (Merck, 2012a). Related to pregnancy, an implant may be inserted before discharge following delivery, miscarriage, or abortion.

#### Nexplanon Insertion Technique

With the patient lying down, her nondominant arm, forearm, and hand are outstretched on the bed with the inner aspects of each exposed upward, and the elbow is flexed. The insertion site is marked with a sterile pen 8 to 10 cm proximal to the medial condyle of the humerus. A second mark is placed 4 centimeters proximally and delineates the final path of the implant. The Nexplanon is inserted using sterile technique. The area is cleaned aseptically, and a 1-percent lidocaine anesthetic track is injected beneath the skin along the planned insertion path. The implant is then placed as shown in Figure 38-4. After placement, both patient and provider should palpate and identify both ends of the 4-cm implant. To minimize bruising at the site, a pressure bandage is created around the arm and is removed the following day.

![Figure 38-4](image)

**FIGURE 38-4** Nexplanon insertion. A sterile pen marks the insertion site, which is 8 to 10 cm proximal to the medial humeral condyle. A second mark is placed 4 cm proximally along the arm’s long axis. The area is cleaned aseptically, and a 1-percent lidocaine anesthetic track is injected...
along the planned insertion path. **A.** The insertion device is grasped at its gripper bubbles found on either side, and the needle cap is removed outward. The device can be seen within the needle bore. The needle bevel then pierces the skin at a 30-degree angle. **B.** Once the complete bevel is subcutaneous, the needle is quickly angled downward to lie horizontally. **C.** Importantly, the skin is tented upward by the needle as the needle is slowly advanced horizontally and subdermally. **D.** Once the needle is completely inserted, the lever on the top of the device is pulled backward toward the operator. This retracts the needle and thereby deposits the implant. The device is then lifted away from the skin. After placement, both patient and operator should palpate the 4-cm implant.

With sterile implant removal, the proximal end of the implant is depressed with a finger to allow the distal end to bulge toward the skin. After anesthetizing the skin over this bulge, the skin is incised 2 mm toward the elbow along the long axis of the arm. The proximal butt of the implant is then pushed toward this incision. Once visible, the distal implant is grasped with a hemostat and removed. If present, superficial adhesions surrounding an implant may be dissected away with hemostat tips placed into the incision.

### PROGESTIN-ONLY CONTRACEPTIVE GROUP

#### Actions and Side Effects

Progestin-only contraceptives include the implants just described, pills, and injectables. As their primary contraceptive action, these progestins suppress luteinizing hormone (LH) and in turn block ovulation. As other effects, cervical mucus is thickened to retard sperm passage, and atrophy renders the endometrium unfavorable for implantation. Fertility is restored rapidly following cessation of progestin-only contraception, with the exception of DMPA as described on page 711 (Mansour, 2011).

For all progestin-only methods, irregular uterine bleeding is a distinct disadvantage. It may manifest as metrorrhagia or menorrhagia and is the most frequently reported adverse event leading to method discontinuation. Often, counseling and reassurance regarding this effect is sufficient. Particularly troublesome bleeding may be improved by one to two cycles of COCs, by a 1- to 3-week course of estrogen alone, or by a short course of NSAIDs combined with the established method. Fortunately, with prolonged use, progestins induce endometrial atrophy, which leads to sustained amenorrhea. And, for the well-counseled patient, this is often an advantage.

Most progestin-only contraceptive methods do not significantly affect lipid metabolism, glucose levels, hemostatic factors, liver function, thyroid function, and blood pressure (Dorflinger, 2002). Moreover, these have not been shown to increase the risk for thromboembolism, stroke, or cardiovascular disease (Mantha, 2012; World Health Organization, 1998). However, as described on page 711, the increased low-density lipoprotein (LDL) cholesterol and decreased high-density lipoprotein (HDL) cholesterol levels seen with DMPA may be less desirable if there are cardiac or vascular risks.

Progestin-only methods do not impair milk production and are an excellent choice for lactating women. There are no increased risks of genital tract or breast neoplasia (Wilailak, 2012; World Health Organization, 1991a,b, 1992). Weight gain and bone mineral density loss are not prominent side effects of this contraceptive group, except for DMPA, as noted on page 711 (Funk, 2005; Lopez, 2011). Functional ovarian cysts develop with a greater frequency in women using
progestin-only agents, although they do not usually necessitate intervention (Brache, 2002; European Society of Human Reproduction and Embryology, 2001). Last, an association between depression and DMPA or POPs is unclear (Civic, 2000; Svendal, 2012; Westhoff, 1995). Women with depression may be prescribed these methods, but surveillance following initiation is reasonable.

### Contraindications to Progestin-Only Contraceptives

These methods are ideal for most women, but contraindications and cautions are associated with a few conditions. Current breast cancer and pregnancy are the only two absolute contraindications. However, conditions for which limited and cautious use should be considered are listed in Table 38-3.

There are a few instances in which manufacturer restrictions differ from the US MEC. First, manufacturer prescribing information lists thrombosis or thromboembolic disorders as contraindications (Merck, 2012a; Pfizer, 2012). However, for individuals with these disorders, US MEC considers progestin-containing methods category 2. Second, for many progestin products manufacturers note prior ectopic pregnancy as a contraindication. This is secondary to progesterone’s effect to slow fallopian tube motility and thereby delay fertilized egg transport to the endometrial cavity. But again, US MEC considers progestin injectables and implants category 1, and progestin-only pills are category 2 for those with prior ectopic pregnancy.

### VERY EFFECTIVE CONTRACEPTION: HORMONAL CONTRACEPTIVES

These currently are available in forms that contain both estrogen and progestin or contain only progestin. Progestin-only injectables and pills are considered very effective, yet second-tier agents, due to the need for increased patient compliance. Similarly, products containing both estrogen and progestin, often termed combination hormonal contraception (CHC), are considered in this tier. These may be supplied as pills, transvaginal rings, or transdermal patches.

#### Combination Hormonal Contraceptives Mechanism of Action

The contraceptive actions of CHCs are multiple, but the most important effect is suppression of hypothalamic gonadotropin-releasing factors. This in turn blocks pituitary secretion of follicle-stimulating hormone (FSH) and LH to inhibit ovulation. The progestin component provides ovulation prevention by suppressing LH; they thicken cervical mucus and thereby retard sperm passage; and they render the endometrium unfavorable for implantation. Estrogen blocks ovulation by suppressing FSH release. It also stabilizes the endometrium, which prevents intermenstrual bleeding—also known as *breakthrough bleeding*. The net effect is an extremely effective yet highly reversible method (Mansour, 2011).

#### Composition Oral Contraceptive Pills

**Composition**

Combination oral contraceptive pills are the most frequently used birth control method in the
In a 2006 to 2010 survey, 17 percent of US women were using these (Jones, 2012). COCs are marketed in an almost bewildering variety (Table 38-4). Most are also available as generics, and the FDA (2013) confirms the bioequivalence of COC generics. The American College of Obstetricians and Gynecologists (2013b) supports the use of either branded or generic preparations.

Pharmacologically, ethinyl estradiol is the most common estrogen present in COC formulations in the United States. Less frequently, mestranol or estradiol valerate is used. Unwanted effects most often attributed to the estrogen component include breast tenderness, fluid retention, weight gain, nausea, and headache.

COCs also contain one of several progestins that are structurally related to progesterone, testosterone, or spironolactone. Thus, these progestins bind variably to progesterone, androgen, estrogen, glucocorticoid, and mineralocorticoid receptors. These affinities explain many pill-
related side effects and are often used to compare one progestin with another.

Most progestins used in COCs are related to testosterone and may impart androgenic side effects such as acne and adverse HDL and LDL levels. To avoid these effects, progestins more structurally similar to the progestone molecule have been developed. Medroxyprogesterone acetate is one example, but it is mainly used in a progestin-only injectable form. Another, nomegestrol acetate, is used in a COC approved outside the United States. Despite these pharmacological differences, the true advantage of one progestin over another is less apparent clinically (Lawrie, 2011; Moreau, 2007).

Another progestin, drospirenone, is structurally similar to spironolactone. The doses used in currently marketed COCs have effects similar to 25 mg of this diuretic hormone (Seeger, 2007). Drospirenone displays antiandrogenic activity, provides an antialdosterone action to minimize water retention, and has antimineralocorticoid properties that may, in theory, cause potassium retention and hyperkalemia (Krattenmacher, 2000). Thus, it is avoided in women with renal or adrenal insufficiency or with hepatic dysfunction. Moreover, serum potassium level monitoring is recommended in the first month for patients chronically treated concomitantly with any drug associated with potassium retention. These include NSAIDs, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II antagonists, heparin, aldosterone antagonists, and potassium-saving diuretics (Bayer HealthCare Pharmaceuticals, 2012).

Since the development of COCs, their estrogen and progestin content has dropped remarkably to minimize adverse effects. Currently, the lowest acceptable dose is limited by the ability to prevent pregnancy and to avoid unacceptable breakthrough bleeding. Thus, the daily estrogen content varies from 10 to 50 μg of ethinyl estradiol, and most contain 35 μg or less.

With COCs termed monophasic pills, the progestin dose remains constant throughout the cycle. In others, the dose frequently is varied, and terms biphasic, triphasic, or quadriphasic pill are used depending on the number of dose changes within the cycle. In some formulations, the estrogen dose also varies. In general, phasic pills were developed to reduce the total progestin content per cycle without sacrificing contraceptive efficacy or cycle control. The theoretical advantage of a lower total progesterone dose per cycle has not been borne out clinically (Moreau, 2007). Cycle control also appears to be comparable among mono- through triphasic pills (van Vliet, 2006, 2011a,b).

Administration

Hormones are taken daily for a specified time (21 to 81 days) and then replaced by placebo for a specified time (4 to 7 days), which is called the “pill-free interval.” During these pill-free days, withdrawal bleeding is expected.

With the trend to lower estrogen doses to minimize side effects, there is concern for follicular development and ovulation. To counter this, the active-pill duration in some formulations is extended to 24 days. And, these 24/4 regimens do appear to reduce ovulation and breakthrough bleeding rates (Fels, 2013).

Alternatively, longer durations of active hormone, designed to minimize the number of withdrawal episodes, have been introduced (Edelman, 2006). These extended-cycle products produce a 13-week cycle, that is, 12 weeks of hormone use, followed by a week for withdrawal menses. The product Amethyst provides continuous active hormone pills for 365 days each year. Such extended or continuous regimens may be especially suited for women with significant menstrual symptoms.

For general initiation, women should ideally begin COCs on the first day of a menstrual cycle.
In such cases, a supplementary contraceptive method is unnecessary. With the more traditional “Sunday start,” women begin pills on the first Sunday that follows menses onset, and an additional method is needed for 1 week to prevent conception. If menses begin on a Sunday, then pills are begun that day and no supplementary method is required. Alternatively, with the “Quick Start” method, COCs are started on any day, commonly the day prescribed, regardless of cycle timing. An additional method is used during the first week. This latter approach improves short-term compliance (Westhoff, 2002, 2007b). If the woman is already pregnant during Quick Start initiation, COCs are not teratogenic (Lammer, 1986; Rothman, 1978; Savolainen, 1981). Similarly same-day initiation can be implemented with the contraceptive vaginal ring or patch (Murthy, 2005; Schafer, 2006).

For maximum efficiency, pills should be taken at the same time each day. If one dose is missed, contraception is likely not diminished with higher-dose monophasic COCs. Doubling the next dose will minimize breakthrough bleeding and maintain the pill schedule. If several doses are missed or if lower-dose pills are used, the pill may be stopped, and an effective barrier technique used until menses. The pill may then be restarted. Alternatively, a new pack can be started immediately following identification of missed pills, and a barrier method used for 1 week. If there is no withdrawal bleeding, the woman should continue her pills but seek attention to exclude pregnancy.

With initiation of COCs, spotting or bleeding is common. It does not reflect contraceptive failure and typically resolves within one to three cycles. If unscheduled bleeding persists, those with bleeding during the first part of a pill pack may benefit from an increase in the pill’s estrogen dose, whereas those with bleeding during the second part may improve with a higher progestin dose (Nelson, 2011).

### Method-Specific Effects

#### Altered Drug Efficacy

Combination oral contraceptives interfere with the actions of some drugs. In such cases, doses can be adjusted as shown in Table 38-5. Conversely, some drugs decrease the COC effectiveness. Three groups are notable: the antitubercular drugs rifampin and rifabutin; efavirenz and ritonavir-boosted protease inhibitors, which are used to treat HIV infection; and enzyme-inducing anticonvulsants, which include phenytoin (Dilantin), carbamazepine (Tegretol), oxcarbazepine (Trileptal), barbiturates, primidone (Mysoline), and topiramate (Topamax) (Gaffield, 2011; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). With these, a method other than COCs is preferable. However, if a COC is selected for concurrent use with an agent from these three groups, then a preparation containing a minimum of 30 μg ethinyl estradiol should be chosen.

In obese women, COCs are highly effective (Lopez, 2010). That said, some but not all studies point to a potential increased pregnancy risk with COC use due to lowered hormone bioavailability (Brunner, 2005; Holt, 2002, 2005; Westhoff, 2010). With the transdermal patch method, however, there is stronger evidence that obesity may alter pharmacokinetics and lower efficacy (p. 701).
Metabolic Changes

Although their effects on carbohydrate metabolism are considered clinically insignificant, COCs do have notable effects on lipid and protein synthesis. In general, COCs increase serum levels of triglycerides and total cholesterol. Estrogen decreases LDL cholesterol concentrations but increases HDL and very-low density (VLDL) cholesterol levels. Some progestins cause the reverse. Despite this, the clinical consequences of these perturbations have almost certainly been overstated. Oral contraceptives are not atherogenic, and their impact on lipids is inconsequential for most women (Wallach, 2000). But in women with dyslipidemias, the American College of Obstetricians and Gynecologists (2013e) recommends assessment of lipid levels following COC initiation. Moreover, for women with LDL cholesterol levels > 160 mg/dL or for those with multiple additional risk factors for cardiovascular disease, alternative contraceptive methods are recommended.

With COCs, protein metabolism is affected, and estrogens prompt increased hepatic production of various globulins. First, fibrinogen and many of the clotting factor levels are increased in direct proportion to estrogen dose and may lead to thrombosis (Comp, 1996). Angiotensinogen production is also augmented by COCs, and its conversion by renin to angiotensin I may be associated with “pill-induced hypertension” discussed subsequently. Last, COCs increase sex-hormone binding globulin (SHBG) levels, which decrease bioavailable testosterone concentrations and improve androgenic side effects.

Regarding carbohydrate metabolism, there are fortunately limited effects with current low-dose formulations in women who do not have diabetes (Lopez, 2012a). And, the risk of developing diabetes is not increased (Kim, 2002). Moreover, COCs may be used in non-smoking, diabetic women younger than 35 years who have no associated vascular disease (American College of Obstetricians and Gynecologists, 2013e). Last, studies have not supported a connection between COCs and weight gain (Gallo, 2011).

Other metabolic changes, often qualitatively similar to those of pregnancy, have been identified in women taking oral contraceptives. For example, total plasma thyroxine (T$_4$) and thyroid-binding proteins are elevated. These pregnancy-like effects should be considered when evaluating laboratory tests in women using COCs.

Cardiovascular Effects

Despite increased plasma angiotensinogen (renin substrate) levels, most women using low-dose COCs formulations rarely develop clinically significant hypertension (Chasan-Taber, 1996). However, it is common practice for patients to return 8 to 12 weeks after COC initiation for evaluation of blood pressure and other symptoms.

During initial contraception selection, a history of gestational hypertension does not preclude subsequent COC use. Also, COCs are permissible in women with well-controlled uncomplicated hypertension who are non-smokers, otherwise healthy, and younger than 35 (American College of Obstetricians and Gynecologists, 2013e). In contrast, severe forms of hypertension, especially those with end-organ involvement, usually preclude COC use.

For women with prior stroke, COCs should not be considered due to risks for repeat events. The risk for a first stroke is substantially increased in women who have hypertension, who smoke, or who have migraine headaches with visual aura or other focal neurological changes and use oral contraceptives (MacClellan, 2007). However, for non-smoking women younger than 35, the risk of ischemic and hemorrhagic strokes is extremely low, and method benefits considerably outweigh risks (World Health Organization, 1996, 1998). Moreover, because of this low risk, the American
College of Obstetricians and Gynecologists (2013e) notes that COCs may be considered for women with migraines that lack focal neurological signs if they are otherwise healthy, normotensive nonsmokers younger than 35 years.

For women with prior myocardial infarction, COCs should not be considered. Also, in women with multiple cardiovascular risk factors, which include smoking, hypertension, older age, and diabetes, the risk for myocardial infarction outweighs the benefits of this method. However, for those without these risks, low-dose oral contraceptives are not associated with an increased risk of myocardial infarction (Margolis, 2007; World Health Organization, 1997).

It has long been known that the risk of deep-vein thrombosis and pulmonary embolism is increased in women who use COCs (Stadel, 1981). These clearly are estrogen-dose related, and rates have substantively decreased with lower-dose formulations containing 10 to 35 μg of ethinyl estradiol. The incidence of venous thromboembolism (VTE) with COC use is only 3 to 4 per 10,000 woman-years and is lower than the incidence of 5 to 6 per 10,000 woman-years estimated for pregnancy (Chap. 52, p. 1028) (Mishell, 2000). The enhanced risk of VTE appears to decrease rapidly once COCs are stopped. And because these complications are increased in women smokers older than 35 years, COCs are not recommended for this population (Craft, 1989).

Those most at risk for VTE include women with thrombophilias (Comp, 1996). Other clinical factors that increase the risk of VTE with COC use are hypertension, obesity, diabetes, smoking, and a sedentary lifestyle (Pomp, 2007, 2008). Moreover, COC use during the month before a major operative procedure appears to double the risk for postoperative VTE (Robinson, 1991). Thus, the American College of Obstetricians and Gynecologists (2013d) recommends balancing the risks of VTE with those of unintended pregnancy during the 4 to 6 weeks required to reverse the thrombogenic effects of COCs before surgery. In the early puerperium, VTE risks are also increased, and COCs are not recommended for women within the first 4 weeks after delivery. For all women, an increased VTE risk with drospirenone-containing COCs has been shown in two studies. Accordingly, the FDA has encouraged an assessment of benefits and VTE risks in users of these pills (Food and Drug Administration, 2011; Jick, 2011; Parkin, 2011).

Neoplasia

Fortunately, most studies indicate that overall, COCs are not associated with an increased risk of cancer (Hannaford, 2007). In fact, a protective effect against ovarian and endometrial cancer has been shown (Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2008; Tsilidis 2011). Protection from these cancers decreases, however, as time from pill use lengthens (Tworoger, 2007). In contrast, the relative risk of cervical dysplasia and cervical cancer is increased in current COC users, but this declines after use is discontinued. Following 10 or more years, risk returns to that of never users (International Collaboration of Epidemiological Studies of Cervical Cancer, 2007).

Although COC use in the past was linked to development of hepatic focal nodular hyperplasia and benign hepatic adenoma, large studies do not support this (Heinemann, 1998). Moreover, there is also no evidence for increased risk of hepatocellular cancer (Maheshwari, 2007). For women with known tumors, COCs may be used in those with focal nodular hyperplasia, but avoided in those with benign hepatic adenoma and hepatocellular carcinoma (Kapp, 2009b). Rates of colorectal cancer appear to be reduced in ever users (Bosetti, 2009; Kabat, 2008).

It is unclear whether COCs contribute to the development of breast cancer, and major studies show no risk or a small risk among current users, which drops with time following cessation (Collaborative Group on Hormonal Factors in Breast Cancer, 1996; Marchbanks, 2002). In women who are carriers of the BRCA1 or BRCA2 gene mutation, risks for breast cancer are not
increased by COC use (Brohet, 2007; Iodice, 2010). With regard to benign breast disease, COCs appear to lower rates (Vessey, 2007).

Other Effects

As summarized in Table 38-6, many noncontraceptive benefits are associated with COC use (American College of Obstetricians and Gynecologists, 2012c). And indeed, COCs may be used for these effects, even in those without contraceptive needs.

Low-dose estrogen formulations are not associated with depression or premenstrual mood changes and may actually improve the latter (Joffe, 2007). This is especially true with the drospirenone-containing COCs. Several studies have shown symptom improvement in women with premenstrual dysphoric disorder (PMDD) who use the drospirenone-containing COCYaz (Lopez, 2012b; Pearlstein, 2005; Yonkers, 2005). And, the FDA has approved indications for this pill to include treatment of PMDD and moderate acne vulgaris for women requesting oral contraception.

Cholestasis and cholestatic jaundice are uncommon, but they resolve when COCs are discontinued. For women who have active hepatitis, COCs should not be initiated, but these may be continued in women who experience a flare of their liver disease while already taking COCs. Use of progestin-only contraception in these women is not restricted. Moreover, there is no reason to withhold COCs from women who have recovered. With cirrhosis, mild compensated disease does not limit the use of COCs or progestin-only methods. However, in those with severe decompensated disease, all hormonal methods should be avoided (Kapp, 2009a).

The progestin component of COCs reduces serum free testosterone levels and inhibits 5α-reductase to limit conversion of testosterone to its active metabolite, dihydrotestosterone. The estrogen component increases SHBG production and also lowers circulating androgen levels. The expected results of these actions are to improve androgenic conditions such as acne and hirsutism.

Hyperpigmentation of the face and forehead—chloasma—is more likely in women who demonstrated such a change during pregnancy. This is less common with low-dose estrogen formulations. Cervical mucorrhea, likely due to cervical ectopy, is common in response to the estrogen component of COCs (Critchlow, 1995). Although previously used for treating functional
ovarian cysts, low-dose COC formulations have no effects related to cyst resolution or prevention (European Society of Human Reproduction and Embryology, 2001; Grimes, 2011).

Transdermal Patch

The Ortho Evra patch is another combination hormonal contraceptive formulation. It has an inner layer containing an adhesive and hormone matrix, and a water-resistant outer layer. Thus, women can wear the patch in bathtubs, showers, swimming pools, saunas, and whirlpools without decreased efficacy. The patch may be applied to buttocks, upper outer arm, lower abdomen, or upper torso, but the breasts are avoided. Because the hormones are combined with the adhesive, improper skin adherence will lower hormone absorption and efficacy. Therefore, if a patch is so poorly adhered that it requires reinforcement with tape, it should be replaced.

Initiation of the patch is the same as for COCs, and a new patch is applied weekly for 3 weeks followed by a patch-free week to allow withdrawal bleeding. Although a patch is ideally worn no longer than 7 days, hormone levels remain in an effective range for up to 9 days. This affords a 2-day window for patch change delays (Abrams, 2001).

In general, the transdermal patch and vaginal ring produce metabolic changes, side effects, and efficacy rates comparable to those with COC pills. However, the patch has been associated with a higher VTE risk in some but not other studies (Cole, 2007; Jick, 2010; Lidegaard, 2012). And despite this lack of convincing association, the FDA (2008) ordered labeling for the patch to state that users may be at increased risk for developing VTE. Obesity—90 kg or greater—may be associated with an increased risk for patch contraceptive failure (Zieman, 2002). Last, application-site reaction and breast tenderness are more frequent during initial cycles in patch wearers (Urdl, 2005).

Transvaginal Ring

The NuvaRing is yet another form of combination hormonal contraception and is a flexible intravaginal ring. Constructed of ethinyl vinyl acetate, the ring measures 54 mm in diameter and 4 mm in cross section (Fig. 38-5). During insertion, the ring is compressed and threaded into the vagina, but no specific final intravaginal position is required. Its core releases ethinyl estradiol and the progestin etonogestrel, which are absorbed across the vaginal epithelium. Before being dispensed, the rings are refrigerated, and once dispensed, their shelf life is 4 months. The ring is placed within 5 days of menses onset and after 3 weeks of use, is removed for 1 week to allow withdrawal bleeding. Contraception will still be afforded if a ring is left in place for a fourth week (Merck, 2012b).
Patient satisfaction is high with this method, although vaginitis, ring-related events, and leukorrhea are more common (Oddsson, 2005). Despite this, no deleterious affect on vaginal flora or on lower reproductive-tract or endometrial epithelia has been found (Bulten, 2005; Veres, 2004). Approximately 70 percent of partners feel the ring during intercourse (Dieben, 2002). If this is bothersome, the ring may be removed for intercourse but should be replaced within 3 hours to maintain efficacy.

Injectable Progestin Contraceptives

Both intramuscular depot medroxyprogesterone acetate (Depo-Provera), 150 mg every 3 months, and norethisterone enanthate, 200 mg every 2 months, are injectable progestin contraceptives that have been effectively used worldwide for years. Available in the United States, DMPA is injected into the deltoid or gluteus muscle, but massage is avoided to ensure that the drug is released slowly. Alternatively, a subcutaneous version, depo-subQ provera 104, is also available and is injected into the subcutaneous tissue of the anterior thigh or abdomen every 3 months.

DMPA is an effective method, and as with other progestin-only methods, contraception is provided by ovulation inhibition, increased cervical mucus viscosity, and creation of an endometrium unfavorable for ovum implantation. Initial injection is given within the first 5 days following menses onset. Therapeutic serum levels sufficient to exert a consistent contraceptive effect are observed by 24 hours. Thus, no additional contraceptive method is required with initiation within this window. Alternatively, limited data support a “Quick Start” or initiation of DMPA regardless of cycle day. If so implemented, investigators recommend an initial negative pregnancy test result before injection, a supplemental contraceptive method during the 7 days following injection, and a second pregnancy test after 3 to 6 weeks to identify an early pregnancy (Rickert, 2007; Sneed, 2005). Fortunately, pregnancies conceived during DMPA use are no
associated with an increased risk of fetal malformation (Katz, 1985). For women who present for intramuscular DMPA reinjection more than 13 weeks or subcutaneous DMPA reinjection more than 14 weeks after the prior dose, the manufacturer recommends exclusion of pregnancy before reinjection (Pfizer, 2010, 2012).

**Actions and Side Effects**

Injected progestins offer the convenience of a 3-month dosing schedule, contraceptive effectiveness comparable with or better than COCs, and minimal to no lactation impairment. Iron deficiency anemia is less likely in long-term users because of amenorrhea, which develops in up to 50 percent after 1 year and in 80 percent after 5 years.

Similar to other progestin-only contraceptive, irregular menstrual bleeding is common, and a fourth of women discontinued DMPA in the first year because of this (Cromer, 1994). Unique to DMPA, prolonged anovulation can follow discontinuation, which results in delayed fertility resumption. After injections are stopped, one fourth of patients do not resume regular menses for up to 1 year (Gardner, 1970). Accordingly, DMPA may not be ideal for women who plan to use birth control only briefly before attempting conception.

As with other progestins, DMPA has not been associated with cardiovascular events or stroke in otherwise healthy women. However, in those with severe hypertension, an increased risk of stroke has been found in DMPA users (World Health Organization, 1998). Moreover, the US MEC expresses concerns regarding hypoestrogenic effects and reduced HDL levels from DMPA in women with vascular disease or multiple risks for cardiovascular disease.

Weight gain is generally attributed to DMPA, and these increases are comparable between the two depot forms (Bahamondes, 2001; Nault, 2013; Westhoff, 2007c). In long-term users, loss of bone mineral density is also a potential problem (Petitti, 2000; Scholes, 1999). In 2004, the FDA added a black box warning to DMPA labeling, which notes that this concern is probably most relevant for adolescents, who are building bone mass, and perimenopausal women, who will soon have increased bone loss during menopause. That said, it is the opinion of the World Health Organization (1998) and American College of Obstetricians and Gynecologists (2008) that DMPA should not be restricted in those high-risk groups. And, it seems prudent to reevaluate overall risks and benefits during extended use (d’Arcangues, 2006).

It is somewhat reassuring that bone loss appears to be reversible after discontinuation of therapy but is still not complete after 18 to 24 months (Clark, 2006; Gai, 2011; Scholes, 2002).

**Progestin-Only Pills**

So-called mini-pills are progestin-only contraceptives that are taken daily. These contraceptives have not achieved widespread popularity and are used by only 0.4 percent of American women (Hall, 2012). Unlike COCs, they do not reliably inhibit ovulation. Rather, their effectiveness depends more on cervical mucus thickening and endometrial atrophy. Because mucus changes are not sustained longer than 24 hours, mini-pills should be taken at the same time every day to be maximally effective. If a progestin-only pill is taken even 4 hours late, a supplemental form of contraception must be used for the next 48 hours. Progestin-only pills are contraindicated in women with known breast cancer or pregnancy. Other cautions are listed in Table 38-3.
Male Condom

For many years, male and female condoms, vaginal diaphragms, and periodic abstinence have been used for contraception with variable success (see Table 38-2). The contraceptive efficacy of the male condom is enhanced appreciably by a reservoir tip and probably by the addition of a spermicide. Such agents, as well as those used for lubrication, should be water-based because oil-based products destroy latex condoms and diaphragms.

When used properly, condoms provide considerable but not absolute protection against a broad range of STDs. These include gonorrhea, syphilis, trichomoniasis, and HIV, herpetic, and chlamydial infections.

For individuals sensitive to latex, condoms made from lamb intestines are effective, but they do not provide infection protection. Fortunately, nonallergenic condoms have been developed that are made of polyurethane or of synthetic elastomers. Polyurethane condoms are effective against STDs but have a higher breakage and slippage rate than latex condoms (Gallo, 2006).

Female Condom

The only female condom available is marketed as the FC2 Female Condom. It is a synthetic nitrile sheath with one flexible polyurethane ring at each end. Its open ring remains outside the vagina, whereas its closed internal ring is fitted under the symphysis like a diaphragm (Fig. 38-6). The female condom can be used with both water-based and oil-based lubricants. Male condoms should not be used concurrently because simultaneous use may cause friction that leads to condom slipping, tearing, and displacement. Following use, the female condom outer ring should be twisted to seal the condom so that no semen spills. As an added value, in vitro tests have shown the female condom to be impermeable to HIV and other STDs.
FIGURE 38-6  *FC2 Female Condom* insertion and positioning. **A.** The inner ring is squeezed for insertion. The sheath is inserted similarly to a diaphragm. **B.** The inner ring is pushed inward with an index finger.

**Diaphragm Plus Spermicide**

The diaphragm consists of a circular latex dome of various diameters supported by a circumferential latex-covered metal spring. It is effective when used in combination with spermicidal jelly or cream. The spermicide is applied into the dome cup and along the rim. The device is then positioned so that the cup faces the cervix and so that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. In this fashion, the centrally placed spermicide is held against the cervix. When appropriately positioned, one rim is lodged deep in the posterior vaginal fornix, and the opposite rim fits behind the inner surface of the symphysis and immediately below the urethra (Fig. 38-7). If a diaphragm is too small, it will not remain in place. If it is too large, it is uncomfortable when forced into position. A coexistent cystocele or uterine prolapse typically leads to instability and expulsion. Because size and spring flexibility must be individualized, the diaphragm is available only by prescription.
FIGURE 38-7 A diaphragm in place creates a physical barrier between the vagina and cervix.

With use, the diaphragm and spermicide can be inserted hours before intercourse, but if more than 6 hours elapse, additional spermicide should be placed in the upper vagina for maximum protection and be reapplied before each coital episode. The diaphragm should not be removed for at least 6 hours after intercourse. Because toxic shock syndrome has been described following its use, it may be worthwhile to remove the diaphragm at 6 hours, or at least the next morning, to minimize this rare event. Diaphragm use is associated with a slightly increased rate of urinary infections, presumably from urethral irritation by the ring under the symphysis.

### Cervical Cap

*FemCap* is currently the only available cervical cap in the United States. Made of silicone rubber, it has a sailor-cap shape with a dome that covers the cervix and a flared brim, which allows the cap to be held in place by the muscular walls of the upper vagina. Available in 22-, 26-, and 30-mm sizes, it should be used with a spermicide applied once at insertion to both sides of the dome cup. For contraception, it should remain in place for 6 hours following coitus and may remain for up to 48 hours. Even with proper fitting and correct use, pregnancy rates with this method are higher than with the diaphragm (Gallo, 2002; Mauck, 1999).

### Fertility Awareness-Based Methods

All of these family planning methods attempt to identify the fertile days each cycle and advise sexual abstinence during these days. However, their limited efficacy is shown in Table 38-2. Common forms of these fertility awareness-based (FAB) methods include Standard Days.
Calendar Rhythm, Temperature Rhythm, Cervical Mucus, and Symptothermal Methods.

The **Standard Days Method** counsels women to avoid unprotected intercourse during cycle days 8 through 19. For successful use, women must have regular monthly cycles of 26 to 32 days. Those who use this method can mark a calendar or can use **Cycle-Beads**, which is a ring of counting beads, to keep track of their days.

The **Calendar Rhythm Method** requires counting the number of days in the shortest and longest menstrual cycle during a 6- to 12-month span. From the shortest cycle, 18 days are subtracted to calculate the first fertile day. From the longest cycle, 11 days are subtracted to identify the last fertile day. This is problematic because ovulation most often occurs 14 days before the onset of the next menses. Because this is not necessarily 14 days after the onset of the last menses, the calendar rhythm method is not reliable.

The **Temperature Rhythm Method** relies on slight changes—sustained 0.4°F increases—in the basal body temperature that usually occur just before ovulation. This method is much more likely to be successful if during each menstrual cycle, intercourse is avoided until well after the ovulatory temperature rise. For this method to be most effective, the woman must abstain from intercourse from the first day of menses through the third day after the temperature increase.

The **Cervical Mucus Method**, also called the Two-Day Method or Billings Method, relies on awareness of vaginal “dryness” and “wetness.” These reflect changes in the amount and quality of cervical mucus at different times in the menstrual cycle. With the Billings Method, abstinence is required from the beginning of menses until 4 days after slippery mucus is identified. With the Two-Day method, intercourse is considered safe if a woman did not note mucus on the day of planned intercourse or the day prior.

The **Symptothermal Method** combines changes in cervical mucus—onset of fertile period; changes in basal body temperature—end of fertile period; and calculations to estimate the time of ovulation. This method is more complex to learn and apply, but it does not appreciably improve efficacy.

---

**LESS EFFECTIVE CONTRACEPTION: SPERMICIDES**

These contraceptives are marketed variously as creams, jellies, suppositories, films, and aerosol foam. They are especially useful for women who need temporary protection, for example, during the first week after starting COCs. Most can be purchased without a prescription.

Typically, spermicides function by providing a physical barrier to sperm penetration and a chemical spermicidal action. The active ingredient is nonoxynol-9 or octoxynol-9. Although these are spermicidal, they do not provide STD protection. Ideally, spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse. Their duration of maximal effectiveness is usually no more than 1 hour, and thereafter, they must be reinserted before repeat intercourse. Douching should be avoided for at least 6 hours after coitus.

High pregnancy rates are primarily attributable to inconsistent use rather than to method failure. Even if inserted regularly and correctly, however, they are considered a less effective method (see Table 38-2). Fortunately, if pregnancy does occur, they are not considered teratogenic (Briggs, 2011).

---

**Contraceptive Sponge**
The Today contraceptive sponge is an over-the-counter, one-size-fits-all device. The nonoxynol-9–impregnated polyurethane disc is 2.5 cm thick and 5.5 cm wide and has a dimple on one side and satin loop on the other (Fig. 38-8). The sponge can be inserted up to 24 hours prior to intercourse, and while in place, it provides contraception regardless of coital frequency. It should remain in place for 6 hours after intercourse. Pregnancy is prevented primarily by the spermicide nonoxynol-9 and to a lesser extent, by covering the cervix and absorbing semen.

**FIGURE 38-8** Today sponges. The sponge is moistened with tap water and gently squeezed to create light suds. It is then positioned with the dimple directly against the cervix. The fabric loop trails within the vagina and can be hooked with a finger to later extract the sponge.

Although the sponge is possibly more convenient than the diaphragm or condom, it is less effective than either (Kuyoh, 2003). Most common causes for discontinuance are pregnancy, irritation, discomfort, or vaginitis (Beckman, 1989). Although toxic shock syndrome (TSS) has been reported with the contraceptive sponge, it is rare, and evidence suggests that the sponge may actually limit production of the responsible staphylococcal exotoxin (Remington, 1987). Still, it is recommended that the sponge not be used during menses or the puerperium.

**EMERGENCY CONTRACEPTION**

Many women present for contraceptive care following unprotected sexual intercourse. In this situation, several emergency contraception (EC) regimens substantially decrease the likelihood of an unwanted pregnancy when used correctly. Current methods include COCs, POPs, progesterone antagonists, and copper-containing IUDs (Table 38-7). Patients can obtain information regarding emergency contraception by calling 1-888-NOT-2-LATE or accessing The Emergency Contraception Website: [http://not-2-late.com](http://not-2-late.com).
Hormonal Emergency Contraception

Also known as the Yuzpe method, one EC method provides a minimum of 100 μg of ethinyl estradiol and 0.5 mg of levonorgestrel in each of two doses. As shown in Table 38-7, a sufficient dose may be achieved by two or more pills. The first dose is taken ideally within 72 hours of intercourse but may be given up to 120 hours. The initial dose is followed 12 hours later by a second equivalent dose.

With progestin-only regimens, 1.5 mg of levonorgestrel is taken, either as a single, one-time 1.5-mg dose or as two tablets, each containing 0.75 mg levonorgestrel. With these regimens, the first dose is ideally taken within 72 hours of unprotected coitus but may be given up to 120 hours. With the two-pill regimen, the second dose follows 12 hours later, although a 24-hour interval between the doses is also effective (Ngai, 2005).

One progesterone-receptor modulator currently available for EC is ulipristal acetate and is marketed as Ella. It is taken as a single 30-mg tablet up to 120 hours after unprotected intercourse (Brache, 2010; Watson, 2010).

The major mechanism with all hormonal regimens is inhibition or delay of ovulation. Emergency hormonal contraceptive regimens are more effective the sooner they are taken and decrease the risk of pregnancy by up to 94 percent (American College of Obstetricians and
Gynecologists, 2012b). Although highly effective, if EC fails to prevent pregnancy or is mistimed, no associations with major congenital malformation or pregnancy complications have been noted with estrogen- or progestin-containing regimens. Data regarding ulipristal acetate in this setting are limited.

With EC administration, nausea and vomiting can be a significant side effect (Gemzell-Danielsson, 2013). Accordingly, an oral antiemetic may be prescribed at least 1 hour before each dose. If a woman vomits within 2 hours of a dose, the dose must be repeated.

**Copper-Containing Intrauterine Devices**

For women who are candidates, copper IUD insertion is an effective EC method and provides an effective 10-year method of contraception (Cheng, 2012). If an IUD is placed up to 5 days after unprotected coitus, the failure rate approximates only 0.1 percent (Fasoli, 1989; Wu, 2010).

**PUERPERAL CONTRACEPTION**

For mothers who are nursing exclusively, ovulation during the first 10 weeks after delivery is unlikely. Nursing, however, is not a reliable method of family planning for women whose infants are on a daytime-only feeding schedule. Moreover, waiting for first menses involves a risk of pregnancy, because ovulation usually antedates menstruation. Certainly, after the first menses, contraception is essential unless the woman desires pregnancy.

For nursing mothers, progestin-only contraceptives are the preferred choice in most cases. In addition, IUDs have been recommended for the lactating sexually active woman. Estrogen-progestin contraceptives may reduce both the rate and the duration of milk production, although data are limited (Truitt, 2010). Moreover, very small quantities of the hormones are excreted in breast milk, but no adverse effects on infants have been reported (World Health Organization, 1988). Thus, in many cases, the benefits from pregnancy prevention by the use of COCs after the first 4 puerperal weeks would appear to outweigh the risks in selected patients. Immediate postpartum COC initiation is avoided due to VTE risks (Centers for Disease Control and Prevention, 2011).

Sterilization is a popular choice of contraception for millions of men and women. This procedure is indicated in those requesting sterilization and who clearly understand its permanence as well as its difficult and often unsuccessful reversal. The American College of Obstetricians and Gynecologists (2009, 2013) recommends that all persons considering sterilization should also be counseled regarding alternative contraceptive choices.

FEMALE STERILIZATION

Almost a fourth of all women using contraception in the United States from 2006 through 2008 chose a form of sterilization (Mosher, 2010). And, for women aged 35 to 44 years, surgical sterilization was their most commonly reported form of birth control (Brunner Huber, 2009).

Female sterilization is usually accomplished by occlusion or division of the fallopian tubes. Puerperal sterilization procedures performed in conjunction with cesarean or vaginal delivery follow approximately 8 percent of all live births in the United States (Chan, 2010). Nonpuerperal tubal sterilization is done at a time unrelated to recent pregnancy and is also termed interval sterilization. These latter procedures are usually accomplished via laparoscopy as outpatient surgery. Hysteroscopic or minilaparotomy approaches to occlusion are also available.

Puerperal Tubal Sterilization

For several days after delivery, the uterine fundus lies at the level of the umbilicus, and fallopian tubes are accessible directly beneath the abdominal wall. Moreover, abdominal laxity allows easy
repositioning of the incision over each uterine cornu. Thus, puerperal sterilization is technically simple, and hospitalization need not be prolonged.

Some prefer to perform sterilization immediately following delivery, although others wait for 12 to 24 hours. At Parkland Hospital, puerperal tubal ligation is performed in the obstetrical surgical suite the morning after delivery. This minimizes hospital stay but lowers the likelihood that postpartum hemorrhage would complicate recovery following surgery. In addition, the status of the newborn can be better ascertained before surgery.

Various techniques are now used to disrupt tubal patency. In general, a midtubal segment of fallopian tube is excised, and the severed ends seal by fibrosis and peritoneal regrowth. Commonly used methods of interval sterilization include the Parkland, Pomeroy, and modified Pomeroy techniques (American College of Obstetricians and Gynecologists, 2013). Irving and Uchida techniques or Kroener fimbriectomy are rarely used because they involve increased dissection, operative time, and chance of mesosalpingeal injury. With fimbriectomy, unfavorably high failure rates stem from recanalization of the proximal tubal segment (Pati, 2000).

**Surgical Technique**

If scheduled for the first postpartum day, puerperal sterilization is typically completed using spinal analgesia. If done more proximate to delivery, the same epidural catheter used for labor analgesia can be used for sterilization analgesia. General anesthesia may be less desirable due to residual pregnancy-related airway changes (Bucklin, 2003).

The bladder is emptied before surgery. A small infraumbilical incision is made. Adequate exposure is critical, and Army-Navy or appendiceal retractors are usually suitable. For obese women, a slightly larger incision and narrow Deaver retractors may be required. If bowel or omentum is obstructing, then Trendelenburg position may be helpful. Digitally packing with a single, moist, fanned-out piece of surgical gauze may also be used, but a hemostat should always be attached to the distal end to avert its retention. It is sometimes helpful to tilt the entire table to the opposite side of the tube being exposed.

The fallopian tube is identified and grasped at its midportion with a Babcock clamp, and the distal fimbria confirmed. This prevents confusing the round ligament with the midportion of the tube. A common reason for sterilization failure is ligation of the wrong structure, typically the round ligament. Therefore, identification and isolation of the distal tube prior to ligation is necessary. Whenever the tube is inadvertently dropped, it is mandatory to repeat this identification procedure. Surgical steps for ligation are outlined in Figures 39-1 and 39-2.
FIGURE 39-1 Parkland method. A. An avascular site in the mesosalpinx adjacent to the fallopian tube is perforated with a small hemostat. The jaws are opened to separate the fallopian tube from the adjacent mesosalpinx for approximately 2.5 cm. B. The freed fallopian tube is ligated proximally and distally with 0-chromic suture. The intervening segment of approximately 2 cm is excised, and the excision site is inspected for hemostasis. This method was designed to avoid the initial intimate proximity of the cut ends of the fallopian tube inherent with the Pomeroy procedure. (From Word, 2012, with permission.)
After surgery, diet is given as tolerated. Ileus is infrequent and should prompt concern for bowel injury, albeit rare. Most women have an uncomplicated course and are discharged on the first postoperative day.

**Nonpuerperal (Interval) Surgical Tubal Sterilization**

These techniques and other modifications basically consist of (1) ligation and resection at laparotomy as described earlier for puerperal sterilization; (2) application of permanent rings, clips, or inserts to the fallopian tubes by laparoscopy or hysteroscopy; or (3) electrocoagulation of a tubal segment, usually through a laparoscope. A detailed description and illustration of these can be found in *Williams Gynecology, 2nd edition* (Thompson, 2012).

In the United States, a laparoscopic approach to interval tubal sterilization is the most common. The procedure is frequently performed in an ambulatory surgical setting under general anesthesia. In almost all cases, the woman can be discharged within several hours. Minilaparotomy using a 3-cm suprapubic incision is also popular, especially in resource-poor countries (Kulier, 2004). Although not commonly used, the peritoneal cavity can be entered through the posterior vaginal fornix—colpotomy or culdotomy—to perform tubal interruption. Major morbidity is rare with either minilaparotomy or laparoscopy.
Long-Term Complications

Contraceptive Failure

Pregnancy following sterilization is uncommon. The Collaborative Review of Sterilization (CREST) study followed 10,863 women who had undergone tubal sterilization from 1978 through 1986 (Peterson, 1996). The cumulative failure rate for the various tubal procedures was 18.5 per 1000 or approximately 0.5 percent. The study found puerperal sterilization to be highly effective. The 5-year failure rate was 5 per 1000, and for 12 years, it was 7 per 1000.

Puerperal sterilization fails for two major reasons. First, surgical errors occur and include transection of the round ligament or only partial transection of the tube. For this reason, both tubal segments are submitted for pathological confirmation. Second, a fistulous tract or spontaneous reanastomosis may form between the severed tubal stumps.

Interval tubal sterilization may fail for several reasons. First, it may be due to equipment failure such as a defective current for electrosurgery or an insufficiently occlusive clip (Belot, 2008). Second, failure may result from fistula formation, especially with electrosurgical procedures, or the fallopian tube may undergo spontaneous reanastomosis. A third possibility is that the woman may have been already pregnant at the time of surgery—a so-called luteal phase pregnancy. To limit this possibility, surgery may ideally be performed during the follicular phase, and an effective contraceptive method used before surgery. Last, in some cases, no reason is found. Importantly, Soderstrom (1985) found that most sterilization failures were not preventable.

Approximately 30 percent of pregnancies that follow a failed tubal sterilization procedure are ectopic. This rate rises to 50 percent for those following a bipolar coagulation procedure (McCausland, 1980; Peterson, 1997). Thus, any symptoms of pregnancy in a woman after tubal sterilization must be investigated, and an ectopic pregnancy excluded.

Other Effects

Ovarian and breast cancer risks are either decreased or unaffected following sterilization (Ness, 2011; Press, 2011). Women who have undergone tubal sterilization are highly unlikely to subsequently have salpingitis (Levgur, 2000). An almost twofold increased incidence of functional ovarian cysts follows tubal sterilization (Holt, 2003). Several investigators have evaluated the risk of menorrhagia and intermenstrual bleeding following tubal sterilization, and most have found no association (DeStefano, 1985; Peterson, 2000; Shy, 1992).

Less objective but important psychological sequelae of sterilization have also been evaluated. In the CREST study, Costello (2002) found that tubal ligation did not change sexual interest or pleasure in 80 percent of women. In most of the 20 percent of women who did report a change, positive effects were 10 to 15 times more likely.

Invariably, a number of women express regrets regarding sterilization, and this is especially true if performed at a younger age (Curtis, 2006; Kelekçi, 2005). In the CREST study, Jamieson (2002) reported that 7 percent of women who had undergone tubal ligation had regrets by 5 years. This is not limited to their own sterilization, because 6.1 percent of women whose husbands had undergone vasectomy had similar regrets.

Reversal of Tubal Sterilization

No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed by either surgery or by assisted reproductive techniques. Both approaches are technically difficult,
Salpingectomy and Hysterectomy

Newer evidence suggests that the fallopian tube may be the origin of pelvic serous carcinomas, especially those of the ovary. With this knowledge, the Society of Gynecologic Oncologists (2013) has issued a practice statement recommending salpingectomy to lower cancer risks. Specifically, for women at average risk of ovarian cancer, risk-reducing salpingectomy should be discussed and considered with patients at the time of abdominal or pelvic surgery, with hysterectomy, or in lieu of tubal ligation. Initial steps of salpingectomy are shown in Figure 39–3. Further illustration and discussion of surgical steps are outlined in *Williams Gynecology, 2nd edition* (Word, 2012).

**Figure 39-3** With salpingectomy, the mesosalpinx is sequentially clamped, cut, and ligated. (From Word, 2012, with permission.)

In the absence of uterine or other pelvic disease, hysterectomy solely for sterilization at the time of cesarean delivery, early in the puerperium, or even remote from pregnancy is difficult to justify. It carries significantly increased surgical morbidity compared with tubal sterilization (Jamieson, 2000; Nieboer, 2009).

Transcervical Sterilization

Intratubal Devices

There are several devices that are inserted via hysteroscopy to occlude the proximal fallopian tubes. These interval sterilization options include *Essure*, a microinsert that has a fine stainless-
A steel inner coil enclosed in polyester fibers and an expandable outer coil of Nitinol—a nickel and titanium alloy (Fig. 39-4). The outer coil expands after placement, allowing the inner fibers also to expand. These synthetic fibers incite a chronic inflammatory response to prompt local tissue ingrowth that leads to complete tubal lumen occlusion (Valle, 2000).

FIGURE 39-4 Essure microinsert placement hysteroscopically and ingrowth of tissue. (From Thompson, 2012, with permission.)

For hysteroscopic placement, sedation, paracervical block, or both may be used, and in-office insertion is often selected. Devices cannot be placed in all women, and some do not tolerate the procedure awake (Duffy, 2005). Bilateral placement is achieved in 95 to 98 percent of cases (Anderson, 2011; Cooper, 2003; Miño, 2007). Rarely, intractable pelvic pain following insertion may require Essure removal (Beckwith, 2008; Lannon, 2007).

Because complete tubal blockage is not 100 percent, it must be confirmed by hysterosalpingography (HSG) 3 months following surgery (American College of Obstetricians and Gynecologists, 2012). With such confirmation, efficacy rates for these devices reach 98 to 99 percent (Anderson, 2011; Smith, 2010). Failures following transcervical sterilization include noncompliance with HSG or its misinterpretation, conception before insertion, insert expulsion, migration of one or both of the inserts, uterine perforation, and method failure (Levy, 2007; Veersema, 2010). Although data are limited to small case series, pregnancies conceived with Essure in place do not appear to be at increased risk from the device (Galen, 2011; Mijatovic, 2012; Veersema, 2013).

The other insert, Adiana, also stimulates tissue ingrowth for tubal occlusion using a cylindrical, 1.5 × 3.5 mm, nonabsorbent silicone elastomer matrix. However, for financial reasons, production of this device has now been discontinued by the manufacturer (Hologic, 2012).
Intratubal Chemical Methods

Although none is currently available in the United States, several chemical substances are used to cause sclerosis or obstruction of the tubal ostia (Abbott, 2007; Ogburn, 2007). Placement of quinacrine pellets into the uterine fundus with an IUD-type inserter method has been used worldwide in more than 100,000 women. The World Health Organization has lifted its ban on quinacrine use because studies have shown no evidence of carcinogenesis (Lippes, 2002). The major drawbacks are 1-, 5-, and 10-year cumulative pregnancy rates of 3, 10, and 12 percent, respectively (Sokal, 2008a,b, 2010).

MALE STERILIZATION

Currently, up to a half million men in the United States undergo vasectomy each year (Barone, 2006; Magnani, 1999). Through a small incision, the vas deferens lumen is disrupted to block the passage of sperm from the testes (Fig. 39-5). Alternatively, the no-scalpel method accomplishes this through a needle puncture in the scrotum. The latter method is associated with fewer minor surgical complications than the traditional incision technique, but each is equally effective (Cook, 2007).

FIGURE 39-5 Anatomy of male reproductive system showing procedure for vasectomy.

Vasectomy is safer than tubal sterilization because it is less invasive and is performed with local analgesia (American College of Obstetricians and Gynecologists, 2013). In a review to compare the two, Hendrix and associates (1999) found that, compared with vasectomy, female tubal sterilization has a 20-fold increased complication rate, a 10- to 37-fold failure rate, and costs three times as much.
One disadvantage is that sterilization following vasectomy is not immediate. Complete release of sperm stored in the reproductive tract beyond the interrupted vas deferens takes approximately 3 months or 20 ejaculations. Although guidelines vary regarding the number and timing of postprocedural semen analyses, many investigators suggest that collection of only one azoospermic semen analysis at 3 months is sufficient evidence of sterility (Bodiwala, 2007; Griffin, 2005). During the period before azoospermia is documented, another form of contraception should be used.

The failure rate for vasectomy during the first year is 9.4 per 1000 procedures but only 11.4 per 1000 at 2, 3, and 5 years (Jamieson, 2004). Failures result from unprotected intercourse too soon after ligation, incomplete occlusion of the vas deferens, or recanalization (Awsare, 2005; Deneux-Tharaux, 2004).

### Long-Term Effects

Other than regrets, long-term consequences are rare. A major one is troublesome chronic scrotal pain, which develops in up to 15 percent of men (Leslie, 2007; Manikandan, 2004). Previous concerns for atherogenesis, immune-complex mediated disease, testicular cancer, and prostate cancer have been allayed (Bernal-Delgado, 1998; Giovannucci, 1992; Goldacre, 1983; MØller 1994).

### Restoration of Fertility

Reanastomosis of the vas deferens can be completed most effectively using microsurgical techniques. Conception rates following reversal are adversely affected by longer duration from vasectomy, poor sperm quality found at reversal, and type of reversal procedure required (American Society for Reproductive Medicine, 2008).

Hypertensive Disorders

TERMINOLOGY AND DIAGNOSIS

INCIDENCE AND RISK FACTORS

ETIOPATHOGENESIS

PATHOPHYSIOLOGY

PREDICTION AND PREVENTION

MANAGEMENT

LONG-TERM CONSEQUENCES

How pregnancy incites or aggravates hypertension remains unsolved despite decades of intensive research. Indeed, hypertensive disorders remain among the most significant and intriguing unsolved problems in obstetrics.

Hypertensive disorders complicate 5 to 10 percent of all pregnancies, and together they are one member of the deadly triad—along with hemorrhage and infection—that contributes greatly to maternal morbidity and mortality. Of these disorders, the preeclampsia syndrome, either alone or superimposed on chronic hypertension, is the most dangerous. As subsequently discussed, new-onset hypertension during pregnancy—termed gestational hypertension—is followed by signs and symptoms of preeclampsia almost half the time, and preeclampsia is identified in 3.9 percent of all pregnancies (Martin, 2012).

The World Health Organization (WHO) systematically reviews maternal mortality worldwide and in developed countries, 16 percent of maternal deaths were reported to be due to hypertensive disorders (Khan, 2006). This proportion is greater than three other leading causes that include hemorrhage—13 percent, abortion—8 percent, and sepsis—2 percent. In the United States from 1998 to 2005, Berg and colleagues (2010) reported that 12.3 percent of 4693 pregnancy-related maternal deaths were caused by preeclampsia or eclampsia. The rate was similar to that of 10 percent for maternal deaths in France from 2003 through 2007 (Saucedo, 2013). Importantly, more than half of these hypertension-related deaths were preventable (Berg, 2005).
In this country for the past two decades, pregnancy hypertension was considered using the terminology and classification promulgated by the Working Group of the National High Blood Pressure Education Program—NHBPEP (2000). To update these, a Task Force was appointed by President James Martin for the American College of Obstetricians and Gynecologists (2013b) to provide evidence-based recommendations for clinical practice. The basic classification was retained, as it describes four types of hypertensive disease:

1. Gestational hypertension—evidence for the preeclampsia syndrome does not develop and hypertension resolves by 12 weeks postpartum
2. Preeclampsia and eclampsia syndrome
3. Chronic hypertension of any etiology
4. Preeclampsia superimposed on chronic hypertension.

Importantly, this classification differentiates the preeclampsia syndrome from other hypertensive disorders because it is potentially more ominous. This concept aids interpretation of studies that address the etiology, pathogenesis, and clinical management of pregnancy-related hypertensive disorders.

**Diagnosis of Hypertensive Disorders**

Hypertension is diagnosed empirically when appropriately taken blood pressure exceeds 140 mm Hg systolic or 90 mm Hg diastolic. Korotkoff phase V is used to define diastolic pressure. Previously, incremental increases of 30 mm Hg systolic or 15 mm Hg diastolic from midpregnancy blood pressure values had also been used as diagnostic criteria, even when absolute values were < 140/90 mm Hg. These incremental changes are no longer recommended criteria because evidence shows that such women are not likely to experience increased adverse pregnancy outcomes (Levine, 2000; North, 1999). That said, women who have a rise in pressure of 30 mm Hg systolic or 15 mm Hg diastolic should be observed more closely because eclamptic seizures develop in some of these women whose blood pressures have stayed < 140/90 mm Hg (Alexander, 2006). A sudden rise in mean arterial pressure later in pregnancy—also known as “delta hypertension”—may also signify preeclampsia even if blood pressure is < 140/90 mm Hg (Macdonald-Wallis, 2012; Vollaard, 2007).

**Concept of “Delta Hypertension”**

The systolic and diastolic blood pressure levels of 140/90 mm Hg have been arbitrarily used since the 1950s to define “hypertension” in nonpregnant individuals. As discussed in detail in Chapter 50 (p. 1000), these levels were selected by insurance companies for a group of middle-aged men. It seems more realistic to define normal-range blood pressures that fall between an upper and lower limit for blood pressure measurements for a particular population—such as young, healthy, pregnant women. A schematic example is shown in Figure 40-1 using arbitrary blood pressure readings. Data curves for both women show blood pressure measurements near the 25th percentile until 32 weeks. These begin to rise in patient B, who by term has substantively increased blood pressures. However, her pressures are still < 140/90 mm Hg, and thus she is considered to be “normotensive.” We termed this rather acute increase in blood pressure as “delta hypertension.” As discussed later, some of these women will develop eclamptic seizures or HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome while still normotensive.
**FIGURE 40-1** Schematic shows normal reference ranges for blood pressure changes across pregnancy. Patient A (*blue*) has blood pressures near the 20th percentile throughout pregnancy. Patient B (*red*) has a similar pattern with pressures at about the 25th percentile until about 36 weeks when blood pressure begins to increase. By term, it is substantively higher and in the 75th percentile, but she is still considered “normotensive.”

### Gestational Hypertension

This diagnosis is made in women whose blood pressures reach 140/90 mm Hg or greater for the first time after midpregnancy, but in whom *proteinuria is not identified* (Table 40-1). Almost half of these women subsequently develop preeclampsia syndrome, which includes findings such as headaches or epigastric pain, proteinuria, and thrombocytopenia. Even so, when blood pressure increases appreciably, it is dangerous to both mother and fetus to ignore this rise only because proteinuria has not yet developed. As Chesley (1985) emphasized, 10 percent of eclamptic seizures develop before overt proteinuria can be detected. Finally, gestational hypertension is reclassified by some as *transient hypertension* if evidence for preeclampsia does not develop and the blood pressure returns to normal by 12 weeks postpartum.

---
Preeclampsia Syndrome

As emphasized throughout this chapter, preeclampsia is best described as a pregnancy-specific syndrome that can affect virtually every organ system. And, although preeclampsia is much more than simply gestational hypertension with proteinuria, appearance of proteinuria remains an important diagnostic criterion. Thus, proteinuria is an objective marker and reflects the system-wide endothelial leak, which characterizes the preeclampsia syndrome.

Abnormal protein excretion is arbitrarily defined by 24-hour urinary excretion exceeding 300 mg; a urine protein:creatinine ratio ≥ 0.3; or persistent 30 mg/dL (1+ dipstick) protein in random urine samples (Lindheimer, 2008a). None of these values is sacrosanct, and urine concentrations vary widely during the day, as do dipstick readings. Thus, assessment may show a dipstick value of 1+ to 2+ from concentrated urine specimens from women who excrete < 300 mg/day. As discussed on page 740, it is likely that determination of a spot urine:creatinine ratio is a suitable replacement for a 24-hour urine measurement (Chap. 4, p. 65).

It is now appreciated that overt proteinuria may not be a feature in some women with the preeclampsia syndrome (Sibai, 2009). Because of this, the Task Force (2013) suggested other diagnostic criteria, which are shown in Table 40-1. Evidence of multiorgan involvement may include thrombocytopenia, renal dysfunction, hepatocellular necrosis ("liver dysfunction"), central nervous system perturbations, or pulmonary edema.

Indicators of Preeclampsia Severity

The markers listed in Table 40-1 are also used to classify preeclampsia syndrome severity. Although many use a dichotomous “mild” and “severe” classification, the Task Force (2013)
discourages the use of “mild preeclampsia.” It is problematic that there are criteria for the diagnosis of “severe” preeclampsia, but the default classification is either implied or specifically termed as “mild,” “less severe,” or “nonsevere” (Alexander, 2003; Lindheimer, 2008b). There are no generally agreed-on criteria for “moderate” preeclampsia—an elusive third category. We use the criteria listed in Table 40-2, which are categorized as “severe” versus “nonsevere.” Importantly, while it is pragmatic that nonsevere classifications include “moderate” and “mild,” these have not been specifically defined.

Some symptoms are considered to be ominous. Headaches or visual disturbances such as scotomata can be premonitory symptoms of eclampsia. Epigastric or right upper quadrant pain frequently accompanies hepatocellular necrosis, ischemia, and edema that ostensibly stretches

\(^c\) Most disregard degrees of proteinuria as being nonsevere or severe.

BP = blood pressure.
Glisson capsule. This characteristic pain is frequently accompanied by elevated serum hepatic transaminase levels. Finally, *thrombocytopenia* is also characteristic of worsening preeclampsia as it signifies platelet activation and aggregation as well as microangiopathic hemolysis. Other factors indicative of severe preeclampsia include renal or cardiac involvement and obvious fetal-growth restriction, which also attests to its duration.

As will be discussed, the more profound these signs and symptoms, the less likely they can be temporized, and the more likely delivery will be required. *A caveat is that differentiation between nonsevere and severe gestational hypertension or preeclampsia can be misleading because what might be apparently mild disease may progress rapidly to severe disease.*

**Eclampsia**

In a woman with preeclampsia, a convulsion that cannot be attributed to another cause is termed *eclampsia*. The seizures are generalized and may appear before, during, or after labor. The proportion who do not develop seizures until after 48 hours postpartum approximates 10 percent (Sibai, 2005). In some reports, up to a fourth of eclamptic seizures develop beyond 48 hours postpartum (Chames, 2002). Our experiences from Parkland Hospital, however, are that delayed postpartum eclampsia continues to occur in about 10 percent of cases—similar to what we first reported more than 20 years ago (Alexander, 2006; Brown, 1987). This lower percentage was also found in 222 women with eclampsia from The Netherlands (Zwart, 2008).

### Preeclampsia Superimposed on Chronic Hypertension

Regardless of its cause, any chronic hypertensive disorder predisposes a woman to develop superimposed preeclampsia syndrome. Chronic underlying hypertension is diagnosed in women with documented blood pressures ≥ 140/90 mm Hg before pregnancy or before 20 weeks’ gestation, or both. Hypertensive disorders can create difficult problems with diagnosis and management in women who are not first seen until after midpregnancy. This is because blood pressure normally decreases during the second and early third trimesters in both normotensive and chronically hypertensive women (Chap. 50, p. 1003). Thus, a woman with previously undiagnosed chronic vascular disease who is seen before 20 weeks frequently has blood pressures within the normal range. During the third trimester, however, as blood pressures return to their originally hypertensive levels, it may be difficult to determine whether hypertension is chronic or induced by pregnancy. Even a careful search for evidence of preexisting end-organ damage may be futile, as many of these women have mild disease and no evidence of ventricular hypertrophy, retinal vascular changes, or renal dysfunction.

In some women with chronic hypertension, their blood pressure increases to obviously abnormal levels, and this is typically after 24 weeks. If new-onset or worsening baseline hypertension is accompanied by new-onset proteinuria or other findings listed in Table 40-1, then superimposed preeclampsia is diagnosed. Compared with “pure” preeclampsia, superimposed preeclampsia commonly develops earlier in pregnancy. It also tends to be more severe and often is accompanied by fetal-growth restriction. The same criteria shown in Table 40-2 are also used to further characterize severity of superimposed preeclampsia.

**INCIDENCE AND RISK FACTORS**
Preeclampsia Syndrome

Young and nulliparous women are particularly vulnerable to developing preeclampsia, whereas older women are at greater risk for chronic hypertension with superimposed preeclampsia. The incidence is markedly influenced by race and ethnicity—and thus by genetic predisposition. By way of example, in nearly 2400 nulliparas enrolled in a Maternal-Fetal Medicine Units (MFMU) Network study, the incidence of preeclampsia was 5 percent in white, 9 percent in Hispanic, and 11 percent in African-American women (Myatt, 2012a,b).

Other factors include environmental, socioeconomic, and even seasonal influences (Lawlor, 2005; Palmer, 1999; Spencer, 2009). With consideration for these vicissitudes, in several worldwide studies reviewed by Staff and coworkers (2014), the incidence of preeclampsia in nulliparous populations ranged from 3 to 10 percent. The incidence of preeclampsia in multiparas is also variable but is less than that for nulliparas. Specifically, population studies from Australia, Canada, Denmark, Norway, Scotland, Sweden, and Massachusetts indicate an incidence of 1.4 to 4 percent (Roberts, 2011).

There are several other risk factors associated with preeclampsia. These include obesity, multifetal gestation, maternal age, hyperhomocysteinemia, and metabolic syndrome (Conde-Agudelo, 2000; Scholten, 2013; Walker, 2000). The relationship between maternal weight and the risk of preeclampsia is progressive. It increases from 4.3 percent for women with a body mass index (BMI) < 20 kg/m$^2$ to 13.3 percent in those with a BMI > 35 kg/m$^2$ (Fig. 48-5, p. 966). In women with a twin gestation compared with those with singletons, the incidence of gestational hypertension—13 versus 6 percent, and the incidence of preeclampsia—13 versus 5 percent, are both significantly increased (Sibai, 2000). It is interesting that this latter incidence is unrelated to zygosity (Maxwell, 2001).

Although smoking during pregnancy causes various adverse pregnancy outcomes, ironically, it has consistently been associated with a reduced risk for hypertension during pregnancy (Bainbridge, 2005; Zhang, 1999). Kraus and associates (2013) posit that this is because smoking upregulates placental adrenomedullin expression, which regulates volume homeostasis.

Women with preeclampsia in the first pregnancy are at greater risk in a second pregnancy compared with women normotensive during their first pregnancy (McDonald, 2009). And conversely, in the woman who was normotensive during her first pregnancy, the incidence of preeclampsia in a subsequent pregnancy is much lower than for a first pregnancy. In a population-based retrospective cohort analysis, Getahun and colleagues (2007) studied almost 137,000 second pregnancies in such women. The incidence for preeclampsia in secundigravida white women was 1.8 percent compared with 3 percent in African-American women.

Eclampsia

Presumably because it is somewhat preventable by adequate prenatal care, the incidence of eclampsia has decreased over the years in areas where health care is more readily available. In countries with adequate resources, its incidence averages 1 in 2000 deliveries. Ventura and associates (2000) estimated that the incidence in the United States in 1998 was 1 in 3250 births. According to the Royal College of Obstetricians and Gynaecologists (2006), it approximates 1 in 2000 in the United Kingdom. Akkawi and coworkers (2009) reported it to be 1 in 2500 in Dublin. Andersgaard and associates (2006) as 1 per 2000 for Scandinavia, and Zwart and colleagues (2008) as 1 per 1600 for The Netherlands.
ETIOPATHOGENESIS

Any satisfactory theory concerning the etiology and pathogenesis of preeclampsia must account for the observation that gestational hypertensive disorders are more likely to develop in women with the following characteristics:

- Are exposed to chorionic villi for the first time
- Are exposed to a superabundance of chorionic villi, as with twins or hydatidiform mole
- Have preexisting conditions of endothelial cell activation or inflammation such as diabetes or renal or cardiovascular disease
- Are genetically predisposed to hypertension developing during pregnancy.

A fetus is not a requisite for preeclampsia to develop. And, although chorionic villi are essential, they need not be intrauterine. For example, Worley and associates (2008) reported a 30-percent incidence in women with an extrauterine pregnancy exceeding 18 weeks’ gestation. Regardless of precipitating etiology, the cascade of events leading to the preeclampsia syndrome is characterized by abnormalities that result in vascular endothelial damage with resultant vasospasm, transudation of plasma, and ischemic and thrombotic sequelae.

Phenotypic Expression of Preeclampsia Syndrome

The preeclampsia syndrome is widely variable in its clinical phenotypic expression. There are at least two major subtypes differentiated by whether or not remodeling of uterine spiral arterioles by endovascular trophoblastic invasion is defective. This concept has given rise to the “two-stage disorder” theory of preeclampsia etiopathogenesis. Ness and Roberts (1996) consider that the two-stage disorder includes “maternal and placental preeclampsia.” According to Redman and coworkers (2014), stage 1 is caused by faulty endovascular trophoblastic remodeling that downstream causes the stage 2 clinical syndrome. Importantly, stage 2 is susceptible to modification by preexisting maternal conditions that are manifest by endothelial cell activation or inflammation. Such conditions include cardiovascular or renal disease, diabetes, obesity, immunological disorders, or hereditary influences.

Such compartmentalization is artificial, and it seems logical to us that preeclampsia syndrome presents clinically as a spectrum of worsening disease. Moreover, evidence is accruing that many “isoforms” exist as discussed below. Examples include differences in maternal and fetal characteristics, placental findings, and hemodynamic findings (Phillips, 2010; Valensise, 2008; van der Merwe, 2010).

Etiology

Writings describing eclampsia have been traced as far back as 2200 BC (Lindheimer, 2014). And, an imposing number of mechanisms have been proposed to explain its cause. Those currently considered important include:

1. Placental implantation with abnormal trophoblastic invasion of uterine vessels
2. Immunological maladaptive tolerance between maternal, paternal (placental), and fetal tissues
3. Maternal maladaptation to cardiovascular or inflammatory changes of normal pregnancy
4. Genetic factors including inherited predisposing genes and epigenetic influences.

**Abnormal Trophoblastic Invasion**

Normal implantation is characterized by extensive remodeling of the spiral arterioles within the decidua basalis as shown schematically in Figure 40-2 (Chap. 5, p. 93). Endovascular trophoblasts replace the vascular endothelial and muscular linings to enlarge the vessel diameter. The veins are invaded only superficially. In some cases of preeclampsia, however, there may be incomplete trophoblastic invasion. With this, decidual vessels, but not myometrial vessels, become lined with endovascular trophoblasts. The deeper myometrial arterioles do not lose their endothelial lining and musculoelastic tissue, and their mean external diameter is only half that of corresponding vessels in normal placentas (Fisher, 2014). In general, the magnitude of defective trophoblastic invasion is thought to correlate with severity of the hypertensive disorder (Madazli, 2000).

**FIGURE 40-2** Schematic representation of normal placental implantation shows proliferation of extravillous trophoblasts from an anchoring villus. These trophoblasts invade the decidua and extend into the walls of the spiral arteriole to replace the endothelium and muscular wall to create a dilated low-resistance vessel. With preeclampsia, there is defective implantation characterized by incomplete invasion of the spiral arteriolar wall by extravillous trophoblasts. This results in a small-caliber vessel with high resistance to flow.

Using electron microscopy, De Wolf and coworkers (1980) examined arteries taken from the implantation site. They reported that early preeclamptic changes included endothelial damage, insudation of plasma constituents into vessel walls, proliferation of myointimal cells, and medial necrosis. Lipid accumulated first in myointimal cells and then within macrophages. These lipid-laden cell changes, shown in Figure 40-3, were referred to as atherosis by Hertig (1945). Nelson
and colleagues (2014) completed placental examination in more than 1200 women with preeclampsia. These investigators reported that vascular lesions including spiral arteriole narrowing, atherosis, and infarcts were more common in placentas from women diagnosed with preeclampsia before 34 weeks.

**FIGURE 40-3** Atherosis in a blood vessel from a placental bed. A. Photomicrograph shows disruption of the endothelium that results in a narrowed lumen because of subendothelial accumulation of plasma proteins and foamy macrophages. Some of the foamy macrophages are shown by curved arrows, and straight arrows highlight areas of endothelial disruption. B. Schematic diagram of the photomicrograph. (Modified from Rogers, 1999, with permission.)

Thus, the abnormally narrow spiral arteriolar lumen likely impairs placental blood flow. McMahon and colleagues (2014) have provided evidence that decreased soluble antiangiogenic growth factors may be involved in faulty endovascular remodeling. Diminished perfusion and a hypoxic environment eventually lead to release of *placental debris* or *microparticles* that incite a systemic inflammatory response (Lee, 2012; Redman, 2012). Fisher and Roberts (2014) have provided an elegant review of the molecular mechanisms involved in these interactions.

Defective placentation is posited to further cause the susceptible (pregnant) woman to develop gestational hypertension, the preeclampsia syndrome, preterm delivery, a growth-restricted fetus, and/or placental abruption (Brosens, 2011; Kovo, 2010; McElrath, 2008; Nelson, 2014). In addition, Staff and coworkers (2013) have hypothesized that acute atherosis identifies a group of women at increased risk for later atherosclerosis and cardiovascular disease.

**Immunological Factors**

Maternal immune tolerance to paternally derived placental and fetal antigens is discussed in Chapter 5 (p. 97). Loss of this tolerance, or perhaps its *dysregulation*, is another theory cited to account for preeclampsia syndrome (Erlebacher, 2013). Certainly, the histological changes at the maternal-placental interface are suggestive of acute graft rejection. Some of the factors possibly associated with dysregulation include “immunization” from a previous pregnancy, some inherited
human leukocyte antigen (HLA) and natural killer (NK)-cell receptor haplotypes, and possibly shared susceptibility genes with diabetes and hypertension (Fukui, 2012; Ward, 2014).

Inferential data also suggest preeclampsia to be an immune-mediated disorder. For example, the risk of preeclampsia is appreciably enhanced in circumstances in which formation of blocking antibodies to placental antigenic sites might be impaired. In this scenario, the first pregnancy would carry a higher risk. Tolerance dysregulation might also explain an increased risk when the paternal antigenic load is increased, that is, with two sets of paternal chromosomes—a “double dose.” Namely, women with molar pregnancies have a high incidence of early-onset preeclampsia. Women with a trisomy 13 fetus also have a 30- to 40-percent incidence of preeclampsia. These women have elevated serum levels of antiangiogenic factors, and the gene for one of these factors, sFlt-1, is on chromosome 13 (Bdolah, 2006). Conversely, women previously exposed to paternal antigens, such as a prior pregnancy with the same partner, are “immunized” against preeclampsia. This phenomenon is not as apparent in women with a prior abortion. Strickland and associates (1986) studied more than 29,000 pregnancies at Parkland Hospital. These investigators reported that hypertensive disorder rates were decreased in women who previously had miscarried compared with nulligravidas. However, the difference, although statistically significant, was not great—22 versus 25 percent. Other studies have shown that multiparas impregnated by a new consort have an increased risk of preeclampsia (Mostello, 2002).

Redman and colleagues (2014) reviewed the possible role of immune maladaptation in preeclampsia pathophysiology. In women destined to be preeclamptic, extravillous trophoblasts early in pregnancy express reduced amounts of immunosuppressive nonclassic HLA G. Black women more commonly have the 1597ΔC allele that further predisposes to preeclampsia (Loisel, 2013). Zhou and coworkers (2012b) have shown this to be associated with high levels of placental oxidative products. These changes may contribute to defective placental vascularization in stage 1 of the preeclampsia syndrome (p. 732). Recall that as discussed in Chapter 4 (p. 56), during normal pregnancy, T-helper (Th) lymphocytes are produced so that type 2 activity is increased in relation to type 1—termed type 2 bias (Redman, 2012, 2014). Th2 cells promote humoral immunity, whereas Th1 cells stimulate inflammatory cytokine secretion. Beginning in the early second trimester in women who develop preeclampsia, Th1 action is increased and the Th1/Th2 ratio changes. Contributors to an enhanced immunologically mediated inflammatory reaction are stimulated by placental microparticles and by adipocytes (Redman, 2012, 2014).

Endothelial Cell Activation

In many ways, inflammatory changes are believed to be a continuation of the stage 1 changes caused by defective placentation as discussed above. In response to placental factors released by ischemic changes or by any other inciting cause, a cascade of events begins (Davidge, 2014). Thus, antiangiogenic and metabolic factors and other inflammatory mediators are thought to provoke endothelial cell injury.

Endothelial cell dysfunction may result from an extreme activated state of leukocytes in the maternal circulation (Faas, 2000; Gervasi, 2001). Briefly, cytokines such as tumor necrosis factor-α (TNF-α) and the interleukins (IL) may contribute to the oxidative stress associated with preeclampsia. This is characterized by reactive oxygen species and free radicals that lead to formation of self-propagating lipid peroxides (Manten, 2005). These in turn generate highly toxic radicals that injure endothelial cells, modify their nitric oxide production, and interfere with prostaglandin balance. Other consequences of oxidative stress include production of the lipid-laden macrophage foam cells seen in atherosis and shown in Figure 40-3; activation of
microvascular coagulation manifest by thrombocytopenia; and increased capillary permeability manifest by edema and proteinuria.

These observations on the effects of oxidative stress in preeclampsia have given rise to increased interest in the potential benefit of antioxidants to prevent preeclampsia. Unfortunately, dietary supplementation with vitamins E (α-tocopherol) and C (ascorbic acid) to prevent preeclampsia has thus far proven unsuccessful (Task Force, 2013). This is discussed subsequently.

### Nutritional Factors

John and colleagues (2002) showed that in the general population, a diet high in fruits and vegetables with antioxidant activity is associated with decreased blood pressure. Zhang and associates (2002) reported that the incidence of preeclampsia was doubled in women whose daily intake of ascorbic acid was less than 85 mg. These studies were followed by randomized trials to study dietary supplementation. Villar and coworkers (2006) showed that calcium supplementation in populations with a low dietary calcium intake had a small effect to lower perinatal mortality rates but no effect on preeclampsia incidence (p. 748). According to the 2013 Task Force, in several trials, supplementation with the antioxidant vitamins C or E showed no benefits.

### Genetic Factors

From a hereditary viewpoint, preeclampsia is a multifactorial, polygenic disorder. In their comprehensive review, Ward and Taylor (2014) cite an incident risk for preeclampsia of 20 to 40 percent for daughters of preeclamptic mothers; 11 to 37 percent for sisters of preeclamptic women; and 22 to 47 percent for twins. In a study by Nilsson and colleagues (2004) that included almost 1.2 million Swedish births, there was a genetic component for gestational hypertension and for preeclampsia. They also reported 60-percent concordance in monozygotic female twin pairs.

The hereditary predisposition for preeclampsia likely is the result of interactions of literally hundreds of inherited genes—both maternal and paternal—that control myriad enzymatic and metabolic functions throughout every organ system. Plasma-derived factors may induce some of these genes in preeclampsia (Mackenzie, 2012). Thus, the clinical manifestation in any given woman with the preeclampsia syndrome will occupy a spectrum as previously discussed. In this regard, phenotypic expression will differ among similar genotypes depending on interactions with environmental factors (Yang, 2013).

### Candidate Genes

Hundreds of genes have been studied for their possible association with preeclampsia (Buurma, 2013; Ward, 2014). Several of those that may have positive significant association with preeclampsia are listed in Table 40-3. Polymorphisms of the genes for Fas receptor, hypoxia-inducible factor-1α protein (HIF-1α), IL-1β, lymphotoxin-α, transforming growth factor beta 3 (TGF-β3), apolipoprotein E (ApoE), and TNF-α have also been studied with varying result (Borowski, 2009; Hefler, 2001; Jamalzei, 2013; Lachmeijer, 2001; Livingston, 2001; Wilson, 2009). Because of the heterogeneity of the preeclampsia syndrome and especially of the other genetic and environmental factors that interact with its complex phenotypic expression, it is doubtful that any one candidate gene will be found responsible. Indeed, Majander and associates (2013) have linked preeclampsia predisposition to fetal genes on chromosome 18.

**Other Genetic Variables**

An extensive list of other variables affect genotypic and phenotypic expression of the preeclampsia syndrome. Some include maternal and paternal genotypes, associated disorders, genomic ethnicity, gene-gene interactions, epigenetic phenomena, and gene-environmental interactions. Combinations of these are infinite. Ethnoracial factors are important as discussed regarding the high incidence of preeclampsia in African-American women. It may be that Latina women have a lower prevalence because of interactions of American Indian and white race genes (Shahabi, 2013).

**Pathogenesis**

**Vasospasm**

The concept of vasospasm with preeclampsia was advanced by Volhard (1918) based on his direct observations of small blood vessels in the nail beds, ocular fundi, and bulbar conjunctivae. It was also surmised from histological changes seen in various affected organs (Hinselmann, 1924; Landesman, 1954). Endothelial activation causes vascular constriction with increased resistance and subsequent hypertension. At the same time, endothelial cell damage causes interstitial leakage through which blood constituents, including platelets and fibrinogen, are deposited sub endothelially. Wang and associates (2002) have also demonstrated disruption of endothelial junctional proteins. Suzuki and coworkers (2003) described ultrastructural changes in the sub endothelial region of resistance arteries in preeclamptic women. The much larger venous circuit is similarly involved, and with diminished blood flow because of maldistribution, ischemia of the surrounding tissues can lead to necrosis, hemorrhage, and other end-organ disturbances characteristic of the syndrome. One important clinical correlate is the markedly attenuated blood volume seen in women with severe preeclampsia (Zeeman, 2009).
Endothelial Cell Injury

As discussed on page 733, during the past two decades, endothelial cell injury has become the centerpiece in the contemporary understanding of preeclampsia pathogenesis (Davidge, 2014). In this scheme, protein factor(s)—likely placental—are secreted into the maternal circulation and provoke activation and dysfunction of the vascular endothelium. Many of the facets of the clinical syndrome of preeclampsia are thought to result from these widespread endothelial cell changes. Grundmann and associates (2008) have reported that circulating endothelial cell—CEC—levels are elevated fourfold in the peripheral blood of preeclamptic women. Similarly, Petrozella and colleagues (2012) demonstrated increased levels of circulating endothelial microparticles—EMPs—in preeclamptic women.

Intact endothelium has anticoagulant properties, and endothelial cells blunt the response of vascular smooth muscle to agonists by releasing nitric oxide. Damaged or activated endothelial cells may produce less nitric oxide and secrete substances that promote coagulation and increase sensitivity to vasopressors (Gant, 1974). Further evidence of endothelial activation includes the characteristic changes in glomerular capillary endothelial morphology, increased capillary permeability, and elevated blood concentrations of substances associated with endothelial activation. These latter substances are transferable, and serum from women with preeclampsia stimulates some of these substances in greater amounts. It seems likely that multiple factors in plasma of preeclamptic women combine to have these vasoactive effects (Myers, 2007; Walsh, 2009).

Increased Pressor Responses

As discussed in Chapter 4 (p. 61), pregnant women normally develop refractoriness to infused vasopressors (Abdul-Karim, 1961). Women with early preeclampsia, however, have increased vascular reactivity to infused norepinephrine and angiotensin II (Raab, 1956; Talledo, 1968). Moreover, increased sensitivity to angiotensin II clearly precedes the onset of gestational hypertension (Gant, 1974).

Prostaglandins

Several prostanoids are thought to be central to preeclampsia syndrome pathophysiology. Specifically, the blunted pressor response seen in normal pregnancy is at least partially due to decreased vascular responsiveness mediated by endothelial prostaglandin synthesis. For example, compared with normal pregnancy, endothelial prostacyclin (PGI₂) production is decreased in preeclampsia. This action appears to be mediated by phospholipase A₂ (Davidge, 2014). At the same time, thromboxane A₂ secretion by platelets is increased, and the prostacyclin:thromboxane A₂ ratio decreases. The net result favors increased sensitivity to infused angiotensin II and, ultimately, vasoconstriction (Spitz, 1988). These changes are apparent as early as 22 weeks in women who later develop preeclampsia (Chavarria, 2003).

Nitric Oxide

This potent vasodilator is synthesized from l-arginine by endothelial cells. Withdrawal of nitric oxide results in a clinical picture similar to preeclampsia in a pregnant animal model (Conrad, 1989). Inhibition of nitric oxide synthesis increases mean arterial pressure, decreases heart rate, and reverses the pregnancy-induced refractoriness to vasopressors. In humans, nitric oxide likely is the compound that maintains the normal low-pressure vasodilated state characteristic of
fetoplacental perfusion (Myatt, 1992; Weiner, 1992). It also is produced by fetal endothelium, and here it is increased in response to preeclampsia, diabetes, and sepsis (Parra, 2001; von Mandach, 2003).

The effects of nitric oxide production in preeclampsia are unclear (Davidge, 2014). It appears that the syndrome is associated with decreased endothelial nitric oxide synthase expression, thus increasing nitric oxide inactivation. These responses may be race related, with African-American women producing more nitric oxide (Wallace, 2009).

### Endothelins

These 21-amino acid peptides are potent vasoconstrictors, and endothelin-1 (ET-1) is the primary isoform produced by human endothelium (George, 2011). Plasma ET-1 levels are increased in normotensive pregnant women, but women with preeclampsia have even higher levels (Ajne, 2003; Clark, 1992). According to Taylor and Roberts (1999), the placenta is not the source of increased ET-1 concentrations, and they likely arise from systemic endothelial activation. Interestingly, treatment of preeclamptic women with magnesium sulfate lowers ET-1 concentrations (Sagsoz, 2003).

### Angiogenic and Antiangiogenic Proteins

Placental vasculogenesis is evident by 21 days after conception. There is an ever-expanding list of pro- and antiangiogenic substances involved in placental vascular development. The families of vascular endothelial growth factor (VEGF) and angiopoietin (Ang) are most extensively studied. 

**Angiogenic imbalance** is used to describe excessive amounts of antiangiogenic factors that are hypothesized to be stimulated by worsening hypoxia at the uteroplacental interface. Trophoblast of women destined to develop preeclampsia overproduces at least two antiangiogenic peptides that enter the maternal circulation (Karumanchi, 2014):

1. **Soluble Fms-like tyrosine kinase 1 (sFlt-1)** is a variant of the Flt-1 receptor for placental growth factor (PIGF) and for VEGF. Increased maternal sFlt-1 levels inactivate and decrease circulating free PIGF and VEGF concentrations, leading to endothelial dysfunction (Maynard, 2003). As shown in Figure 40-4, sFlt-1 levels begin to increase in maternal serum months before preeclampsia is evident. Haggerty and colleagues (2012) observed that these high levels in the second trimester were associated with a doubling of the risk for preeclampsia. This divergence from normal levels appears to occur even sooner with early-onset preeclampsia (Vatten, 2012).

2. **Soluble endoglin (sEng)** is a placenta-derived 65-kDa molecule that blocks endoglin, which is a surface coreceptor for the TGFβ family. Also called CD105, this soluble form of endoglin inhibits various TGFβ isoforms from binding to endothelial receptors and results in decreased endothelial nitric oxide-dependent vasodilatation (Levine, 2006; Venkatesha, 2006). Serum levels of sEng also begin to increase months before clinical preeclampsia develops (Haggerty, 2012).
The cause of placental overproduction of antiangiogenic proteins remains an enigma. Concentrations of the soluble forms are not increased in the fetal circulation or amniotic fluid, and their levels in maternal blood dissipate after delivery (Staff, 2007). Research currently is focused on immunological mechanisms, oxidative stress, mitochondrial pathology, and hypoxia genes (Karumanchi, 2014). Clinical research is directed at use of antiangiogenic proteins in the prediction and diagnosis of preeclampsia. In a systematic review, Widmer and associates (2007) concluded that third-trimester elevation of sFlt-1 levels and decreased PlGF concentrations...
correlate with preeclampsia development after 25 weeks. These results require verification in prospective studies. Subsequently, Haggerty and coworkers (2012) reported that doubling of expressions of sFlt-1 and sEng increased the preeclampsia risk 39 and 74 percent, respectively.

**PATHOPHYSIOLOGY**

Although the cause of preeclampsia remains unknown, evidence for its manifestation begins early in pregnancy with covert pathophysiological changes that gain momentum across gestation and eventually become clinically apparent. Unless delivery supervenes, these changes ultimately result in multiorgan involvement with a clinical spectrum ranging from an attenuated manifestation to one of cataclysmic deterioration that is life threatening for both mother and fetus. As discussed, these are thought to be a consequence of endothelial dysfunction, vasospasm, and ischemia. Although the many maternal consequences of the preeclampsia syndrome are usually described in terms of individual organ systems, they frequently are multiple, and they overlap clinically.

**Cardiovascular System**

Severe disturbances of normal cardiovascular function are common with preeclampsia syndrome. These are related to: (1) increased cardiac afterload caused by hypertension; (2) cardiac preload, which is affected negatively by pathologically diminished hypervolemia of pregnancy and is increased by intravenous crystalloid or oncotic solutions; and (3) endothelial activation with interendothelial extravasation of intravascular fluid into the extracellular space and importantly, into the lungs.

**Hemodynamic Changes and Cardiac Function**

The cardiovascular aberrations of pregnancy-related hypertensive disorders vary depending on several modifiers. These factors include hypertension severity, underlying chronic disease, preeclampsia severity, and in which part of the clinical spectrum these are studied. In some women, these cardiovascular changes may precede hypertension onset (De Paco, 2008; Easterling, 1990; Khalil, 2012; Melchiorre, 2013). Nevertheless, with the clinical onset of preeclampsia, cardiac output declines, due at least in part to increased peripheral resistance. When assessing cardiac function in preeclampsia, consideration is given to echocardiographic measures of myocardial function and to clinically relevant ventricular function.

**Myocardial Function.** Serial echocardiographic studies have documented in preeclampsia evidence for ventricular remodeling that is accompanied by diastolic dysfunction in 40 percent of women (Melchiorre, 2012). In some of these women, functional differences persisted up to 16 months after delivery (Evans, 2011). Ventricular remodeling was judged to be an adaptive response to maintain normal contractility with the increased afterload of preeclampsia. In the otherwise healthy pregnant woman, these changes are usually clinically inconsequential. But when combined with underlying ventricular dysfunction—for example, concentric ventricular hypertrophy from chronic hypertension—further diastolic dysfunction may cause cardiogenic pulmonary edema as discussed in Chapters 47 (p. 943) and 49 (p. 990).

**Ventricular Function.** Despite the relatively high frequency of diastolic dysfunction with preeclampsia, in most women clinical cardiac function is appropriate. This has been shown by
several studies in which ventricular function was assessed using invasive hemodynamic methods (Hibbard, 2014). Importantly, both normally pregnant women and those with preeclampsia syndrome can have normal or slightly hyperdynamic ventricular function (Fig. 40-5). Thus, both have a cardiac output that is appropriate for left-sided filling pressures. Data from preeclamptic women obtained by invasive hemodynamic studies are confounded because of the heterogeneity of populations and interventions that also may significantly alter these measurements. Some of these are crystalloid infusions, antihypertensive agents, and magnesium sulfate.

**FIGURE 40-5** Ventricular function in normally pregnant women (*striped area*) and in women with eclampsia (*boxed area*) is plotted on a Braunwald ventricular function curve. Normal values are from Clark, 1989, and those for eclampsia are from Hankins, 1984. LVSWI = left ventricular stroke work index; PCWP = pulmonary capillary wedge pressure.

Ventricular function studies of preeclamptic women from several investigations are shown in Figure 40-6. Although cardiac function was hyperdynamic in all women, filling pressures were dependent on the volume of intravenous fluids. Specifically, aggressive hydration resulted in overtly hyperdynamic ventricular function in most women. However, this was accompanied by elevated pulmonary capillary wedge pressures. In some of these women, pulmonary edema may develop despite normal ventricular function because of an alveolar endothelial-epithelial leak. This is compounded by decreased oncotnic pressure from a low serum albumin concentration (American College of Obstetricians and Gynecologists, 2012b).
FIGURE 40-6 Ventricular function in women with severe preeclampsia–eclampsia plotted on the Braunwald ventricular function curve. The pulmonary capillary wedge pressures (PCWP) are lower in those managed with restricted fluid administration (striped area in A) compared with women managed with aggressive fluid therapy (striped area in B). In those managed with aggressive fluid infusions, eight developed pulmonary edema despite normal to hyperdynamic ventricular function in all but one. LVSWI = left ventricular stroke work index. (Data for A from Benedetti, 1980; Hankins, 1984; data for B from Rafferty, 1980; Phelan, 1982.)

Thus, increased cardiac output and hyperdynamic ventricular function is largely a result of low wedge pressures and not a result of augmented myocardial contractility. By comparison, women given appreciably larger volumes of fluid commonly had filling pressures that exceeded normal, but their ventricular function remained hyperdynamic because of concomitantly increased cardiac output.

From these studies, it is reasonable to conclude that aggressive fluid administration to otherwise normal women with severe preeclampsia substantially elevates normal left-sided filling pressures and increases a physiologically normal cardiac output to hyperdynamic levels.

Blood Volume
For nearly 100 years, hemoconcentration has been a hallmark of eclampsia. This was not precisely quantified until Zeeman and colleagues (2009) expanded the previous observations of Pritchard and associates (1984) and showed in eclamptic women that the normally expected
hypervolemia is severely curtailed (Fig. 40-7). Women of average size should have a blood volume of nearly 4500 mL during the last several weeks of a normal pregnancy. In nonpregnant women, this volume approximates only 3000 mL. With eclampsia, however, much or all of the anticipated normal excess 1500 mL is lost. Such hemoconcentration results from generalized vasoconstriction that follows endothelial activation and leakage of plasma into the interstitial space because of increased permeability. In women with preeclampsia, and depending on its severity, hemoconcentration is usually not as marked. Women with gestational hypertension, but without preeclampsia, usually have a normal blood volume (Silver, 1998).

**FIGURE 40-7** The two bar graphs on the left compare mean blood volumes in nonpregnant and term normally pregnant women. On the right, graphs display values for a group of 29 women with eclampsia and their nonpregnant values. The red bar reflects values for a subset of 14 who had a subsequent normotensive pregnancy. Extensions above bars represent one standard deviation. Comparison between values with identical lowercase letters, that is, a-a, b-b, c-c, d-d, are significant $p < .001$. (Data from Zeeman, 2009, with permission.)

For women with severe hemoconcentration, it was once taught that an acute fall in hematocrit suggested resolution of preeclampsia. In this scenario, hemodilution follows endothelial healing with return of interstitial fluid into the intravascular space. Although this is somewhat correct, it is important to recognize that a substantive cause of this fall in hematocrit is usually the consequence of blood loss at delivery (Chap. 41, p. 783). It may also partially result from increased erythrocyte destruction as subsequently described. Vasospasm and endothelial leakage of plasma may persist for a variable time after delivery as the endothelium is restored to normalcy. As this takes place, vasoconstriction reverses, and as the blood volume increases, the hematocrit usually falls. Thus, women with eclampsia:
• Are unduly sensitive to vigorous fluid therapy administered in an attempt to expand the contracted blood volume to normal pregnancy levels
• Are sensitive to amounts of blood loss at delivery that are considered normal for a normotensive woman.

### Hematological Changes

Several hematological abnormalities are associated with the preeclampsia syndrome. Among those commonly identified is thrombocytopenia, which at times may become severe enough to be life threatening. Occasionally, the levels of some plasma clotting factors may be decreased, and erythrocytes display abnormal morphology and undergo rapid hemolysis.

#### Thrombocytopenia

Decreased platelet concentrations with eclampsia were described as early as 1922 by Stancke. The platelet count is routinely measured in women with any form of gestational hypertension. The frequency and intensity of thrombocytopenia vary and are dependent on the severity and duration of the preeclampsia syndrome and the frequency with which platelet counts are performed (Heilmann, 2007; Hupuczi, 2007). Overt thrombocytopenia—defined by a platelet count < 100,000/μL—indicates severe disease (see Table 40-2). In general, the lower the platelet count, the higher the rates of maternal and fetal morbidity and mortality (Leduc, 1992). In most cases, delivery is advisable because thrombocytopenia usually continues to worsen. After delivery, the platelet count may continue to decline for the first day or so. It then usually increases progressively to reach a normal level within 3 to 5 days. As discussed on page 768, in some instances with HELLP syndrome, the platelet count continues to fall after delivery. If these do not reach a nadir until 48 to 72 hours, then preeclampsia syndrome may be incorrectly attributed to one of the thrombotic microangiopathies (George, 2013). These syndromes are discussed in Chapter 56 (p. 1116).

#### Other Platelet Abnormalities

In addition to thrombocytopenia, there are myriad other platelet alterations described with the preeclampsia syndrome. These were reviewed by Kenny and coworkers (2014) and include platelet activation with increased α-degranulation producing β-thromboglobulin, factor 4, and increased clearance. Paradoxically, in most studies, in vitro platelet aggregation is decreased compared with the normal increase characteristic of pregnancy. This likely is due to platelet “exhaustion” following in vivo activation. Although the cause is unknown, immunological processes or simply platelet deposition at sites of endothelial damage may be implicated. Platelet-bound and circulating platelet-bindable immunoglobulins are increased, which suggest platelet surface alterations.

#### Neonatal Thrombocytopenia

Severe thrombocytopenia does not develop in the fetus or infant born to preeclamptic women despite severe maternal thrombocytopenia (Kenny, 2014; Pritchard, 1987). Importantly, maternal thrombocytopenia in hypertensive women is not a fetal indication for cesarean delivery.

#### Hemolysis

Severe preeclampsia is frequently accompanied by evidence of hemolysis as manifest by elevated serum lactate dehydrogenase levels and decreased haptoglobin levels. Other evidence comes from
schizocytosis, spherocytosis, and reticulocytosis in peripheral blood (Cunningham, 1985; Pritchard, 1954, 1976). These derangements result in part from microangiopathic hemolysis caused by endothelial disruption with platelet adherence and fibrin deposition. Sanchez-Ramos and colleagues (1994) described increased erythrocyte membrane fluidity with HELLP syndrome Cunningham and coworkers (1995) postulated that these changes were due to serum lipid alterations, and Mackay and associates (2012) found substantively decreased long-chain fatty acid content in erythrocytes of preeclamptic women. Erythrocytic membrane changes, increased adhesiveness, and aggregation may also promote a hypercoagulable state (Gamzu, 2001).

**HELLP Syndrome.** Subsequent to reports of hemolysis and thrombocytopenia with severe preeclampsia, descriptions followed that abnormally elevated serum liver transaminase levels were commonly found and were indicative of hepatocellular necrosis (Chesley, 1978). Weinstein (1982) referred to this combination of events as the **HELLP syndrome**—and this moniker now is used worldwide. Also, and as shown in Table 40-2, facets of the HELLP syndrome are included in criteria that differentiate severe from nonsevere preeclampsia. The HELLP syndrome is discussed in further detail on page 742.

### Coagulation Changes

Subtle changes consistent with intravascular coagulation, and less often erythrocyte destruction, commonly are found with preeclampsia and especially eclampsia (Kenny, 2014). Some of these changes include increased factor VIII consumption, increased levels of fibrinopeptides A and E and of d-dimers, and decreased levels of regulatory proteins—antithrombin III and protein C and S. Except for thrombocytopenia discussed above, coagulation aberrations generally are mild and are seldom clinically significant (Kenny, 2014; Pritchard, 1984). Unless there is associated placental abruption, plasma fibrinogen levels do not differ remarkably from levels found in normal pregnancy. Fibrin degradation products such as d-dimers are elevated only occasionally. **Fibronectin,** a glycoprotein associated with vascular endothelial cell basement membrane, is elevated in women with preeclampsia (Brubaker, 1992). As preeclampsia worsens, so do abnormal findings with **thromboelastography** (Pisani-Conway, 2013). Despite these changes, routine laboratory assessments of coagulation, including prothrombin time, activated partial thromboplastin time, and plasma fibrinogen level, were found to be unnecessary in the management of pregnancy-associated hypertensive disorders (Barron, 1999).

### Volume Homeostasis

The normal pregnancy-induced extra- and intracellular volume increases that are accompanied by vasodilatation undergo further complex shifts with the preeclampsia syndrome. In addition to blood volume changes shown in Figure 40-7, there are many hormonal, fluid, and electrolyte aberrations.

### Endocrine Changes

Plasma levels of **renin, angiotensin II, angiotensin 1–7, aldosterone,** and **atrial natriuretic peptide** are substantively increased during normal pregnancy. **Deoxycorticosterone (DOC)** is a potent mineralocorticoid that is also increased remarkably in normal pregnancy (Chap. 4, p. 71). This compound results from conversion of plasma progesterone to DOC rather than increased maternal adrenal secretion. Because of this, DOC secretion is not reduced by sodium retention or
hypertension. This may explain why women with preeclampsia retain sodium (Winkel, 1980). In pregnancy, the mineralocorticoid receptor becomes less sensitive to aldosterone (Armanini, 2012).

Vasopressin levels are similar in nonpregnant, normally pregnant, and preeclamptic women even though the metabolic clearance is increased in the latter two (Dürr, 1999).

Atrial natriuretic peptide is released during atrial wall stretching from blood volume expansion, and it responds to cardiac contractility (Chap. 4, p. 61). Serum levels rise in pregnancy, and its secretion is further increased in women with preeclampsia (Borghi, 2000; Luft, 2009). Levels of its precursor—proatrial natriuretic peptide—are also increased in preeclampsia (Sugulle, 2012).

**Fluid and Electrolyte Changes**

In women with severe preeclampsia, the volume of extracellular fluid, manifest as edema, is usually much greater than that in normal pregnant women. The mechanism responsible for pathological fluid retention is thought to be endothelial injury (Davidge, 2014). In addition to generalized edema and proteinuria, these women have reduced plasma oncotic pressure. This reduction creates a filtration imbalance and further displaces intravascular fluid into the surrounding interstitium.

Electrolyte concentrations do not differ appreciably in women with preeclampsia compared with those of normal pregnant women. This may not be the case if there has been vigorous diuretic therapy, sodium restriction, or administration of free water with sufficient oxytocin to produce antidiuresis.

Following an eclamptic convulsion, the serum pH and bicarbonate concentration are lowered due to lactic acidosis and compensatory respiratory loss of carbon dioxide. The intensity of acidosis relates to the amount of lactic acid produced—metabolic acidosis—and the rate at which carbon dioxide is exhaled—respiratory acidosis.

**Kidney**

During normal pregnancy, renal blood flow and glomerular filtration rate are increased appreciably (Chap. 4, p. 63). With development of preeclampsia, there may be a number of reversible anatomical and pathophysiological changes. Of clinical importance, renal perfusion and glomerular filtration are reduced. Levels that are much less than normal nonpregnant values are infrequent and are the consequence of severe disease.

A small degree of decreased glomerular filtration may result from reduced plasma volume. Most of the decrement, however, is from increased renal afferent arteriolar resistance that may be elevated up to fivefold (Conrad, 2014; Cornelis, 2011). There are also morphological changes characterized by glomerular endotheliosis blocking the filtration barrier. This is discussed further subsequently. Diminished filtration causes serum creatinine levels to rise to values seen in nonpregnant individuals, that is, 1 mg/mL, and sometimes even higher (Lindheimer, 2008a). Abnormal values usually begin to normalize 10 days or later after delivery (Spaan, 2012a).

In most preeclamptic women, urine sodium concentration is elevated. Urine osmolality, urine:plasma creatinine ratio, and fractional excretion of sodium also indicate that a prerenal mechanism is involved. Kirshon and coworkers (1988) infused dopamine intravenously into oliguric women with preeclampsia, and this renal vasodilator stimulated increased urine output, fractional sodium excretion, and free water clearance. As was shown in Figure 40-6, sodium-
containing crystalloid infusion increases left ventricular filling pressure, and although oliguria temporarily improves, rapid infusions may cause clinically apparent pulmonary edema. *Intensive intravenous fluid therapy is not indicated as “treatment” for preeclamptic women with oliguria. Exceptions are diminished urine output from hemorrhage or fluid loss from vomiting or fever.*

Plasma uric acid concentration is typically elevated in preeclampsia. The elevation exceeds the reduction in glomerular filtration rate and likely is also due to enhanced tubular reabsorption (Chesley, 1945). At the same time, preeclampsia is associated with diminished urinary excretion of calcium, perhaps because of increased tubular reabsorption (Taufield, 1987). Another possibility is from increased placental urate production compensatory to increased oxidative stress.

**Proteinuria**

As shown in Table 40-1, some degree of proteinuria will establish the diagnosis of preeclampsia syndrome. Proteinuria may develop late, and some women may already be delivered or have had an eclamptic convulsion before it appears. For example, 10 to 15 percent of women with HELLP syndrome did not have proteinuria at presentation (Sibai, 2004). In another report, 17 percent of eclamptic women did not have proteinuria by the time of seizures (Zwart, 2008).

Problematically, the optimal method of establishing abnormal levels of either urine protein or albumin remains to be defined. Chen and associates (2008) have shown that clean-catch and catheterized urine specimens correlate well. But dipstick qualitative determinations depend on urinary concentration and are notorious for false-positive and -negative results. For a 24-hour quantitative specimen, the “consensus” threshold value used is > 300 mg/24 h (Task Force, 2013). Tun and colleagues (2012) have shown equivalent efficacy using protein excretion of 165 mg in a 12-hour sample. Importantly, these values have not been irrefutably established.

Determination of urinary protein:creatinine ratio may supplant the cumbersome 24-hour quantification (Ethridge, 2013; Kyle, 2008; Morris, 2012). In a systematic review, Papanna and associates (2008) concluded that random urine protein:creatinine ratios that are below 130 to 150 mg/g, that is, 0.13 to 0.15, indicate a low likelihood of proteinuria exceeding 300 mg/day. Midrange ratios, that is, 300 mg/g or 0.3 have poor sensitivity and specificity. Stout and colleagues (2013) found that values < 0.08 or > 1.19 had negative- or positive-predictive values of 86 and 96 percent, respectively. At this time, most recommend that with midrange ratio values, 24-hour protein excretion should be quantified.

There are several methods used to measure proteinuria, and none detect all of the various proteins normally excreted (Nayeri, 2013). A more accurate method involves measurement of albumin excretion. Albumin filtration exceeds that of larger globulins, and with glomerular disease such as preeclampsia, most of the protein in urine is albumin. There are test kits that permit rapid measurement of urinary albumin:creatinine ratios in an outpatient setting (Kyle, 2008).

Although worsening or nephrotic-range proteinuria has been considered by most to be a sign of severe disease, this does not appear to be the case (Airoldi, 2007). Certainly, this concept was not accepted by the 2013 Task Force. Finally, increasing proteinuria is more common in multifetal pregnancy complicated by preeclampsia (Zilberberg, 2013).

**Anatomical Changes**

Sheehan and Lynch (1973) commonly found changes identifiable at autopsy by light and electron microscopy in the kidneys of eclamptic women. Glomeruli are enlarged by approximately 20
percent, they are “bloodless,” and capillary loops variably are dilated and contracted. Endothelial cells are swollen—termed glomerular capillary endotheliosis by Spargo and associates (1959). Endothelial cells are often so swollen that they block or partially block the capillary lumens (Fig. 40-8). Homogeneous subendothelial deposits of proteins and fibrin-like material are seen.

![Diagram of glomerular capillary endotheliosis](image)

**FIGURE 40-8** Schematic showing glomerular capillary endotheliosis. The capillary of the normal glomerulus shown on the left has wide endothelial fenestrations, and the pedicels emanating from the podocytes are widely spaced (arrow). The illustration on the right is of a glomerulus with changes induced by the preeclampsia syndrome. The endothelial cells are swollen and their fenestrae narrowed, as are the pedicels that now abut each other.

Endothelial swelling may result from angiogenic factor “withdrawal” caused by free angiogenic proteins complexing with the circulating antiangiogenic protein receptor discussed on page 735 (Conrad, 2014; Eremina, 2007; Karumanchi, 2009). The angiogenic proteins are crucial for podocyte health, and their inactivation leads to podocyte dysfunction and endothelial swelling. One marker of this is excretion of podocyte proteins such as nephrin, podocalyxin, and βig-h3 (transforming growth factor, β-induced) (Wang, 2012b). Also, eclampsia is characterized by increased excretion of urinary podocytes, a phenomenon shared by other proteinuric disorders (Garrett, 2013; Wagner, 2012). Of interest, podocytes are epithelia, and thus renal pathology involves both endothelial and epithelial cells (see Fig. 40-8).

**Acute Kidney Injury**

Rarely is acute tubular necrosis caused by preeclampsia alone. Although mild degrees are encountered in neglected cases, clinically apparent renal failure is invariably induced by coexistent hemorrhage with hypovolemia and hypotension (Chap. 41, p. 814). This is usually
caused by severe obstetrical hemorrhage for which adequate blood replacement is not given. Drakeley and coworkers (2002) described 72 women with preeclampsia and renal failure. Half had HELLP syndrome, and a third had placental abruption. As discussed on page 742, Haddad and colleagues (2000) reported that 5 percent of 183 women with HELLP syndrome had kidney injury. Half of these, however, also had a placental abruption, and most had postpartum hemorrhage. Rarely, irreversible renal cortical necrosis develops (Chap. 53, p. 1064).

Liver

Hepatic changes in women with fatal eclampsia were described in 1856 by Virchow. The characteristic lesions were regions of periportal hemorrhage in the liver periphery. In their elegant autopsy studies, Sheehan and Lynch (1973) described that some degree of hepatic infarction accompanied hemorrhage in almost half of women who died with eclampsia. These corresponded with reports that had appeared during the 1960s describing elevated serum hepatic transaminase levels. Along with the earlier observations by Pritchard and associates (1954), who described hemolysis and thrombocytopenia with eclampsia, this constellation of hemolysis, hepatocellular necrosis, and thrombocytopenia was later termed HELLP syndrome by Weinstein (1985) to call attention to its seriousness (p. 742).

Lesions as extensive as those shown in Figure 40-9 are unusual, even in the autopsy series by Sheehan and Lynch (1973). From a pragmatic point, liver involvement with preeclampsia may be clinically significant in several circumstances.

FIGURE 40-9 Gross liver specimen from a woman with preeclampsia who died from aspiration pneumonitis. Periportal hemorrhagic necrosis was seen microscopically. (From Cunningham, 1993.)

First, symptomatic involvement is considered a sign of severe disease. It typically manifests by moderate to severe right-upper quadrant or midepigastriac pain and tenderness. In many cases, such women also have elevated levels of serum aminotransferase, namely, aspartate aminotransferase (AST) or alanine aminotransferase (ALT). In some cases, however, the amount of hepatic tissue
involved with infarction may be surprisingly extensive yet still clinically insignificant. In our experiences, infarction may be worsened by hypotension from obstetrical hemorrhage, and it occasionally causes hepatic failure—so-called shock liver (Alexander, 2009).

Second, asymptomatic elevations of serum hepatic transaminase levels—AST and ALT—are also considered markers for severe preeclampsia. Values seldom exceed 500 U/L, but have been reported to be greater than 2000 U/L in some women (Chap. 55, p. 1085). In general, serum levels inversely follow platelet levels, and they both usually normalize within 3 days following delivery as previously discussed on page 738.

In a third example of liver involvement, hemorrhagic infarction may extend to form a hepatic hematoma. These in turn may extend to form a subcapsular hematoma that may rupture. They can be identified using computed tomography (CT) scanning or magnetic resonance (MR) imaging as shown in Figure 40-10. Unruptured hematomas are probably more common than clinically suspected and are more likely to be found with HELLP syndrome (Carlson, 2004; Vigil-De Gracia, 2012). Although once considered a surgical condition, contemporaneous management usually consists of observation and conservative treatment of hematomas unless hemorrhage is ongoing. In some cases, however, prompt surgical intervention may be lifesaving. Vigil-De Gracia and coworkers (2012) reviewed 180 cases of hepatic hematoma or rupture. More than 90 percent had HELLP syndrome, and in 90 percent, the capsule had ruptured. The maternal mortality rate was 22 percent, and the perinatal mortality rate was 31 percent. In rare cases, liver transplant is necessary (Hunter, 1995; Wicke, 2004).

FIGURE 40-10 Abdominal CT imaging performed postpartum in a woman with severe HELLP syndrome and right-upper quadrant pain. A large subcapsular hematoma (asterisk) is seen confluent with intrahepatic infarction and hematoma (arrowhead). Numerous flame-shaped hemorrhages are seen at the hematoma interface (arrows).

Last, acute fatty liver of pregnancy is sometimes confused with preeclampsia (Nelson, 2013;
Sibai, 2007a). It too has an onset in late pregnancy, and often there is accompanying hypertension, elevated serum transaminase and creatinine levels, and thrombocytopenia (Chap. 55, p. 1086).

**HELLP Syndrome**

There is no universally accepted strict definition of this syndrome, and thus its incidence varies by investigator. When it is identified, the likelihood of hepatic hematoma and rupture is substantially increased. In a multicenter study, Haddad and colleagues (2000) described 183 women with HELLP syndrome of whom 40 percent had adverse outcomes including two maternal deaths. The incidence of subcapsular liver hematoma was 1.6 percent. Other complications included eclampsia—6 percent, placental abruption—10 percent, acute kidney injury—5 percent, and pulmonary edema—10 percent. Other serious complications included stroke, coagulopathy, acute respiratory distress syndrome, and sepsis.

Women with preeclampsia complicated by the HELLP syndrome typically have worse outcomes than those without these findings (Kozic, 2011; Martin, 2012, 2013). In their review of 693 women with HELLP syndrome, Keiser and coworkers (2009) reported that 10 percent had concurrent eclampsia. Sep and associates (2009) also described a significantly increased risk for complications in women with HELLP syndrome compared with those with “isolated preeclampsia.” These included eclampsia—15 versus 4 percent; preterm birth—93 versus 78 percent; and perinatal mortality rate—9 versus 4 percent, respectively. Because of these marked clinical differences, these investigators postulate that HELLP syndrome has a distinct pathogenesis. Others have shown a difference in the ratio of antiangiogenic and inflammatory acute-phase proteins in these two conditions and have reached similar conclusions (Reimer, 2013). Given all of the variables contributing to the incidence and pathophysiology of preeclampsia as discussed on page 736, this is a reasonable conclusion. Sibai and Stella (2009) have discussed some of these aspects under the rubric of “atypical preeclampsia-eclampsia.”

**Pancreas**

According to Sheehan and Lynch (1973), there are no convincing data that the pancreas has special involvement with preeclampsia syndrome. If so, the occasional case reports of concurrent hemorrhagic pancreatitis are likely unrelated (Swank, 2012). That said, severe hemoconcentration may predispose to pancreatic inflammation.

**Brain**

Headaches and visual symptoms are common with severe preeclampsia, and associated convulsions define eclampsia. The earliest anatomical descriptions of brain involvement came from autopsy specimens, but CT- and MR-imaging and Doppler studies have added many important insights into cerebrovascular involvement.

**Neuroanatomical Lesions**

Most gross anatomical descriptions of the brain in eclamptic women are taken from eras when mortality rates were high. One consistent finding was that brain pathology accounted for only about a third of fatal cases such as the one shown in Figure 40-11. In fact, most deaths were from pulmonary edema, and brain lesions were coincidental. Thus, although gross intracerebral hemorrhage was seen in up to 60 percent of eclamptic women, it was fatal in only half of these cases.
(Melrose, 1984; Richards, 1988; Sheehan, 1973). As shown in Figure 40-12, other principal lesions found at autopsy of eclamptic women were cortical and subcortical petechial hemorrhages. The classic microscopic vascular lesions consist of fibrinoid necrosis of the arterial wall and perivascular microinfarcts and hemorrhages. Other frequently described major lesions include subcortical edema, multiple nonhemorrhagic areas of “softening” throughout the brain, and hemorrhagic areas in the white matter. There also may be hemorrhage in the basal ganglia or pons, often with rupture into the ventricles.

FIGURE 40-11 This autopsy brain slice shows a fatal hypertensive hemorrhage in a primigravida with eclampsia.
Cerebrovascular Pathophysiology

Clinical, pathological, and neuroimaging findings have led to two general theories to explain cerebral abnormalities with eclampsia. Importantly, endothelial cell dysfunction that characterizes the preeclampsia syndrome likely plays a key role in both. The first theory suggests that in response to acute and severe hypertension, cerebrovascular overregulation leads to vasospasm (Trommer, 1988). This presumption is based on the angiographic appearance of diffuse or multifocal segmental narrowings suggestive of vasospasm (Ito, 1995). In this scheme, diminished cerebral blood flow is hypothesized to result in ischemia, cytotoxic edema, and eventually tissue infarction. Although this theory was widely embraced for many years, there is little objective evidence to support it.

The second theory is that sudden elevations in systemic blood pressure exceed the normal cerebrovascular autoregulatory capacity (Hauser, 1988; Schwartz, 2000). Regions of forced vasodilation and vasoconstriction develop, especially in arterial boundary zones. At the capillary level, disruption of end-capillary pressure causes increased hydrostatic pressure, hyperperfusion, and extravasation of plasma and red cells through endothelial tight-junction openings. This leads to vasogenic edema. This theory is incomplete because very few eclamptic women have mean arterial pressures that exceed limits of autoregulation—approximately 160 mm Hg.

It seems reasonable to conclude that the most likely mechanism is a combination of the two. Thus, a preeclampsia-associated interendothelial cell leak develops at blood pressure (hydraulic)
levels much lower than those usually causing vasogenic edema and is coupled with a loss of upper-limit autoregulation (Zeeman, 2009). With imaging studies, these changes manifest as facets of the reversible posterior leukoencephalopathy syndrome (Hinchey, 1996). This subsequently became referred to as the posterior reversible encephalopathy syndrome—PRES. This term is misleading because although PRES lesions principally involve the posterior brain—the occipital and parietal cortices—in at least a third of cases, they also involve other brain areas (Edlow, 2013; Zeeman, 2004a). The most frequently affected region is the parietooccipital cortex—the boundary zone of the anterior, middle, and posterior cerebral arteries. Also, in most cases, these lesions are reversible (Cipolla, 2014).

Cerebral Blood Flow

Autoregulation is the mechanism by which cerebral blood flow remains relatively constant despite alterations in cerebral perfusion pressure. In nonpregnant individuals, this mechanism protects the brain from hyperperfusion when mean arterial pressures increase to as high as 160 mm Hg. These are pressures far greater than those seen in all but a very few women with eclampsia. Thus, to explain eclamptic seizures, it was theorized that autoregulation must be altered by pregnancy. Although species differences must be considered, studies by Cipolla and colleagues (2007, 2009, 2014) have convincingly shown that autoregulation is unchanged across pregnancy in rodents. That said, some, but not others, have provided evidence of impaired autoregulation in women with preeclampsia (Janzarik, 2014; van Veen, 2013).

Zeeman and associates (2003) showed that cerebral blood flow during the first two trimesters of normal pregnancy is similar to nonpregnant values, but thereafter, it significantly decreases by 20 percent during the last trimester. These investigators also documented significantly increased cerebral blood flow in women with severe preeclampsia compared with that of normotensive pregnant women (Zeeman, 2004b). Taken together, these findings suggest that eclampsia occurs when cerebral hyperperfusion forces capillary fluid interstitially because of endothelial damage, which leads to perivascular edema characteristic of the preeclampsia syndrome. In this regard, eclampsia is an example of the posterior reversible encephalopathy syndrome as previously discussed.

Neurological Manifestations

There are several neurological manifestations of the preeclampsia syndrome. Each signifies severe involvement and requires immediate attention. First, headache and scotomata are thought to arise from cerebrovascular hyperperfusion that has a predilection for the occipital lobes. According to Sibai (2005) and Zwart and coworkers (2008), 50 to 75 percent of women have headaches and 20 to 30 percent have visual changes preceding eclamptic convulsions. The headaches may be mild to severe and intermittent to constant. In our experiences, they are unique in that they do not usually respond to traditional analgesia, but they do improve after magnesium sulfate infusion is initiated.

Convulsions are a second potential manifestation and are diagnostic for eclampsia. These are caused by excessive release of excitatory neurotransmitters—especially glutamate; massive depolarization of network neurons; and bursts of action potentials (Meldrum, 2002). Clinical and experimental evidence suggest that extended seizures can cause significant brain injury and later brain dysfunction.

As a third manifestation, blindness is rare with preeclampsia alone, but it complicates eclamptic convulsions in up to 15 percent of women (Cunningham, 1995). Blindness has been reported to develop up to a week or more following delivery (Chambers, 2004). There are at least two types of blindness as discussed subsequently.
Last, generalized cerebral edema may develop and is usually manifest by mental status changes that vary from confusion to coma. This situation is particularly dangerous because fatal transtentorial herniation may result.

**Neuroimaging Studies**

With CT imaging, localized hypodense lesions at the gray- and white-matter junction, primarily in the parietooccipital lobes, are typically found in eclampsia. Such lesions may also be seen in the frontal and inferior temporal lobes, the basal ganglia, and thalamus (Brown, 1988). The spectrum of brain involvement is wide, and increasing involvement can be identified with CT imaging. Edema of the occipital lobes or diffuse cerebral edema may cause symptoms such as blindness, lethargy, and confusion (Cunningham, 2000). In the latter cases, widespread edema shows as a marked compression or even obliteration of the cerebral ventricles. Such women may develop signs of impending life-threatening transtentorial herniation.

Several MR imaging acquisitions are used to study eclamptic women. Common findings are hyperintense T2 lesions—posterior reversible encephalopathy syndrome (PRES)—in the subcortical and cortical regions of the parietal and occipital lobes ([Fig. 40-13](#)). There is also relatively common involvement of the basal ganglia, brainstem, and cerebellum (Brewer, 2013; Zeeman, 2004a). Although these PRES lesions are almost universal in women with eclampsia, their incidence in women with preeclampsia is less frequent. They are more likely to be found in women who have severe disease and who have neurological symptoms (Schwartz, 2000). And although usually reversible, a fourth of these hyperintense lesions represent cerebral infarctions that have persistent findings (Loureiro, 2003; Zeeman, 2004a).

![FIGURE 40-13 Cranial magnetic resonance imaging in a nullipara with eclampsia. Multilobe T2-FLAIR high-signal lesions are apparent. FLAIR = fluid-attenuated inversion recovery. (Image contributed by Dr. Gerda Zeeman.)](image)
Visual Changes and Blindness
Scotomata, blurred vision, or diplopia are common with severe preeclampsia and eclampsia. These usually improve with magnesium sulfate therapy and/or lowered blood pressure. Blindness is less common, is usually reversible, and may arise from three potential areas. These are the visual cortex of the occipital lobe, the lateral geniculate nuclei, and the retina. In the retina, pathological lesions may be ischemia, infarction, or detachment (Roos, 2012).

Occipital blindness is also called *amaurosis*—from the Greek *dimming*. Affected women usually have evidence of extensive occipital lobe vasogenic edema on imaging studies. Of 15 women cared for at Parkland Hospital, occipital blindness lasted from 4 hours to 8 days, but it resolved completely in all cases (Cunningham, 1995). Rarely, extensive cerebral infarctions may result in total or partial visual defects (Fig. 40-14).

**FIGURE 40-14** Cranial magnetic resonance imaging performed 3 days postpartum in a woman with eclampsia and HELLP syndrome. Neurovisual defects persisted at 1 year, causing job disability. (From Murphy, 2005, with permission.)

Blindness from retinal lesions is caused either by serous retinal detachment or rarely by retinal infarction, which is termed *Purtscher retinopathy* (Fig. 40-15). *Serous retinal detachment* is usually unilateral and seldom causes total visual loss. In fact, asymptomatic serous retinal detachment is relatively common (Saito, 1998). In most cases of eclampsia-associated blindness, visual acuity subsequently improves, but if caused by retinal artery occlusion, vision may be permanently impaired (Lara-Torre, 2002; Roos, 2012). In some women, these findings are additive. Moseman and Shelton (2002) described a woman with permanent blindness due to a combination of retinal infarctions and bilateral lesions in the lateral geniculate nuclei.
FIGURE 40-15 Purtscher retinopathy caused by choroidal ischemia and infarction in preeclampsia syndrome. A. Ophthalmoscopy shows scattered yellowish, opaque lesions of the retina (arrows). B. The late phase of fluorescein angiography shows areas of intense hyperfluorescence representing pooling of extravasated dye. (From Lam, 2001, with permission.)

Cerebral Edema
Clinical manifestations suggesting widespread cerebral edema are worrisome. During 13 years at Parkland Hospital, 10 of 175 women with eclampsia were diagnosed with symptomatic cerebral edema (Cunningham, 2000). Symptoms ranged from lethargy, confusion, and blurred vision to obtundation and coma. In most cases, symptoms waxed and waned. Mental status changes generally correlated with the degree of involvement seen with CT and MR imaging studies. These women are very susceptible to sudden and severe blood pressure elevations, which can acutely worsen the already widespread vasogenic edema. Thus, careful blood pressure control is essential. In the 10 women with generalized edema, three became comatose and had imaging findings of impending transtentorial herniation. One of these three died from herniation. Consideration is given for treatment with mannitol or dexamethasone.

Long-Term Neurocognitive Sequelae
Women with eclampsia have been shown to have some cognitive decline when studied 5 to 10 years following an eclamptic pregnancy. This is discussed further on page 770.

Uteroplacental Perfusion
Defects in endovascular trophoblastic invasion and placentation germane to development of the preeclampsia syndrome and fetal-growth restriction were discussed on page 732. Of immense clinical importance, compromised uteroplacental perfusion is almost certainly a major culprit in
the increased perinatal morbidity and mortality rates. Thus, measurement of uterine, intervillous, and placental blood flow would likely be informative. Attempts to assess these in humans have been hampered by several obstacles that include inaccessibility of the placenta, the complexity of its venous effluent, and the need for radioisotopes or invasive techniques.

Measurement of uterine artery blood flow velocity has been used to estimate resistance to uteroplacental blood flow (Chap. 17, p. 345). Vascular resistance is estimated by comparing arterial systolic and diastolic velocity waveforms. By the completion of placentation, impedance to uterine artery blood flow is markedly decreased, but with abnormal placentation, abnormally high resistance persists (Everett, 2012; Ghidini, 2008; Napolitano, 2012). Earlier studies were done to assess this by measuring peak systolic:diastolic velocity ratios from uterine and umbilical arteries in preeclamptic pregnancies. The results were interpreted as showing that in some cases, but certainly not all, there was increased resistance (Fleischer, 1986; Trudinger, 1990).

Another Doppler waveform—uterine artery “notching”—has been reported to be associated with increased risks for preeclampsia or fetal-growth restriction (Groom, 2009). In the MFMU Network study reported by Myatt and colleagues (2012a), however, notching had a low predictive value except for early-onset severe disease.

Matijevic and Johnson (1999) measured resistance in uterine spiral arteries. Impedance was higher in peripheral than in central vessels—a so-called ring-like distribution. Mean resistance was higher in all women with preeclampsia compared with that in normotensive controls. Ong and associates (2003) used MR imaging and other techniques to assess placental perfusion ex vivo in the myometrial arteries removed from women with preeclampsia or fetal-growth restriction. These investigators confirmed that in both conditions myometrial arteries exhibited endothelium-dependent vasodilatory response. Moreover, other pregnancy conditions are also associated with increased resistance (Urban, 2007). One major adverse effect, fetal-growth restriction, is discussed in Chapter 44 (p. 874).

Pimenta and colleagues (2013) assessed placental vascularity using a three-dimensional power Doppler histogram. These researchers described the placental vascularity index, which was decreased in women with any pregnancy-associated hypertensive disorders—11.1 percent compared with 15.2 percent in normal controls.

Despite these findings, evidence for compromised uteroplacental circulation is found in only a few women who go on to develop preeclampsia. Indeed, when preeclampsia develops during the third trimester, only a third of women with severe disease have abnormal uterine artery velocimetry (Li, 2005). In a study of 50 women with HELLP syndrome, only a third had abnormal uterine artery waveforms (Bush, 2001). In general, the extent of abnormal waveforms correlates with severity of fetal involvement (Ghidini, 2008; Groom, 2009).

**PREDICTION AND PREVENTION**

**Prediction**

Measurement during early pregnancy—or across pregnancy—of various biological, biochemical, and biophysical markers implicated in preeclampsia syndrome pathophysiology has been proposed to predict its development. Attempts have been made to identify early markers of faulty placentation, impaired placental perfusion, endothelial cell activation and dysfunction, and activation of coagulation. For the most, these have resulted in testing strategies with poor sensitivity and with poor positive-predictive value for preeclampsia (Conde-Agudelo, 2014;
Lindheimer, 2008b; Odibo, 2013). Currently, no screening tests are predictably reliable, valid, and economical (Kleinrouweler, 2012). There are, however, combinations of tests, some yet to be adequately evaluated, that may be promising (Dugoff, 2013; Kuc, 2011; Navaratnam, 2013; Olsen, 2012).

The list of predictive factors evaluated during the past three decades is legion. Although most have been evaluated in the first half of pregnancy, some have been tested as predictors of severity in the third trimester (Chaiworapongs, 2013; Mosimann, 2013; Rana, 2012). Others have been used to forecast recurrent preeclampsia (Demers, 2014). Some of these tests are listed in Table 40-4, which is by no means all inclusive. Conde-Agudelo and coworkers (2014) have recently provided a thorough review of many of these testing strategies.

### Vascular Resistance Testing and Placental Perfusion

Most of these are cumbersome, time consuming, and overall inaccurate.

### Provocative Pressor Tests

Three tests have been extensively evaluated to assess the blood pressure rise in response to a stimulus. The roll-over test measures the hypertensive response in women at 28 to 32 weeks who are resting in the left lateral decubitus position and then roll over to the supine position. Increased blood pressure signifies a positive test. The isometric exercise test employs the same principle by squeezing a handball. The angiotensin II infusion test is performed by giving incrementally increasing doses intravenously, and the hypertensive response is quantified. In their updated metaanalysis, Conde-Agudelo and associates (2014) found sensitivities of all three tests to range from 55 to 70 percent, and specificities approximated 85 percent.

### Uterine Artery Doppler Velocimetry

Faulty trophoblastic invasion of the spiral arteries, which is depicted in Figure 40-2, results in diminished placental perfusion and upstream increased...
uterine artery resistance. Increased uterine artery velocimetry determined by Doppler ultrasound in the first two trimesters should provide indirect evidence of this process and thus serve as a predictive test for preeclampsia (Gebb, 2009a,b; Groom, 2009). As described on page 745 and in Chapter 10 (p. 220), increased flow resistance results in an abnormal waveform represented by an exaggerated diastolic notch. These have value for fetal-growth restriction but not preeclampsia (American College of Obstetricians and Gynecologists, 2013a). Several flow velocity waveforms—alone or in combination—have been investigated for preeclampsia prediction. In some of these, predictive values for early-onset preeclampsia were promising (Herraiz, 2012). At this time, however, none is suitable for clinical use (Conde-Agudelo, 2014; Kleinrouweler, 2012; Myatt, 2012a).

**Pulse Wave Analysis.** Like the uterine artery, finger arterial pulse “stiffness” is an indicator of cardiovascular risk. Investigators have preliminarily evaluated its usefulness in preeclampsia prediction (Vollebregt, 2009).

**Fetal-Placental Unit Endocrine Function**
Several serum analytes that have been proposed to help predict preeclampsia are shown in Table 40-4. Newer ones are continuously added (Jeyabal, 2009; Kanasaki, 2008; Kenny, 2009). Many of these gained widespread use in the 1980s to identify fetal malformations and were also found to be associated with other pregnancy abnormalities such as neural-tube defects and aneuploidy (Chap. 14, p. 289). Although touted for hypertension prediction, in general, none of these tests has been shown to be clinically beneficial for that purpose.

**Tests of Renal Function**

**Serum Uric Acid.** One of the earliest laboratory manifestations of preeclampsia is hyperuricemia (Powers, 2006). It likely results from reduced uric acid clearance from diminished glomerular filtration, increased tubular reabsorption, and decreased secretion (Lindheimer, 2008a). It is used by some to define preeclampsia, but Cnossen and coworkers (2006) reported that its sensitivity ranged from 0 to 55 percent, and specificity was 77 to 95 percent.

**Microalbuminuria.** As a predictive test for preeclampsia, microalbuminuria has sensitivities ranging from 7 to 90 percent and specificities between 29 and 97 percent (Conde-Agudelo, 2014). Poon and colleagues (2008) likewise found unacceptable sensitivity and specificity for urine albumin:creatinine ratios.

**Endothelial Dysfunction and Oxidant Stress**
As discussed on page 733, endothelial activation and inflammation are major participants in the pathophysiology of the preeclampsia syndrome. As a result, compounds such as those listed in Table 40-4 are found in circulating blood of affected women, and some have been assessed for their predictive value.

**Fibronectins.** These high-molecular-weight glycoproteins are released from endothelial cells and extracellular matrix following endothelial injury (Chavarria, 2002). More than 30 years ago, plasma concentrations were reported to be elevated in women with preeclampsia (Stubbs, 1984). Following their systematic review, however, Leeflang and associates (2007) concluded that neither cellular nor total fibronectin levels were clinically useful to predict preeclampsia.
Coagulation Activation. Thrombocytopenia and platelet dysfunction are integral features of preeclampsia as discussed on page 738. Platelet activation causes increased destruction and decreased concentrations, and mean platelet volume rises because of platelet immaturity (Kenny, 2014). Although markers of coagulation activation are increased, the substantive overlap with levels in normotensive pregnant women stultifies their predictive value.

Oxidative Stress. Increased levels of lipid peroxides coupled with decreased antioxidant activity have raised the possibility that markers of oxidative stress might predict preeclampsia. For example, malondialdehyde is a marker of lipid peroxidation. Other markers are various prooxidants or their potentiliators. These include iron, transferrin, and ferritin; blood lipids, including triglycerides, free fatty acids, and lipoproteins; and antioxidants such as ascorbic acid and vitamin E (Bainbridge, 2005; Conde-Agudelo, 2014; Mackay, 2012; Powers, 2000). These have not been found to be predictive, and treatment to prevent preeclampsia with some of them has been studied as discussed on page 748.

Hyperhomocysteinemia causes oxidative stress and endothelial cell dysfunction and is characteristic of preeclampsia. Although women with elevated serum homocysteine levels at midpregnancy had a three- to fourfold risk of preeclampsia, these tests have not been shown to be clinically useful predictors (D’Anna, 2004; Mignini, 2005; Zeeman, 2003).

Angiogenic Factors. As discussed on page 735, evidence has accrued that an imbalance between proangiogenic and antiangiogenic factors is related to preeclampsia pathogenesis. Serum levels of some proangiogenic factors—vascular endothelial growth factor (VEGF) and placental growth factor (PIGF)—begin to decrease before clinical preeclampsia develops. And, recall as shown in Figure 40-4 that at the same time levels of some antiangiogenic factors such as sFlt-1 and sEng become increased (Maynard, 2008). In one study, these abnormalities were identified coincidentally with rising uterine artery Doppler resistance (Coolman, 2012).

Conde-Agudelo and colleagues (2014) reviewed the predictive accuracy of some of these factors for severe preeclampsia. Sensitivities for all cases of preeclampsia ranged from 30 to 50 percent, and specificity was about 90 percent. Their predictive accuracy was higher for early-onset preeclampsia. These preliminary results suggest a clinical role for preeclampsia prediction. However, until this role is better substantiated, their general clinical use is not currently recommended (Boucoiran, 2013; Kleinrouweler, 2012; Widmer, 2007). Automated assays are being studied, and the World Health Organization (WHO) began a multicenter trial in 2008 to evaluate these factors (Sunderji, 2009).

Cell-Free Fetal DNA
As discussed in Chapter 13 (p. 279), cell-free fetal DNA can be detected in maternal plasma. It has been reported that fetal-maternal cell trafficking is increased in pregnancies complicated by preeclampsia (Holzgreve, 1998). It is hypothesized that cell-free DNA is released by accelerated apoptosis of cytotrophoblasts (DiFederico, 1999). From their review, Conde-Agudelo and associates (2014) concluded that cell-free fetal DNA quantification is not yet useful for prediction purposes.

Proteomic, Metabolomic, and Transcriptomic Markers
Methods to study serum and urinary proteins and cellular metabolites have opened a new vista for preeclampsia prediction. Preliminary studies indicate that these may become useful (Bahado-Singh, 2013; Carty, 2011; Liu, 2013; Myers, 2013).
Prevention

Various strategies used to prevent or modify preeclampsia severity have been evaluated. Some are listed in Table 40-5. In general, none of these has been found to be convincingly and reproducibly effective.

**Dietary and Lifestyle Modifications**

A favorite of many theorists and faddists for centuries, dietary “treatment” for preeclampsia has produced some interesting abuses as chronicled by Chesley (1978).

**Low-Salt Diet.** One of the earliest research efforts to prevent preeclampsia was salt restriction (De Snoo, 1937). This interdiction was followed by years of inappropriate diuretic therapy. Although these practices were discarded, it ironically was not until relatively recently that the first randomized trial was done and showed that a sodium-restricted diet was ineffective in preventing preeclampsia in 361 women (Knuist, 1998). Guidelines from the United Kingdom National Institute for Health and Clinical Excellence (2010) recommend against salt restrictions.

**Calcium Supplementation.** Studies performed in the 1980s outside the United States showed that women with low dietary calcium intake were at significantly increased risk for gestational hypertension (Belizan, 1980; López-Jaramillo, 1989; Marya, 1987). Calcium supplementation has been studied in several trials, including one by the National Institute of Child Health and Human Development (NICHD) that included more than 4500 nulliparous women (Levine, 1997). In one recent metaanalysis, Patrelli and coworkers (2012) reported that increased calcium intake lowered the risk for preeclampsia in high-risk women. In aggregate, most of these trials have shown that unless women are calcium deficient, supplementation has no salutary effects (Staff, 2014).

**Fish Oil Supplementation.** Cardioprotective fatty acids found in some fatty fishes are plentiful in diets of Scandinavians and American Eskimos. The most common dietary sources are EPA—eicosapentaenoic acid, ALA—alpha-linoleic acid, and DHA—docosahexaenoic acid. With proclamations that supplementation with these fatty acids would prevent inflammatory-mediated atherogenesis, it was not a quantum leap to posit that they might also prevent preeclampsia. Unfortunately, randomized trials conducted thus far have shown no such benefits (Makrides, 2006; Olafsdottir, 2006; Olsen, 2000; Zhou, 2012a).

**Exercise.** There are a few studies done to assess the protective effects of physical activity on
preeclampsia. In their systematic review, Kasawara and associates (2012) reported a trend toward risk reduction with exercise. More research is needed in this area (Staff, 2014).

Antihypertensive Drugs
Because of the putative effects of sodium restriction, diuretic therapy became popular with the introduction of chlorothiazide in 1957 (Finnerty, 1958; Flowers, 1962). In their metaanalysis, Churchill and colleagues (2007) summarized nine randomized trials that included more than 7000 pregnancies. They found that women given diuretics had a decreased incidence of edema and hypertension but not of preeclampsia.

Because women with chronic hypertension are at high risk for preeclampsia, several randomized trials—only a few placebo-controlled—have been done to evaluate various antihypertensive drugs to reduce the incidence of superimposed preeclampsia. A critical analysis of these trials by Staff and coworkers (2014) failed to demonstrate salutary effects.

Antioxidants
There are inferential data that an imbalance between oxidant and antioxidant activity may play an important role in the pathogenesis of preeclampsia (p. 747). Thus, naturally occurring antioxidants—vitamins C, D, and E—might decrease such oxidation. Indeed, women who developed preeclampsia were found to have reduced plasma levels of these antioxidants (De-Regil, 2012; Raijmakers, 2004). There have now been several randomized studies to evaluate vitamin supplementation for women at high risk for preeclampsia (Poston, 2006; Rumbold, 2006; Villar, 2007). The one by the MFMU Network included almost 10,000 low-risk nulliparas (Roberts, 2009). None of these studies showed reduced preeclampsia rates in women given vitamins C and E compared with those given placebo. The recent metaanalysis by De-Regil and colleagues (2012) likewise showed no benefits of vitamin D supplementation.

The rationale for the use of statins to prevent preeclampsia is that they stimulate hemoxygenase-1 expression that inhibits sFlt-1 release. There are preliminary animal data that statins may prevent hypertensive disorders of pregnancy. The MFMU Network plans a randomized trial to test pravastatin for this purpose (Costantine, 2013).

Antithrombotic Agents
There are sound theoretical reasons that antithrombotic agents might reduce the incidence of preeclampsia. As discussed on page 734, the syndrome is characterized by vasospasm, endothelial cell dysfunction, and inflammation, as well as activation of platelets and the coagulation-hemostasis system. Moreover, prostaglandin imbalance(s) may be operative, and other sequelae include placental infarction and spiral artery thrombosis (Nelson, 2014).

Low-Dose Aspirin. In oral doses of 50 to 150 mg daily, aspirin effectively inhibits platelet thromboxane A2 biosynthesis but has minimal effects on vascular prostacyclin production (Wallenburg, 1986). However, clinical trials have shown limited benefits. For example, results in Table 40-6 are from the MFMU Network, and none of the outcomes shown were significantly improved. Some reports are more favorable. For example, the Paris Collaborative Group performed a metaanalysis that included 31 randomized trials involving 32,217 women (Askie, 2007). For women assigned to receive antiplatelet agents, the relative risk for development of preeclampsia, superimposed preeclampsia, preterm delivery, or any adverse pregnancy outcome was significantly decreased by 10 percent. Another review and metaanalysis reported marginal benefits for low-dose aspirin and severe preeclampsia (Roberge, 2012). A recent small Finnish
A multicenter trial included 152 women at high risk for preeclampsia (Villa, 2013). Although there were no benefits to low-dose aspirin, the accompanying metaanalysis reported a lowering of risk. The 2013 Task Force recommended the use of low-dose aspirin in some high-risk women to prevent preeclampsia.

**Low-Dose Aspirin plus Heparin.** In women with lupus anticoagulant, treatment with low-dose aspirin and heparin mitigates thrombotic sequelae (Chap. 59, p. 1175). Because of the high prevalence of placental thrombotic lesions found with severe preeclampsia, observational trials have been done to evaluate such treatments for affected women. Sergis and associates (2006) reviewed effects of prophylaxis with low-molecular-weight heparin plus low-dose aspirin on pregnancy outcomes in women with a history of severe early-onset preeclampsia and low-birthweight neonates. They reported better pregnancy outcomes in women given low-molecular-weight heparin plus low-dose aspirin compared with those given low-dose aspirin alone. Similar findings were reported in a trial that included 139 women with thrombophilia and a history of early-onset preeclampsia (de Vries, 2012). Despite these small trials, evidence is insufficient to recommend these regimens to prevent preeclampsia (National Institute for Health and Clinical Excellence, 2010; Staff, 2014).

### MANAGEMENT

Pregnancy complicated by gestational hypertension is managed based on severity, gestational age, and presence of preeclampsia. With preeclampsia, management varies with the severity of endothelial cell injury and multiorgan dysfunction.
Preeclampsia cannot always be diagnosed definitively (p. 728). Thus, the Task Force of the American College of Obstetricians and Gynecologists (2013b) recommends more frequent prenatal visits if preeclampsia is “suspected.” Increases in systolic and diastolic blood pressure can be either normal physiological changes or signs of developing pathology. Increased surveillance permits more prompt recognition of ominous changes in blood pressure, critical laboratory findings, and clinical signs and symptoms (Macdonald-Wallis, 2012).

The basic management objectives for any pregnancy complicated by preeclampsia are: (1) termination of pregnancy with the least possible trauma to mother and fetus, (2) birth of an infant who subsequently thrives, and (3) complete restoration of health to the mother. In many women with preeclampsia, especially those at or near term, all three objectives are served equally well by induction of labor. One of the most important clinical questions for successful management is precise knowledge of fetal age.

### Early Diagnosis of Preeclampsia

Traditionally, the frequency of prenatal visits is increased during the third trimester, and this aids early detection of preeclampsia. *Women without overt hypertension, but in whom early developing preeclampsia is suspected during routine prenatal visits, are seen more frequently*. The protocol used successfully for many years at Parkland Hospital for women with new-onset diastolic blood pressures > 80 mm Hg but < 90 mm Hg or with sudden abnormal weight gain of more than 2 pounds per week includes, at minimum, return visits at 7-day intervals. Outpatient surveillance is continued unless overt hypertension, proteinuria, headache, visual disturbances, or epigastric discomfort supervene. Women with overt new-onset hypertension—either diastolic pressures ≥ 90 mm Hg or systolic pressures ≥ 140 mm Hg—are admitted to determine if the increase is due to preeclampsia, and if so, to evaluate its severity. Women with persistent severe disease are generally delivered, as discussed subsequently. Conversely, women with apparently mild disease can often be managed as outpatients, although there should be a low threshold for continued hospitalization for the nullipara, especially if there is proteinuria.

### Evaluation

Hospitalization is considered at least initially for women with new-onset hypertension, especially if there is persistent or worsening hypertension or development of proteinuria. A systematic evaluation is instituted to include the following:

- Detailed examination, which is followed by daily scrutiny for clinical findings such as headache, visual disturbances, epigastric pain, and rapid weight gain
- Weight determined daily
- Analysis for proteinuria or urine protein:creatinine ratio on admittance and at least every 2 days thereafter
- Blood pressure readings in the sitting position with an appropriate-size cuff every 4 hours, except between 2400 and 0600 unless previous readings had become elevated
- Measurements of plasma or serum creatinine and hepatic aminotransferase levels and a hemogram that includes platelet quantification. The frequency of testing is determined by hypertension severity. Some recommend measurement of serum uric acid and lactic acid dehydrogenase levels and coagulation studies. However, the value of these tests has been called into question (Cnossen, 2006; Conde-Agudelo, 2014; Thangaratinam, 2006).
• Evaluation of fetal size and well-being and amniotic fluid volume, with either physical examination or sonography.

Goals of management include early identification of worsening preeclampsia and development of a management plan for timely delivery. If any of these observations lead to a diagnosis of severe preeclampsia as previously defined by the criteria in Table 40–2, further management is subsequently described.

Reduced physical activity throughout much of the day is likely beneficial, but as the 2013 Task Force concluded, absolute bed rest is not desirable. Ample protein and calories should be included in the diet, and sodium and fluid intake should not be limited or forced. Further management depends on: (1) preeclampsia severity, (2) gestational age, and (3) condition of the cervix.

Fortunately, many cases are sufficiently mild and near enough to term that they can be managed conservatively until labor commences spontaneously or until the cervix becomes favorable for labor induction. Complete abatement of all signs and symptoms, however, is uncommon until after delivery. Almost certainly, the underlying disease persists until delivery is accomplished.

### Consideration for Delivery

Termination of pregnancy is the only cure for preeclampsia. Headache, visual disturbances, or epigastric pain are indicative that convulsions may be imminent, and oliguria is another ominous sign. Severe preeclampsia demands anticonvulsant and frequently antihypertensive therapy, followed by delivery. Treatment is identical to that described subsequently for eclampsia. The prime objectives are to forestall convulsions, to prevent intracranial hemorrhage and serious damage to other vital organs, and to deliver a healthy newborn.

When the fetus is preterm, the tendency is to temporize in the hope that a few more weeks in utero will reduce the risk of neonatal death or serious morbidity from prematurity. As discussed, such a policy certainly is justified in milder cases. Assessments of fetal well-being and placental function are performed, especially when the fetus is immature. Most recommend frequent performance of various tests to assess fetal well-being as described by the American College of Obstetricians and Gynecologists (2012a). These include the nonstress test or the biophysical profile (Chap. 17, pp. 338 and 341). Measurement of the lecithin-sphingomyelin (L/S) ratio in amniotic fluid may provide evidence of lung maturity (Chap. 34, p. 655).

With moderate or severe preeclampsia that does not improve after hospitalization, delivery is usually advisable for the welfare of both mother and fetus. This is true even when the cervix is unfavorable (Tajik, 2012). Labor induction is carried out, usually with preinduction cervical ripening from a prostaglandin or osmotic dilator (Chap. 26, p. 525). Whenever it appears that induction almost certainly will not succeed or attempts have failed, then cesarean delivery is indicated.

For a woman near term, with a soft, partially effaced cervix, even milder degrees of preeclampsia probably carry more risk to the mother and her fetus-infant than does induction of labor (Tajik, 2012). The decision to deliver late-preterm fetuses is not clear. Barton and coworkers (2009) reported excessive neonatal morbidity in women delivered before 38 weeks despite having stable, mild, nonproteinuric hypertension. The Netherlands study of 4316 newborns delivered between 340/7 and 366/7 weeks also described substantive neonatal morbidity in these cases (Langenveld, 2011). Most of these deliveries were before 36 weeks, and the higher cesarean delivery rates were associated with more respiratory complications. Conversely, one randomized
trial of 756 women with mild preeclampsia supported delivery after 37 weeks (Koopmans, 2009).

Elective Cesarean Delivery

Once severe preeclampsia is diagnosed, labor induction and vaginal delivery have traditionally been considered ideal. Temporization with an immature fetus is considered subsequently. Several concerns, including an unfavorable cervix, a perceived sense of urgency because of preeclampsia severity, and a need to coordinate neonatal intensive care, have led some to advocate cesarean delivery. Alexander and colleagues (1999) reviewed 278 singleton liveborn neonates weighing 750 to 1500 g delivered of women with severe preeclampsia at Parkland Hospital. In half of the women, labor was induced, and the remainder underwent cesarean delivery without labor. Induction was successful in accomplishing vaginal delivery in a third, and it was not harmful to the very-low-birthweight infants. Alanis and associates (2008) reported similar observations. The results of a systematic review also confirmed these conclusions (Le Ray, 2009).

Hospitalization versus Outpatient Management

For women with mild to moderate stable hypertension—whether or not preeclampsia has been confirmed—surveillance is continued in the hospital, at home for some reliable patients, or in a day-care unit. At least intuitively, reduced physical activity throughout much of the day seems beneficial. Several observational studies and randomized trials have addressed the benefits of inpatient care and outpatient management.

Somewhat related, Abenhaim and coworkers (2008) reported a retrospective cohort study of 677 nonhypertensive women hospitalized for bed rest because of threatened preterm delivery. When outcomes of these women were compared with those of the general obstetrical population, bed rest was associated with a significantly reduced relative risk—RR 0.27—of developing preeclampsia. In a review of two small randomized trials totaling 106 women at high risk for preeclampsia, prophylactic bed rest for 4 to 6 hours daily at home was successful in significantly lowering the incidence of preeclampsia but not gestational hypertension (Meher, 2006).

These and other observations support the claim that restricted activity alters the underlying pathophysiology of the preeclampsia syndrome. That said, complete bed rest is not recommended by the 2013 Task Force. First, this is pragmatically unachievable because of the severe restrictions it places on otherwise well women. Also, as discussed in Chapter 52 (p. 1029), it likely also predisposes to thromboembolism (Knight, 2007).

High-Risk Pregnancy Unit

The concept of prolonged hospitalization for women with hypertension arose during the 1970s. At Parkland Hospital, an inpatient antepartum unit was established in 1973 by Dr. Peggy Whalley in large part to provide care for such women. Initial results from this unit were reported by Hautl (1976) and Gilstrap (1978) and their colleagues. Most hospitalized women have a beneficial response characterized by amelioration or improvement of hypertension. These women are not “cured,” and nearly 90 percent have recurrent hypertension before or during labor. By 2013, more than 10,000 nulliparas with mild to moderate early-onset hypertension during pregnancy had been managed successfully in this unit. Provider costs—not charges—for this relatively simple physical facility, modest nursing care, no drugs other than iron and folate supplements, and few essential laboratory tests are minimal compared with the cost of neonatal intensive care for a preterm infant. None of these women have suffered thromboembolic disease.
Many clinicians believe that further hospitalization is not warranted if hypertension abates within a few days, and this has legitimized third-party payers to deny hospitalization reimbursement. Consequently, many women with mild to moderate hypertension are managed at home. Outpatient management may continue as long as preeclampsia syndrome does not worsen and fetal jeopardy is not suspected. Sedentary activity throughout the greater part of the day is recommended. These women are instructed in detail to report symptoms. Home blood pressure and urine protein monitoring or frequent evaluations by a visiting nurse may prove beneficial. Caution is exercised regarding use of certain automated home blood pressure monitors (Lo, 2002; Ostchega, 2012).

In an observational study by Barton and associates (2002), 1182 nulliparas with mild gestational hypertension—20 percent had proteinuria—were managed with home health care. Their mean gestational ages were 32 to 33 weeks at enrollment and 36 to 37 weeks at delivery. Severe preeclampsia developed in approximately 20 percent, about 3 percent developed HELLP syndrome, and two women had eclampsia. Perinatal outcomes were generally good. In approximately 20 percent, there was fetal-growth restriction, and the perinatal mortality rate was 4.2 per 1000.

Several prospective studies have been designed to compare continued hospitalization with either home health care or a day-care unit. In a pilot study from Parkland Hospital, Horsager and colleagues (1995) randomly assigned 72 nulliparas with new-onset hypertension from 27 to 37 weeks either to continued hospitalization or to outpatient care. In all of these women, proteinuria had receded to less than 500 mg per day when they were randomized. Outpatient management included daily blood pressure monitoring by the patient or her family. Weight and dipstick spot urine protein determinations were evaluated three times weekly. A home health nurse visited twice weekly, and the women were seen weekly in the clinic. Perinatal outcomes were similar in each group. The only significant difference was that women in the home care group developed severe preeclampsia significantly more frequently than hospitalized women—42 versus 25 percent.

A larger randomized trial reported by Crowther and coworkers (1992) included 218 women with mild gestational nonproteinuric hypertension. After evaluation, half remained hospitalized, whereas the other half was managed as outpatients. As shown in Table 40-7, the mean duration of hospitalization was 22.2 days for women with inpatient management compared with only 6.5 days in the home-care group. Preterm delivery before 34 and before 37 weeks was increased twofold in the outpatient group, but maternal and infant outcomes otherwise were similar.

| TABLE 40-7. Randomized Clinical Trials Comparing Hospitalization versus Routine Care for Women with Mild Gestational Hypertension or Preeclampsia |
Another approach, popular in European countries, is day care (Milne, 2009). This approach has been evaluated by several investigators. In the study by Tuffnell and associates (1992), 54 women with hypertension after 26 weeks' gestation were assigned to either day care or routine outpatient management (see Table 40-7). Progression to overt preeclampsia and labor inductions were significantly increased in the routine management group. Turnbull and coworkers (2004) enrolled 395 women who were randomly assigned to either day care or inpatient management (see Table 40-7). Almost 95 percent had mild to moderate hypertension. Of enrolled women, 288 were without proteinuria, and 86 had ≥ 1+ proteinuria. There were no perinatal deaths, and none of the women developed eclampsia or HELLP syndrome. Surprisingly, costs for either scheme were not significantly different. Perhaps not surprisingly, general satisfaction favored day care.

### Summary of Hospitalization versus Outpatient Management

From the above, either inpatient or close outpatient management is appropriate for a woman with mild de novo hypertension, including those with nonsevere preeclampsia. Most of these studies were carried out in academic centers with dedicated management teams. That said, the key to success is close follow-up and a conscientious patient with good home support.

### Antihypertensive Therapy for Mild to Moderate Hypertension

The use of antihypertensive drugs in attempts to prolong pregnancy or modify perinatal outcomes in pregnancies complicated by various types and severities of hypertensive disorders has been of...
considerable interest. Treatment for women with chronic hypertension complicating pregnancy is discussed in detail in Chapter 50 (p. 1005).

Drug treatment for early mild preeclampsia has been disappointing as shown in representative randomized trials listed in Table 40-8. Sibai and colleagues (1987a) evaluated the effectiveness of labetalol and hospitalization compared with hospitalization alone in 200 nulliparas with gestational hypertension from 26 to 35 weeks’ gestation. Although women given labetalol had significantly lower mean blood pressures, there were no differences between the groups in terms of mean pregnancy prolongation, gestational age at delivery, or birthweight. The cesarean delivery rates were similar, as were the number of infants admitted to special-care nurseries. The frequency of growth-restricted infants was doubled in women given labetalol—19 versus 9 percent. The three other studies listed in Table 40-8 were performed to compare labetalol or the calcium-channel blockers, nifedipine and isradipine, with placebo. Except for fewer episodes of severe hypertension, none of these studies showed any benefits of antihypertensive treatment. Moreover, there may have been treatment-induced adverse fetal growth (Von Dadelszen, 2002).

| Table 40-8. Randomized Placebo-Controlled Trials of Antihypertensive Therapy for Early Mild Gestational Hypertension |  |  |
Abalos and associates (2007) reviewed 46 randomized trials of active antihypertensive therapy compared with either no treatment or placebo given to women with mild to moderate gestational hypertension. Except for a halving of the risk for developing severe hypertension, active antihypertensive therapy had no beneficial effects. They further reported that fetal-growth restriction was not increased in treated women. In this vein, it is also controversial whether β-blocking agents cause fetal-growth restriction if given for chronic hypertension (August, 2014; Umans, 2014). Thus, any salutary or adverse effects of antihypertensive therapy seem minimal at most.

### Delayed Delivery

Up through the early 1990s, it was the practice that all women with severe preeclampsia were delivered without delay. During the past 25 years, however, another approach for women with preterm severe preeclampsia has been advocated. This approach calls for “conservative” or “expectant” management with the aim of improving neonatal outcome without compromising maternal safety. Aspects of such management always include careful daily—and usually more...
frequent—inpatient monitoring of the mother and her fetus.

**Expectant Management of Preterm Severe Preeclampsia**

Theoretically, antihypertensive therapy has potential application when severe preeclampsia develops before intact neonatal survival is likely. Such management is controversial, and it may be dangerous. In one of the first studies, Sibai and the Memphis group (1985) attempted to prolong pregnancy because of fetal immaturity in 60 women with severe preeclampsia between 18 and 27 weeks. The results were disastrous. *The perinatal mortality rate was 87 percent. Although no mothers died, 13 suffered placental abruption, 10 had eclampsia, three developed renal failure, two had hypertensive encephalopathy, and one each had an intracerebral hemorrhage and a ruptured hepatic hematoma.*

Because of these catastrophic outcomes, the Memphis group redefined their study criteria and performed a randomized trial of expectant versus aggressive management for 95 women who had severe preeclampsia but with more advanced gestations of 28 to 32 weeks (Sibai, 1994). *Women with HELLP syndrome were excluded from this trial.* Aggressive management included glucocorticoid administration for fetal lung maturation followed by delivery in 48 hours. Expectantly managed women were observed at bed rest and given either labetalol or nifedipine orally if there was severe hypertension. In this study, pregnancy was prolonged for a mean of 15.4 days in the expectant management group. An overall improvement in neonatal outcomes was also reported.

Following these experiences, expectant management became more commonly practiced, but with the caveat that women with HELLP syndrome or growth-restricted fetuses were usually excluded. But in a subsequent follow-up observational study, the Memphis group compared outcomes in 133 preeclamptic women with and 136 without HELLP syndrome who presentec between 24 and 36 weeks (Abramovici, 1999). Women were subdivided into three study groups. The first group included those with *complete HELLP syndrome.* The second group included women with *partial HELLP syndrome*—defined as either one or two but not all three of the defining laboratory findings. The third group included women who had severe preeclampsia without HELLP syndrome laboratory findings. Perinatal outcomes were similar in each group, and importantly, outcomes were not improved with procrastination. Despite this, the investigators concluded that women with partial HELLP syndrome and those with severe preeclampsia alone could be managed expectantly.

Sibai and Barton (2007b) reviewed expectant management of severe preeclampsia from 24 to 34 weeks. More than 1200 women were included, and although the average time gained ranged from 5 to 10 days, the maternal morbidity rates were formidable. As shown in Table 40-9, serious complications in some of these and in later studies included placental abruption, HELLP syndrome, pulmonary edema, renal failure, and eclampsia. Moreover, perinatal mortality rates averaged 90 per 1000. Fetal-growth restriction was common, and in the study from The Netherlands by Ganzevoort and associates (2005a,b), it was an astounding 94 percent. Perinatal mortality rates are disproportionately high in these growth-restricted infants, but maternal outcomes were not appreciably different from pregnancies in women without growth-restricted fetuses (Haddad, 2007; Shear, 2005).

**TABLE 40-9. Maternal and Perinatal Outcomes Reported Since 2005 with Expectant Management of Severe Preeclampsia from 24 to 34 Weeks**
The MEXPRE Latin Study was a multicenter trial that randomly assigned 267 women with severe preeclampsia at 28 to 32 weeks to prompt delivery or to expectant management (Vigil-De Gracia, 2013). The perinatal mortality rate approximated 9 percent in each group, and these investigators found no improvements in composite neonatal morbidity with expectant management. On the other hand, fetal-growth restriction—22 versus 9 percent—and placental abruption—7.6 versus 1.5 percent—were significantly higher in the group managed expectantly.

Barber and associates (2009) conducted a 10-year review of 3408 women with severe preeclampsia from 24 to 32 weeks. They found that increasing lengths of antepartum hospital stays were associated with slight but significantly increased rates of maternal and neonatal morbidity.

### Expectant Management of Midtrimester Severe Preeclampsia

Several small studies have focused on expectant management of severe preeclampsia syndrome before 28 weeks. In their review, Bombrys and coworkers (2008) found eight such studies that included nearly 200 women with severe preeclampsia with an onset < 26 completed weeks. Maternal complications were common. Because there were no neonatal survivors in women presenting before 23 weeks, the Task Force of the American College of Obstetricians and Gynecologists (2013b) recommends pregnancy termination. For women with slightly more advanced pregnancies, however, the decision is less clear. For example, at 23 weeks’ gestation, the perinatal survival rate was 18 percent, but long-term perinatal morbidity is yet unknown. For women with pregnancies at 24 to 26 weeks, perinatal survival approached 60 percent, and it averaged almost 90 percent for those at 26 weeks.

There have been at least five studies published since 2005 of women with severe midtrimester preeclampsia who were managed expectantly (Abdel-Hady, 2010; Belghiti, 2011; Bombrys, 2008;
Maternal complications developed in 60 percent, and there was one death. Perinatal mortality was 65 percent. At this time, there are no comparative studies attesting to the perinatal benefits of such expectant treatment versus early delivery in the face of serious maternal complications that approach 50 percent.

**Glucocorticoids for Lung Maturation**

In attempts to enhance fetal lung maturation, glucocorticoids have been administered to women with severe hypertension who are remote from term. Treatment does not seem to worsen maternal hypertension, and a decrease in the incidence of respiratory distress and improved fetal survival has been cited. That said, there is only one randomized trial of corticosteroids given to hypertensive women for fetal lung maturation. This trial, by Amorim and colleagues (1999), included 218 women with severe preeclampsia between 26 and 34 weeks who were randomly assigned to betamethasone or placebo administration. Neonatal complications, including respiratory distress, intraventricular hemorrhage, and death, were decreased significantly when betamethasone was given compared with placebo. *On the heavily weighted negative side, there were two maternal deaths and 18 stillbirths.* We add these findings to buttress our unenthusiastic acceptance of attempts to prolong gestation in many of these women (Alexander, 2014; Bloom, 2003).

**Corticosteroids to Ameliorate HELLP Syndrome**

Almost 30 years ago, Thiagarajah and associates (1984) suggested that glucocorticoids might aid treatment of the laboratory abnormalities associated with HELLP syndrome. Subsequently Tompkins (1999) and O’Brien (2002) and their colleagues reported less than salutary effects. Martin and coworkers (2003) reviewed observational outcomes of almost 500 such women treated at their institution and reported salutary results with treatment. Unfortunately, their subsequent randomized trial compared two corticosteroids and did not include a nontreated group (Isler, 2001).

Since these observational studies, at least two prospective randomized trials have addressed this question. Fonseca and associates (2005) randomly assigned 132 women with HELLP syndrome to either dexamethasone or placebo administration. Outcomes assessed included duration of hospitalization, recovery time of abnormal laboratory test results, resolution of clinical parameters, and complications that included acute renal failure, pulmonary edema, eclampsia, and death. None of these was significantly different between the two groups. In another randomized study, Katz and coworkers (2008) assigned 105 postpartum women with HELLP syndrome to treatment with dexamethasone or placebo. They analyzed outcomes similar to the Fonseca study and found no advantage to dexamethasone. Shown in Figure 40-16 are recovery times for platelet counts and serum aspartate aminotransferase (AST) levels. These times were almost identical in the two groups. For these reasons, the 2013 Task Force does not recommend corticosteroid treatment for thrombocytopenia with HELLP syndrome. A caveat is that in women with dangerously low platelet counts, corticosteroids *might* serve to increase platelets.
FIGURE 40-16 Recovery times for platelet counts and serum aspartate aminotransferase (AST) levels in women with HELLP syndrome assigned to receive treatment with dexamethasone or placebo. (Data from Katz, 2008.)

Expectant Management—Risks versus Benefits—Recommendations

Taken in toto, these studies do not show overwhelming benefits compared with risks for expectant management of severe preeclampsia in those with gestations from 24 to 32 weeks. The Society for Maternal-Fetal Medicine (2011) has determined that such management is a reasonable alternative in selected women with severe preeclampsia before 34 weeks. The Task Force of the American College of Obstetricians and Gynecologists (2013b) supports this recommendation. As shown in Figure 40-17, such management calls for in-hospital maternal and fetal surveillance with delivery prompted by evidence for worsening severe preeclampsia or maternal or fetal compromise. Although attempts are made for vaginal delivery in most cases, the likelihood of cesarean delivery increases with decreasing gestational age.
Our view is more conservative. Undoubtedly, the overriding reason to terminate pregnancies with severe preeclampsia is maternal safety. There are no data to suggest that expectant management is beneficial for the mother. Indeed, it seems obvious that a delay to prolong gestation...
in women with severe preeclampsia may have serious maternal consequences such as those shown in Table 40-9. Notably, placental abruption develops in up to 20 percent, and pulmonary edema in as many as 4 percent. Moreover, there are substantive risks for eclampsia, cerebrovascular hemorrhage, and especially maternal death. These observations are even more pertinent when considered with the absence of convincing evidence that perinatal outcomes are markedly improved by the average prolongation of pregnancy of about 1 week. If undertaken, the caveats that mandate delivery shown in Table 40-10 should be strictly heeded.

### Eclampsia

Preeclampsia complicated by generalized tonic-clonic convulsions appreciably increases the risk to both mother and fetus. Mattar and Sibai (2000) described outcomes in 399 consecutive women with eclampsia from 1977 through 1998. Major maternal complications included placental abruption—10 percent, neurological deficits—7 percent, aspiration pneumonia—7 percent, pulmonary edema—5 percent, cardiopulmonary arrest—4 percent, and acute renal failure—4 percent. Moreover, 1 percent of these women died.

European maternity units also report excessive maternal and perinatal morbidity and mortality rates with eclampsia. In a report from Scandinavia, Andersgaard and associates (2006) described 232 women with eclampsia. Although there was but a single maternal death, a third of the women experienced major complications that included HELLP syndrome, renal failure, pulmonary edema...
pulmonary embolism, and stroke. The United Kingdom Obstetric Surveillance System (UKOSS) audit reported by Knight (2007) described no maternal deaths in 214 eclamptic women, but five women experienced cerebral hemorrhage. In The Netherlands, there were three maternal deaths among 222 eclamptic women (Zwart, 2008). From Dublin, Akkawi and coworkers (2009) reported four maternal deaths among 247 eclamptic women (Akkawi, 2009). Data from Australia are similar (Thornton, 2013). Thus, in developed countries, the maternal mortality rate approximates 1 percent in women with eclampsia. In perspective, this is a thousand-fold increase above the overall maternal death rates for these countries.

Almost without exception—but at times unnoticed—preeclampsia precedes the onset of eclamptic convulsions. Depending on whether convulsions appear before, during, or after labor, eclampsia is designated as antepartum, intrapartum, or postpartum. Eclampsia is most common in the last trimester and becomes increasingly frequent as term approaches. In more recent years, the incidence of postpartum eclampsia has risen. This is presumably related to improved access to prenatal care, earlier detection of preeclampsia, and prophylactic use of magnesium sulfate (Chames, 2002). Importantly, other diagnoses should be considered in women with convulsions more than 48 hours postpartum or in women with focal neurological deficits, prolonged coma, or atypical eclampsia (Sibai, 2009, 2012).

**Immediate Management of Seizure**

Eclamptic seizures may be violent, and the woman must be protected, especially her airway. So forceful are the muscular movements that the woman may throw herself out of her bed, and if not protected, her tongue is bitten by the violent action of the jaws (Fig. 40-18). This phase, in which the muscles alternately contract and relax, may last approximately a minute. Gradually, the muscular movements become smaller and less frequent, and finally the woman lies motionless. After a seizure, the woman is postictal, but in some, a coma of variable duration ensues. When the convulsions are infrequent, the woman usually recovers some degree of consciousness after each attack. As the woman arouses, a semiconscious combative state may ensue. When the convulsions are infrequent, the woman usually recovers some degree of consciousness after each attack. As the woman arouses, a semiconscious combative state may ensue. In severe cases, coma persists from one convulsion to another, and death may result. In rare instances, a single convulsion may be followed by coma from which the woman may never emerge. As a rule, however, death does not occur until after frequent convulsions. Finally and also rarely, convulsions continue unabated—*status epilepticus*—and require deep sedation and even general anesthesia to obviate anoxic encephalopathy.
FIGURE 40-18 Hematoma of tongue from laceration during an eclamptic convulsion. Thrombocytopenia may have contributed to the bleeding.

Respirations after an eclamptic convulsion are usually increased in rate and may reach 50 or more per minute in response to hypercarbia, lactic acidemia, and transient hypoxia. Cyanosis may be observed in severe cases. High fever is a grave sign as it likely emanates from cerebrovascular hemorrhage.

Proteinuria is usually, but not always, present as discussed on page 730. Urine output may be diminished appreciably, and occasionally anuria develops. There may be hemoglobinuria, but hemoglobinemia is observed rarely. Often, as shown in Figure 40-19, peripheral and facial edema is pronounced, but it may also be absent.
As with severe preeclampsia, an increase in urinary output after delivery is usually an early sign of improvement. If there is renal dysfunction, serum creatinine levels should be monitored. Proteinuria and edema ordinarily disappear within a week postpartum. In most cases, blood pressure returns to normal within a few days to 2 weeks after delivery (Berks, 2009). As subsequently discussed, the longer hypertension persists postpartum and the more severe it is, the more likely it is that the woman also has chronic vascular disease (Podymow, 2010).

In antepartum eclampsia, labor may begin spontaneously shortly after convulsions ensue and may progress rapidly. If the convulsions occur during labor, contractions may increase in frequency and intensity, and the duration of labor may be shortened. Because of maternal hypoxemia and lactic acidemia caused by convulsions, it is not unusual for fetal bradycardia to follow a seizure (Fig. 40-20). Bradycardia usually recovers within 3 to 5 minutes. If it persists more than about 10 minutes, however, then another cause such as placental abruption or imminent delivery must be considered.
FIGURE 40-20 Fetal heart rate tracing shows fetal bradycardia following an intrapartum eclamptic convulsion. Bradycardia resolved and beat-to-beat variability returned approximately 5 minutes following the seizure.

Pulmonary edema may follow shortly after eclamptic convulsions or up to several hours later. This usually is caused by aspiration pneumonitis from gastric-content inhalation during vomiting that frequently accompanies convulsions. In some women, pulmonary edema may be caused by ventricular failure from increased afterload that may result from severe hypertension and further aggravated by vigorous intravenous fluid administration (Dennis, 2012b). Such pulmonary edema from ventricular failure is more common in morbidly obese women and in those with previously unappreciated chronic hypertension.

Occasionally, sudden death occurs synchronously with an eclamptic convulsion, or it follows shortly thereafter. Most often in these cases, death results from a massive cerebral hemorrhage (see Fig. 40-11). Hemiplegia may result from sublethal hemorrhage. Cerebral hemorrhages are more likely in older women with underlying chronic hypertension as discussed on page 761. Rarely, they may be due to a ruptured cerebral berry aneurysm or arteriovenous malformation (Witlin, 1997a).

In approximately 10 percent of women, some degree of blindness follows a seizure. The causes of blindness or impaired vision are discussed on page 744. Blindness with severe preeclampsia without convulsions is usually due to retinal detachment (Vigil-De Gracia, 2011). Conversely, blindness with eclampsia is almost always due to occipital lobe edema (Cunningham, 1995). In both instances, however, the prognosis for return to normal function is good and is usually complete within 1 to 2 weeks postpartum.

Up to 5 percent of women with eclampsia have substantively altered consciousness, including persistent coma, following a seizure. This is due to extensive cerebral edema, and transtentorial herniation may cause death as discussed on page 744 (Cunningham, 2000).

Rarely, eclampsia is followed by psychosis, and the woman becomes violent. This may last for several days to 2 weeks, but the prognosis for return to normal function is good, provided there
was no preexisting mental illness. It is presumed to be similar to postpartum psychosis discussed in detail in Chapter 61 (p. 1210). Antipsychotic medications have proved effective in the few cases of postecalpsia psychosis treated at Parkland Hospital.

**Differential Diagnosis**
Generally, eclampsia is more likely to be diagnosed too frequently rather than overlooked. Epilepsy, encephalitis, meningitis, brain tumor, neurocysticercosis, amnionic fluid embolism, postdural puncture cephalgia, and ruptured cerebral aneurysm during late pregnancy and the puerperium may simulate eclampsia. Until other such causes are excluded, however, all pregnant women with convulsions should be considered to have eclampsia.

**Management of Eclampsia**
It has been long recognized that magnesium sulfate is highly effective in preventing convulsions in women with preeclampsia and in stopping them in those with eclampsia. In his review, Chesley (1978) cited observational data by Pritchard and colleagues (1955, 1975) from Parkland Hospital and from his own institution, Kings County Hospital in Brooklyn. At that time, most eclampsia regimens used in the United States adhered to a similar philosophy still in use today, the tenets of which include the following:

1. Control of convulsions using an intravenously administered loading dose of magnesium sulfate that is followed by a maintenance dose, usually intravenous, of magnesium sulfate
2. Intermittent administration of an antihypertensive medication to lower blood pressure whenever it is considered dangerously high
3. Avoidance of diuretics unless there is obvious pulmonary edema, limitation of intravenous fluid administration unless fluid loss is excessive, and avoidance of hyperosmotic agents
4. Delivery of the fetus to achieve a remission of preeclampsia.

**Magnesium Sulfate to Control Convulsions**
In more severe cases of preeclampsia and in eclampsia, magnesium sulfate administered parenterally is an effective anticonvulsant that avoids producing central nervous system depression in either the mother or the infant. It may be given intravenously by continuous infusion or intramuscularly by intermittent injection (Table 40-11). The dosages for severe preeclampsia are the same as for eclampsia. Because labor and delivery is a more likely time for convulsions to develop, women with preeclampsia-eclampsia usually are given magnesium sulfate during labor and for 24 hours postpartum.

Magnesium sulfate is discontinued 24 hr after delivery

Intermittent Intramuscular Injections

Give 4 g of magnesium sulfate (MgSO$_4$·7H$_2$O USP) as a 20% solution intravenously at a rate not to exceed 1 g/min

Follow promptly with 10 g of 50% magnesium sulfate solution, one half (5 g) injected deeply in the upper outer quadrant of each buttock through a 3-inch-long 20-gauge needle. (Addition of 1.0 mL of 2% lidocaine minimizes discomfort.) If convulsions persist after 15 min, give up to 2 g more intravenously as a 20% solution at a rate not to exceed 1 g/min. If the woman is large, up to 4 g may be given slowly.

Every 4 hr thereafter, give 5 g of a 50% solution of magnesium sulfate injected deeply in the upper outer quadrant of alternate buttocks, but only after ensuring that:

- The patellar reflex is present,
- Respirations are not depressed, and
- Urine output the previous 4 hr exceeded 100 mL

Magnesium sulfate is discontinued 24 hr after delivery

Magnesium sulfate is almost universally administered intravenously. In most units, the intramuscular route has been abandoned. Of concern, magnesium sulfate solutions, although inexpensive to prepare, are not readily available in all parts of the developing world. And even when the solutions are available, the technology to infuse them may not be. Therefore, it should not be overlooked that the drug can be administered intramuscularly and that this route is as effective as intravenous administration (Salinger, 2013). In two reports from India, intramuscular regimens were nearly equivalent in preventing recurrent convulsions and maternal deaths in women with eclampsia (Chowdhury, 2009; Jana, 2013). These observations comport with earlier ones from Parkland Hospital as described by Pritchard and colleagues (1975, 1984).

Magnesium sulfate is not given to treat hypertension. Based on several studies cited subsequently and extensive clinical observations, magnesium most likely exerts a specific anticonvulsant action on the cerebral cortex. Typically, the mother stops convulsing after the initial 4-g loading dose. By an hour or two, she regains consciousness sufficiently to be oriented to place and time.

The magnesium sulfate dosages presented in Table 40-11 usually result in plasma magnesium levels illustrated in Figure 40-21. When magnesium sulfate is given to arrest eclamptic seizures, 10 to 15 percent of women will have a subsequent convolution. If so, an additional 2-g dose of magnesium sulfate in a 20-percent solution is slowly administered intravenously. In a small woman, this additional 2-g dose may be used once, but it can be given twice if needed in a larger woman. In only 5 of 245 women with eclampsia at Parkland Hospital was it necessary to use supplementary anticonvulsant medication to control convulsions (Pritchard, 1984). For these, an intravenous barbiturate is given slowly. Midazolam or lorazepam may be given in a small single dose, but prolonged use is avoided because it is associated with a higher mortality rate (Royal College of Obstetricians and Gynaecologists, 2006).
Maintenance magnesium sulfate therapy is continued for 24 hours after delivery. For eclampsia that develops postpartum, magnesium sulfate is administered for 24 hours after the onset of convulsions. Ehrenberg and Mercer (2006) studied abbreviated postpartum magnesium administration in 200 women with mild preeclampsia. Of 101 women randomized to 12-hour treatment, seven had worsening preeclampsia, and treatment was extended to 24 hours. None of these 101 women and none of the other cohort of 95 given the 24-hour magnesium infusion developed eclampsia. This abbreviated regimen needs further study before being routinely administered for severe preeclampsia or eclampsia.

**Pharmacology and Toxicology.** Magnesium sulfate USP is MgSO$_4$·7H$_2$O and not simple MgSO$_4$. It contains 8.12 mEq per 1 g. Parenterally administered magnesium is cleared almost totally by renal excretion, and magnesium intoxication is unusual when the glomerular filtration rate is normal or only slightly decreased. Adequate urine output usually correlates with preserved glomerular filtration rates. That said, magnesium excretion is not urine flow dependent, and urinary volume per unit time does not, per se, predict renal function. Thus, serum creatinine levels must be measured to detect a decreased glomerular filtration rate.

Eclamptic convulsions are almost always prevented or arrested by plasma magnesium levels maintained at 4 to 7 mEq/L, 4.8 to 8.4 mg/dL, or 2.0 to 3.5 mmol/L. Although laboratories...
typically report total magnesium levels, free or ionized magnesium is the active moiety for suppressing neuronal excitability. Taber and associates (2002) found poor correlation between total and ionized levels. Further studies are necessary to determine if either measurement provides a superior method for surveillance.

After a 4-g intravenous loading dose in nonobese women, magnesium levels observed with the intramuscular regimen and those observed with the maintenance infusion of 2 g/hr are similar (see Fig. 40-21). The obesity epidemic has affected these observations. Tudela and colleagues (2013) reported our observations from Parkland Hospital with magnesium administration to obese women. More than 60 percent of women whose body mass index (BMI) exceeded 30 kg/m² and who were receiving the 2-g/hr dose had subtherapeutic levels at 4 hours. Thus, 40 percent of obese women would require 3 g/hr to maintain effective plasma levels. That said, currently most do not recommend routine magnesium level measurements (American College of Obstetricians and Gynecologists, 2013b; Royal College of Obstetricians and Gynaecologists, 2006).

Patellar reflexes disappear when the plasma magnesium level reaches 10 mEq/L—about 12 mg/dL—presumably because of a curariform action. This sign serves to warn of impending magnesium toxicity. When plasma levels rise above 10 mEq/L, breathing becomes weakened. At 12 mEq/L or higher levels, respiratory paralysis and respiratory arrest follow. Somjen and coworkers (1966) induced marked hypermagnesemia in themselves by intravenous infusion and achieved plasma levels up to 15 mEq/L. Predictably, at such high plasma levels, respiratory depression developed that necessitated mechanical ventilation, but depression of the sensorium was not dramatic as long as hypoxia was prevented.
Treatment with calcium gluconate or calcium chloride, 1 g intravenously, along with withholding further magnesium sulfate, usually reverses mild to moderate respiratory depression. One of these agents should be readily available whenever magnesium is being infused. Unfortunately, the effects of intravenously administered calcium may be short-lived if there is a steady-state toxic level. For severe respiratory depression and arrest, prompt tracheal intubation and mechanical ventilation are lifesaving. Direct toxic effects on the myocardium from high levels of magnesium are uncommon. It appears that cardiac dysfunction associated with magnesium is due to respiratory arrest and hypoxia. With appropriate ventilation, cardiac action is satisfactory even when plasma magnesium levels are exceedingly high (McCubbin, 1981; Morisaki, 2000).

Because magnesium is cleared almost exclusively by renal excretion, the dosages described will become excessive if glomerular filtration is substantially decreased. The initial 4-g loading dose of magnesium sulfate can be safely administered regardless of renal function. It is important to administer the standard loading dose and not to reduce it under the mistaken conception that diminished renal function requires it. This is because after distribution, a loading dose achieves the desired therapeutic level, and the infusion maintains the steady-state level. Thus, only the maintenance infusion rate should be altered with diminished glomerular filtration rate. Renal function is estimated by measuring plasma creatinine. Whenever plasma creatinine levels are > 1.0 mg/mL, serum magnesium levels are measured to guide the infusion rate. With severe renal dysfunction, only the loading dose of magnesium sulfate is required to produce a steady-state therapeutic level.

Acute cardiovascular effects of parenteral magnesium in women with severe preeclampsia have been studied using data obtained by pulmonary and radial artery catheterization. After a 4-g intravenous dose administered over 15 minutes, mean arterial pressure fell slightly, accompanied by a 13-percent increase in cardiac index (Cotton, 1986b). Thus, magnesium decreased systemic vascular resistance and mean arterial pressure. At the same time, it increased cardiac output without evidence of myocardial depression. These findings were coincidental with transient nausea and flushing, and the cardiovascular effects persisted for only 15 minutes despite continued magnesium infusion.

Thurnau and associates (1987) showed that there was a small but highly significant increase in total magnesium concentration in the cerebrospinal fluid with magnesium therapy. The magnitude of the increase was directly proportional to the corresponding serum concentration.

Magnesium is anticonvulsant and neuroprotective in several animal models. Some proposed mechanisms of action include: (1) reduced presynaptic release of the neurotransmitter glutamate, (2) blockade of glutamatergic N-methyl-D-aspartate (NMDA) receptors, (3) potentiation of adenosine action, (4) improved calcium buffering by mitochondria, and (5) blockage of calcium entry via voltage-gated channels (Arango, 2006; Wang, 2012a).

Uterine Effects. Relatively high serum magnesium concentrations depress myometrial contractility both in vivo and in vitro. With the regimen described and the plasma levels that result, no evidence of myometrial depression has been observed beyond a transient decrease in activity during and immediately after the initial intravenous loading dose. Leveno and associates (1998) compared outcomes in 480 nulliparous women given phenytoin for preeclampsia with outcomes in 425 preeclamptic women given magnesium sulfate. Magnesium did not significantly alter the need for oxytocin stimulation of labor, admission-to-delivery intervals, or route of delivery. Similar results have been reported by others (Atkinson, 1995; Szal, 1999; Witlin, 1997b).

The mechanisms by which magnesium might inhibit uterine contractility are not established. It is generally assumed, however, that these depend on its effects on intracellular calcium as discussed.
In detail in Chapter 21 (p. 417). Inhibition of uterine contractility is magnesium dose dependent, and serum levels of at least 8 to 10 mEq/L are necessary to inhibit uterine contractions (Watt-Morse, 1995). This likely explains why there are few if any uterine effects seen clinically when magnesium sulfate is given for preeclampsia. And as discussed in Chapter 42 (p. 852), magnesium is also not considered to be an effective tocolytic agent.

**Fetal and Neonatal Effects.** Magnesium administered parenterally promptly crosses the placenta to achieve equilibrium in fetal serum and less so in amniotic fluid (Hallak, 1993). Levels in amniotic fluid increase with duration of maternal infusion (Gortzak-Uzen, 2005). Current evidence supports the view that magnesium sulfate has small but significant effects on the fetal heart rate pattern—specifically beat-to-beat variability. Hallak and coworkers (1999) compared an infusion of magnesium sulfate with a saline infusion. These investigators reported that magnesium was associated with a small and clinically insignificant decrease in variability. Similarly, in a retrospective study, Duffy and associates (2012) reported a lower heart rate baseline that was within the normal range; decreased variability; and fewer prolonged decelerations. They noted no adverse outcomes.

Overall, maternal magnesium therapy appears safe for perinates. For example, a recent MFMI Network study of more than 1500 exposed preterm neonates found no association between the need for neonatal resuscitation and cord blood magnesium levels (Johnson, 2012). Still, there are a few neonatal adverse events associated with its use. In a Parkland Hospital study of 6654 mostly term exposed newborns, 6 percent had hypotonia (Abbassi-Ghanavati, 2012). In addition, exposed neonates had lower 1- and 5-minute Apgar scores, a higher intubation rate, and more admissions to the special care nursery. The study showed that neonatal depression occurs only if there is severe hypermagnesemia at delivery.

Observational studies have suggested a protective effect of magnesium against the development of cerebral palsy in very-low-birthweight infants (Nelson, 1995; Schendel, 1996). At least five randomized trials have also assessed neuroprotective effects in preterm newborns. These findings are discussed in detail in Chapter 42 (p. 854). Nguyen and colleagues (2013) expanded this possibility to include term newborn neuroprotection. They performed a Cochrane Database review to compare term neonatal outcomes with and without exposure to peripartum magnesium therapy and reported that there were insufficient data to draw conclusions.

Finally, as discussed in Chapter 42 (p. 852), long-term use of magnesium, given for several days for tocolysis, has been associated with neonatal osteopenia (American College of Obstetricians and Gynecologists, 2013c).

**Maternal Safety and Efficacy of Magnesium Sulfate.** The multinational Eclampsia Trial Collaborative Group study (1995) involved 1687 women with eclampsia randomly allocated to different anticonvulsant regimens. In one cohort, 453 women were randomly assigned to be given magnesium sulfate and compared with 452 given diazepam. In a second cohort, 388 eclamptic women were randomly assigned to be given magnesium sulfate and compared with 387 women given phenytoin. The results of these and other comparative studies that each enrolled at least 50 women are summarized in **Table 40-12.** In aggregate, magnesium sulfate therapy was associated with a significantly lower incidence of recurrent seizures compared with women given an alternative anticonvulsant—9.7 versus 23 percent. Importantly, the maternal death rate of 3.1 percent with magnesium sulfate was significantly lower than that of 4.9 percent for the other regimens.

Data adapted from Alexander, 2014.

Magnesium safety and toxicity was recently reviewed by Smith and coworkers (2013). In more than 9500 treated women, the overall rate of absent patellar tendon reflexes was 1.6 percent; respiratory depression 1.3 percent; and calcium gluconate administration 0.2 percent. They reported only one maternal death due to magnesium toxicity. Our anecdotal experiences are similar—in the estimated 50 years of its use in more than 40,000 women, there has been only one maternal death from an overdose (Pritchard, 1984).

Management of Severe Hypertension

Dangerous hypertension can cause cerebrovascular hemorrhage and hypertensive encephalopathy, and it can trigger eclamptic convulsions in women with preeclampsia. Other complications include hypertensive afterload congestive heart failure and placental abruption (Clark, 2012).

Because of these sequelae, the National High Blood Pressure Education Program Working Group (2000) and the 2013 Task Force recommend treatment to lower systolic pressures to or below 160 mm Hg and diastolic pressures to or below 110 mm Hg. Martin and associates (2005) reported provocative observations that highlight the importance of treating systolic hypertension. They described 28 selected women with severe preeclampsia who suffered an associated stroke. Most of these were hemorrhagic strokes—93 percent—and all women had systolic pressures > 160 mm Hg before suffering their stroke. By contrast, only 20 percent of these same women had diastolic pressures > 110 mm Hg. It seems likely that at least half of serious hemorrhagic strokes associated with preeclampsia are in women with chronic hypertension (Cunningham, 2005). Long-standing hypertension results in development of Charcot-Bouchard aneurysms in the deep penetrating arteries of the lenticulostriate branch of the middle cerebral arteries. These vessels supply the basal ganglia, putamen, thalamus, and adjacent deep white matter, as well as the pons and deep cerebellum. These unique aneurysmal weakenings predispose these small arteries to
rupture during sudden hypertensive episodes (Chap. 50, p. 1007).

Antihypertensive Agents
Several drugs are available to rapidly lower dangerously elevated blood pressure in women with the gestational hypertensive disorders. The three most commonly employed are hydralazine, labetalol, and nifedipine. For years, parenteral hydralazine was the only one of these three available. But when parenteral labetalol was later introduced, it was considered to be equally effective for obstetrical use. Orally administered nifedipine has since then gained some popularity as first-line treatment for severe gestational hypertension.

Hydralazine
This is probably still the most commonly used antihypertensive agent in the United States for treatment of women with severe gestational hypertension. Hydralazine is administered intravenously with a 5-mg initial dose, and this is followed by 5- to 10-mg doses at 15- to 20-minute intervals until a satisfactory response is achieved (American College of Obstetricians and Gynecologists, 2012b). Some limit the total dose to 30 mg per treatment cycle (Sibai, 2003). The target response antepartum or intrapartum is a decrease in diastolic blood pressure to 90 to 110 mm Hg. Lower diastolic pressures risk compromised placental perfusion. Hydralazine has proven remarkably effective to prevent cerebral hemorrhage. Its onset of action can be as rapid as 10 minutes. Although repeated administration every 15 to 20 minutes may theoretically lead to undesirable hypotension, this has not been our experience when given in these 5- to 10-mg increments.

At Parkland Hospital, between 5 and 10 percent of all women with intrapartum hypertensive disorders are given a parenteral antihypertensive agent. Most often, we use hydralazine as described. We do not limit the total dose, and seldom has a second antihypertensive agent been needed. We estimate that nearly 6000 women have been so treated at Parkland during the past 50 years. Although less popular in Europe, hydralazine is used in some centers, according to the Royal College of Obstetricians and Gynaecologists (2006). A dissenting opinion for first-line intrapartum use of hydralazine was voiced by the Vancouver group after a systematic review (Magee, 2009). At the same time, however, Umans and coworkers (2014) concluded that objective outcome data did not support the use of one drug over another.

As with any antihypertensive agent, the tendency to give a larger initial dose of hydralazine if the blood pressure is higher must be avoided. The response to even 5- to 10-mg doses cannot be predicted by hypertension severity. Thus, our protocol is to always administer 5 mg as the initial dose. An adverse response to exceeding this initial dose is shown in Figure 40-22. This woman had chronic hypertension complicated by severe superimposed preeclampsia, and hydralazine was injected more frequently than recommended. Her blood pressure decreased in less than 1 hour from 240–270/130–150 mm Hg to 110/80 mm Hg, and fetal heart rate decelerations characteristic of uteroplacental insufficiency became evident. Decelerations persisted until her blood pressure was increased with rapid crystalloid infusion. In some cases, this fetal response to diminished uterine perfusion may be confused with placental abruption and may result in unnecessary and potentially dangerous emergent cesarean delivery.
Hydralazine was given at 5-minute intervals instead of 15-minute intervals. The mean arterial pressure decreased from 180 to 90 mm Hg within 1 hour and was associated with fetal bradycardia. Rapid crystalloid infusion raised the mean pressure to 115 mm Hg, and the fetus recovered.

**Labetalol**

This effective intravenous antihypertensive agent is an $\alpha_1$- and nonselective $\beta$-blocker. Some prefer its use over hydralazine because of fewer side effects (Sibai, 2003). At Parkland Hospital, we give 10 mg intravenously initially. If the blood pressure has not decreased to the desirable level in 10 minutes, then 20 mg is given. The next 10-minute incremental dose is 40 mg and is followed by another 40 mg if needed. If a salutary response is not achieved, then an 80-mg dose is given. Sibai (2003) recommends 20 to 40 mg every 10 to 15 minutes as needed and a maximum dose of 220 mg per treatment cycle. The American College of Obstetricians and Gynecologists (2012b) recommends starting with a 20-mg intravenous bolus. If not effective within 10 minutes, this is followed by 40 mg, then 80 mg every 10 minutes. Administration should not exceed a 220-mg total dose per treatment cycle.

**Hydralazine versus Labetalol**

Comparative studies of these two antihypertensive agents show equivalent results (Umans, 2014). In an older trial, Mabie and colleagues (1987) compared intravenous hydralazine with labetalol for blood pressure control in 60 peripartum women. Labetalol lowered blood pressure more rapidly, and associated tachycardia was minimal. However, hydralazine lowered mean arterial pressures to safe levels more effectively. In a later trial, Vigil-De Gracia and associates (2007) randomly assigned 200 severely hypertensive women intrapartum to be given either: (1) intravenous hydralazine—5 mg, which could be given every 20 minutes and repeated to a maximum of five doses, or (2) intravenous labetalol—20 mg initially, followed by 40 mg in 20 minutes and then 80 mg every 20 minutes if needed up to a maximum 300-mg dose. Maternal and neonatal outcomes were similar. Hydralazine caused significantly more maternal tachycardia and palpitations, whereas labetalol more frequently caused maternal hypotension and bradycardia.
Both drugs have been associated with a reduced frequency of fetal heart rate accelerations (Cahill, 2013).

**Nifedipine**

This calcium-channel blocking agent has become popular because of its efficacy for control of acute pregnancy-related hypertension. The NHBPEP Working Group (2000) and the Royal College of Obstetricians and Gynaecologists (2006) recommend a 10-mg initial oral dose to be repeated in 30 minutes if necessary. *Nifedipine given sublingually is no longer recommended*. Randomized trials that compared nifedipine with labetalol found neither drug definitively superior to the other. However, nifedipine lowered blood pressure more quickly (Scardo, 1999; Shekhar, 2013; Vermillion, 1999).

**Other Antihypertensive Agents**

A few other generally available antihypertensive agents have been tested in clinical trials but are not widely used (Umans, 2014). Belfort and associates (1990) administered the calcium antagonist *verapamil* by intravenous infusion at 5 to 10 mg per hour. Mean arterial pressure was lowered by 20 percent. Belfort and coworkers (1996, 2003) reported that *nimodipine* given either by continuous infusion or orally was effective to lower blood pressure in women with severe preeclampsia. Bolte and colleagues (1998, 2001) reported good results in preeclamptic women given intravenous *ketanserin*, a selective serotonergic (5HT$_{2A}$) receptor blocker. *Nitroprusside* or *nitroglycerine* is recommended by some if there is not optimal response to first-line agents. With these latter two agents, fetal cyanide toxicity may develop after 4 hours. We have not had the need for either due to our consistent success with first-line treatment using hydralazine, labetalol, or a combination of the two given in succession, but never simultaneously.

There are experimental antihypertensive drugs that may become useful for preeclampsia treatment. One is *calcitonin gene related peptide (CGRP)*, a 37-amino acid potent vasodilator. Another is *antidigoxin antibody Fab (DIF)* directed against endogenous digitalis-like factors, also called *cardiotonic steroids* (Bagrov, 2008; Lam, 2013).

**Diuretics**

Potent loop diuretics can further compromise placental perfusion. Immediate effects include depletion of intravascular volume, which most often is already reduced compared with that of normal pregnancy (p. 737). Therefore, before delivery, diuretics are not used to lower blood pressure (Zeeman, 2009; Zondervan, 1988). We limit *antepartum* use of furosemide or similar drugs solely to treatment of pulmonary edema.

**Fluid Therapy**

Lactated Ringer solution is administered routinely at the rate of 60 mL to no more than 125 mL per hour unless there is unusual fluid loss from vomiting, diarrhea, or diaphoresis, or, more likely, excessive blood loss with delivery. Oliguria is common with severe preeclampsia. Thus, coupled with the knowledge that maternal blood volume is likely constricted compared with that of normal pregnancy, it is tempting to administer intravenous fluids more vigorously. But controlled, conservative fluid administration is preferred for the typical woman with severe preeclampsia who already has excessive extracellular fluid that is inappropriately distributed between intravascular and extravascular spaces. As discussed on page 737, infusion of large fluid volumes enhances the maldistribution of extravascular fluid and thereby appreciably increases the risk of
For labor analgesia with neuraxial analgesia, crystalloid solutions are infused slowly in graded amounts (Chap. 25, p. 516).

**Pulmonary Edema**

Women with severe preeclampsia-eclampsia who develop pulmonary edema most often do so postpartum (Cunningham, 1986, 2012; Zinaman, 1985). With pulmonary edema in the eclamptic woman, aspiration of gastric contents, which may be the result of convulsions, anesthesia, or oversedation, should be excluded. As discussed in Chapter 47 (p. 942), there are three common causes of pulmonary edema in women with severe preeclampsia syndrome—pulmonary capillary permeability edema, cardiogenic edema, or a combination of the two.

Some women with severe preeclampsia—especially if given vigorous fluid replacement—will have mild pulmonary congestion from permeability edema (see Fig. 40-6). This is caused by normal pregnancy changes magnified by the preeclampsia syndrome as discussed in Chapter 4 (p. 58). Importantly, plasma oncotic pressure decreases appreciably in normal term pregnancy because of decreased serum albumin concentration, and oncotic pressure falls even more with preeclampsia (Zinaman, 1985). And both increased extravascular fluid oncotic pressure and increased capillary permeability have been described in women with preeclampsia (Brown, 1989; Øian, 1986).

**Invasive Hemodynamic Monitoring**

Knowledge concerning cardiovascular and hemodynamic pathophysiological alterations associated with severe preeclampsia-eclampsia has accrued from studies done using invasive monitoring and a flow-directed pulmonary artery catheter (see Figs. 40-5 and 40-6). Clark and Dildy (2010) have reviewed such monitoring in obstetrics. Two conditions frequently cited as indications are preeclampsia associated with either oliguria or pulmonary edema. Somewhat ironically, it is usually vigorous treatment of the former that results in most cases of the latter. The American College of Obstetricians and Gynecologists (2013a) recommends against routine invasive monitoring. The College notes that such monitoring should be reserved for severely preeclamptic women with accompanying severe cardiac disease, renal disease, or both or in cases of refractory hypertension, oliguria, and pulmonary edema. An alternative noninvasive hemodynamic monitoring strategy has been evaluated in preliminary studies (Moroz, 2013).

**Plasma Volume Expansion**

Because the preeclampsia syndrome is associated with hemoconcentration, attempts to expand blood volume seem intuitively reasonable (Ganzevoort, 2004). This has led some to infuse various fluids, starch polymers, albumin concentrates, or combinations thereof to expand blood volume. There are, however, older observational studies that describe serious complications—especially pulmonary edema—with volume expansion (Benedetti, 1985; López-Llera, 1982; Sibai, 1987b). In general, these studies were not controlled or even comparative (Habek, 2006).

The Amsterdam randomized study reported by Ganzevoort and coworkers (2005a,b) was a well-designed investigation done to evaluate volume expansion. A total of 216 women with severe preeclampsia were enrolled between 24 and 34 weeks’ gestation. The study included women whose preeclampsia was complicated by HELLP syndrome, eclampsia, or fetal-growth restriction. All women were given magnesium sulfate to prevent eclampsia, betamethasone to promote fetal pulmonary maturity, ketanserine to control dangerous hypertension, and normal saline infusions.
restricted only to deliver medications. In the group randomly assigned to volume expansion, each woman was given 250 mL of 6-percent hydroxyethyl starch infused over 4 hours twice daily. Their maternal and perinatal outcomes were compared with a control group and are shown in Table 40-13. None of these outcomes was significantly different between the two groups. Importantly, serious maternal morbidity and a substantive perinatal mortality rate accompanied their “expectant” management (see Table 40-9).

**Neuroprophylaxis—Prevention of Seizures**

There have been several randomized trials designed to test the efficacy of seizure prophylaxis for women with gestational hypertension, with or without proteinuria. In most of these, magnesium sulfate was compared with another anticonvulsant or with a placebo. In all studies, magnesium sulfate was reported to be superior to the comparator agent to prevent eclampsia. Four of the
larger studies are summarized in Table 40-14. In the study from Parkland Hospital, Lucas and colleagues (1995) reported that magnesium sulfate therapy was superior to phenytoin to prevent eclamptic seizures in women with gestational hypertension and preeclampsia. Belfort and coworkers (2003) compared magnesium sulfate and nimodipine—a calcium-channel blocker with specific cerebral vasodilator activity—for eclampsia prevention. In this unblinded randomized trial involving 1650 women with severe preeclampsia, the rate of eclampsia was more than threefold higher for women allocated to the nimodipine group—2.6 versus 0.8 percent.

<sup>a</sup>All comparisons significant $p < 0.05$.

<sup>b</sup>Included women with and without proteinuria and those with all severities of preeclampsia.

<sup>c</sup>Magpie Trial Collaboration Group, 2002.

The largest comparative study was the entitled \textit{MA}G\text{nessium} \textit{Sulfate for Prevention o}f \textit{E}clampsia and reported by the Magpie Trial Collaboration Group (2002). More than 10,000 women with severe preeclampsia from 33 countries were randomly allocated to treatment with magnesium sulfate or placebo. Women given magnesium had a 58-percent significantly lower risk of eclampsia than those given placebo. Smyth and associates (2009) provided follow-up data of infants born to these mothers given magnesium sulfate. At approximately 18 months, child behavior did not differ in those exposed compared with those not exposed to magnesium sulfate.

**Who Should Be Given Magnesium Sulfate?**
Magnesium will prevent proportionately more seizures in women with correspondingly worse disease. As previously discussed, however, severity is difficult to quantify, and thus it is difficult
to decide which individual woman might benefit most from neuroprophylaxis. The 2013 Task Force recommends that women with either eclampsia or severe preeclampsia should be given magnesium sulfate prophylaxis. Again, criteria that establish “severity” are not totally uniform (see Table 40-2). At the same time, however, the 2013 Task Force suggests that all women with “mild” preeclampsia do not need magnesium sulfate neuroprophylaxis. The conundrum is whether or not to give neuroprophylaxis to any of these women with “nonsevere” gestational hypertension or preeclampsia (Alexander, 2006).

In many other countries, and principally following dissemination of the Magpie Trial Collaboration Group (2002) study results, magnesium sulfate is now recommended for women with severe preeclampsia. In some, however, debate continues concerning whether therapy should be reserved for women who have an eclamptic seizure. We are of the opinion that eclamptic seizures are dangerous for reasons discussed on page 742. Maternal mortality rates of up to 5 percent have been reported even in recent studies (Andersgaard, 2006; Benhamou, 2009; Moodley, 2010; Schutte, 2008; Zwart, 2008). Moreover, there are substantially increased perinatal mortality rates in both industrialized countries and underdeveloped ones (Abd El Aal, 2012; Knight, 2007; Ndaboine, 2012; Schutte, 2008; von Dadelszen, 2012). Finally, the possibility of adverse long-term neuropsychological and vision-related sequelae of eclampsia described by Aukes (2009, 2012), Postma (2009), Wiegman (2012), and their coworkers, which are discussed on page 770, have raised additional concerns that eclamptic seizures are not “benign.”

Selective versus Universal Magnesium Sulfate Prophylaxis

There is uncertainty around which women with nonsevere gestational hypertension should be given magnesium sulfate neuroprophylaxis. An opportunity to address these questions was afforded by a change in our prophylaxis protocol for women delivering at Parkland Hospital. Before this time, Lucas and associates (1995) had found that the risk of eclampsia without magnesium prophylaxis was approximately 1 in 100 for women with mild preeclampsia. Up until 2000, all women with gestational hypertension were given magnesium prophylaxis intramuscularly as first described by Pritchard in 1955. After 2000, we instituted a standardized protocol for intravenously administered magnesium sulfate (Alexander, 2006). At the same time, we also changed our practice of universal seizure prophylaxis for all women with gestational hypertension to one of selective prophylaxis given only to women who met our criteria for severe gestational hypertension. These criteria, shown in Table 40-15, included women with ≥ 2+ proteinuria measured by dipstick in a catheterized urine specimen.

<table>
<thead>

</tbody>
</table>
Persistent midepigastric or right-upper quadrant pain

BP = blood pressure.

Following this protocol change, 60 percent of 6518 women with gestational hypertension during a 4½-year period were given magnesium sulfate neuroprophylaxis (Table 40-16). The remaining 40 percent with nonsevere hypertension were not treated, and of these, 27 women developed eclamptic seizures—1 in 92. The seizure rate was only 1 in 358 for 3935 women with criteria for severe disease who were given magnesium sulfate, and thus these cases were treatment failures. To assess morbidity, outcomes in 87 eclamptic women were compared with outcomes in all 6431 noneclamptic hypertensive women. Although most maternal outcomes were similar, almost a fourth of women with eclampsia who underwent emergent cesarean delivery required general anesthesia. This is a great concern because eclamptic women have laryngotracheal edema and are at a higher risk for failed intubation, gastric acid aspiration, and death (American College of Obstetricians and Gynecologists, 2013d). Neonatal outcomes were also a concern because the composite morbidity defined in Table 40-16 was significantly increased tenfold in eclamptic compared with noneclamptic women—12 versus 1 percent, respectively.

Gest. HTN = gestational hypertension.
Data from Alexander, 2006.

Thus, if one uses the Parkland criteria for nonsevere gestational hypertension, about 1 of 100...
such women who are not given magnesium sulfate prophylaxis can be expected to have an eclamptic seizure. A fourth of these women likely will require emergent cesarean delivery with attendant maternal and perinatal morbidity and mortality from general anesthesia. From this, the major question regarding management of nonsevere gestational hypertension remains—whether it is acceptable to avoid unnecessary treatment of 99 women to risk eclampsia in one? The answer appears to be yes as suggested by the 2013 Task Force.

**Delivery**

To avoid maternal risks from cesarean delivery, steps to effect vaginal delivery are used initially in women with eclampsia. Following a seizure, labor often ensues spontaneously or can be induced successfully even in women remote from term (Alanis, 2008). An immediate cure does not promptly follow delivery by any route, but serious morbidity is less common during the puerperium in women delivered vaginally.

**Blood Loss at Delivery**

Hemoconcentration or lack of normal pregnancy-induced hypervolemia is an almost predictable feature of severe preeclampsia-eclampsia as quantified by Zeeman and associates (2009) and shown in Figure 40-7. These women, who consequently lack normal pregnancy hypervolemia, are much less tolerant of even normal blood loss than are normotensive pregnant women. It is of great importance to recognize that an appreciable fall in blood pressure soon after delivery most often means excessive blood loss and not sudden resolution of vasospasm and endothelial damage. When oliguria follows delivery, the hematocrit should be evaluated frequently to help detect excessive blood loss. If identified, hemorrhage should be treated appropriately by careful crystalloid and blood transfusion.

**Analgesia and Anesthesia**

During the past 20 years, the use of conduction analgesia for women with preeclampsia syndrome has proven ideal. Initial problems with this method included hypotension and diminished uterine perfusion caused by sympathetic blockade in these women with attenuated hypervolemia. But pulmonary edema was mitigated by techniques that used slow induction of epidural analgesia with dilute solutions of anesthetic agents to counter the need for rapid infusion of large volumes of crystalloid or colloid to correct maternal hypotension (Hogg, 1999; Wallace, 1995). Moreover, epidural blockade avoids general anesthesia, in which the stimulation of tracheal intubation may cause sudden severe hypertension. Such blood pressure increases, in turn, can cause pulmonary edema, cerebral edema, or intracranial hemorrhage. Finally, tracheal intubation may be particularly difficult and thus hazardous in women with airway edema due to preeclampsia (American College of Obstetricians and Gynecologists, 2013d).

At least three randomized studies have been performed to evaluate these methods of analgesia and anesthesia. Wallace and colleagues (1995) studied 80 women at Parkland Hospital with severe preeclampsia who were to undergo cesarean delivery. They had not been given labor epidural analgesia and were randomized to receive general anesthesia, epidural analgesia, or combined spinal-epidural analgesia. Their average preoperative blood pressures approximated 170/110 mm Hg, and all had proteinuria. Anesthetic and obstetrical management included antihypertensive drug therapy and limited intravenous fluids as previously described. Perinatal outcomes in each group were similar. Maternal hypotension resulting from regional analgesia was managed with judicious intravenous fluid administration. In women undergoing general anesthesia,
maternal blood pressure was managed to avoid severe hypertension (Fig. 40-23). There were no serious maternal or fetal complications attributable to any of the three anesthetic methods. It was concluded that all three are acceptable for use in women with pregnancies complicated by severe preeclampsia if steps are taken to ensure a careful approach to the selected method.

**FIGURE 40-23** Blood pressure effects of general anesthesia versus epidural or spinal–epidural analgesia for cesarean delivery in 80 women with severe preeclampsia. MAP = mean arterial pressure. Time posts (T): OR = operating room; IN = induction of anesthesia; T = tracheal intubation; IN5 = induction + 5 min; IN10 = induction + 10 min; IN20 = induction + 20 min; SKI = skin incision; D = delivery; SKC = skin closure; O = extubation. (From Wallace, 1995, with permission.)

Another randomized study included 70 women with severe preeclampsia receiving spinal analgesia versus general anesthesia (Dyer, 2003). All had a nonreassuring fetal heart rate tracing as the indication for cesarean delivery, and outcomes were equivalent. Dyer and coworkers (2008) later showed that decreased mean arterial blood pressure induced by epidural blockade could be effectively counteracted by phenylephrine infusion to maintain cardiac output.

In a study from the University of Alabama at Birmingham, Head and colleagues (2002) randomly assigned 116 women with severe preeclampsia to receive either epidural or patient-controlled intravenous meperidine analgesia during labor. A standardized protocol limited intravenous fluids to 100 mL/hr. More women—9 percent—from the group assigned to epidural analgesia required ephedrine for hypotension. As expected, pain relief was superior in the epidural group, but maternal and neonatal complications were similar between groups. One woman in each group developed pulmonary edema.

It is important to emphasize that epidural analgesia is not to be considered treatment of preeclampsia. Lucas and associates (2001) studied 738 laboring women at Parkland Hospital who were 36 weeks or more and who had gestational hypertension of varying severity. Patients were randomly assigned to receive either epidural analgesia or patient-controlled intravenous meperidine analgesia. Maternal and neonatal outcomes were similar in the two study groups. However, as shown in Table 40-17, epidural analgesia resulted in a greater decrement of mean
maternal arterial pressure compared with meperidine, but it was not superior in preventing recurrent severe hypertension later in labor.

Data from Lucas, 2001.

For these reasons, judicious fluid administration is essential in severely preeclamptic women who receive regional analgesia. Newsome and coworkers (1986) showed that vigorous crystalloid infusion with epidural blockade in women with severe preeclampsia caused elevation of pulmonary capillary wedge pressures (see Fig. 40-6). Aggressive volume replacement in these women increases their risk for pulmonary edema, especially in the first 72 hours postpartum (Clark, 1985; Cotton, 1986a). When pulmonary edema develops, there is also concern for development of cerebral edema. Finally, Heller and associates (1983) demonstrated that most cases of pharyngolaryngeal edema were related to aggressive volume therapy.

Persistent Severe Postpartum Hypertension

The potential problem of antihypertensive agents causing serious compromise of uteroplacental perfusion and thus of fetal well-being is obviated by delivery. Postpartum, if difficulty arises in controlling severe hypertension or if intravenous hydralazine or labetalol are being used repeatedly, then oral regimens can be given. Examples include labetalol or another β-blocker, nifedipine or another calcium-channel blocker, and possible addition of a thiazide diuretic. Persistent or refractory hypertension is likely due to mobilization of pathological interstitial fluid and redistribution into the intravenous compartment, underlying chronic hypertension, or usually both (Sibai, 2012; Tan, 2002). In women with chronic hypertension and left-ventricular hypertrophy, severe postpartum hypertension can cause pulmonary edema from cardiac failure (Cunningham, 1986, 2012; Sibai, 1987a).

Furosemide

Because persistence of severe hypertension corresponds to the onset and length of diuresis and extracellular fluid mobilization, it seems logical that furosemide-augmented diuresis might serve to hasten blood pressure control. To study this, Ascarelli and coworkers (2005) designed a randomized trial that included 264 postpartum preeclamptic women. After onset of spontaneous
diuresis, patients were assigned to 20-mg oral furosemide given daily or no therapy. Women with mild disease had similar blood pressure control regardless of whether they received treatment or placebo. However, women with severe preeclampsia who were treated, compared with those receiving placebo, had a lower mean systolic blood pressure at 2 days—142 versus 153 mm Hg. They also required less frequently administered antihypertensive therapy during the remainder of hospitalization—14 versus 26 percent, respectively.

We have used a simple method to estimate excessive extracellular/interstitial fluid. The postpartum weight is compared with the most recent prenatal weight, either from the last clinic visit or on admission for delivery. On average, soon after delivery, maternal weight should be reduced by at least 10 to 15 pounds depending on infant and placental weight, amnionic fluid volume, and blood loss. Because of various interventions, especially intravenous crystalloid infusions given during operative vaginal or cesarean delivery, women with severe preeclampsia often have an immediate postpartum weight in excess of their last prenatal weight. If this weight increase is associated with severe persistent postpartum hypertension, then diuresis with intravenous furosemide is usually helpful in controlling blood pressure.

**Plasma Exchange**

Martin and colleagues (1995) have described an atypical syndrome in which severe preeclampsia-eclampsia persists despite delivery. These investigators described 18 such women whom they encountered during a 10-year period. They advocate single or multiple plasma exchange for these women. In some cases, 3 L of plasma was exchanged three times—a 36- to 45-donor unit exposure for each patient—before a response was forthcoming. Others have described plasma exchange performed in postpartum women with HELLP syndrome ( Förster, 2002; Obeidat, 2002). In all these cases, however, the distinction between HELLP syndrome and thrombotic thrombocytopenic purpura or hemolytic uremic syndrome was not clear. As further discussed in Chapter 56 (p. 1116), in our experiences with more than 50,000 women with gestational hypertension among nearly 450,000 pregnancies cared for at Parkland Hospital through 2012, we have encountered very few women with persistent postpartum hypertension, thrombocytopenia, and renal dysfunction who were diagnosed as having a thrombotic microangiopathy (Dashe, 1998). These latter syndromes complicating pregnancy were reviewed by Martin (2008) and George (2013) and their colleagues, who conclude that a rapid diagnostic test for ADAMTS-13 enzyme activity might be helpful to differentiate most of these syndromes.

**Reversible Cerebral Vasoconstriction Syndrome**

This is another cause of persistent hypertension, “thunderclap” headaches, seizures, and central nervous system findings. It is a form of postpartum angiopathy. As shown in Figure 40-24, it is characterized by diffuse segmental constriction of cerebral arteries and may be associated with ischemic and hemorrhagic strokes. The reversible cerebral vasoconstriction syndrome has several inciting causes that include pregnancy, and particularly preeclampsia (Ducros, 2012). It is more common in women, and in some cases, vasoconstriction may be so severe as to cause cerebral ischemia and infarction. The appropriate management is not known at this time (Edlow, 2013).
FIGURE 40-24 Reversible cerebral vasoconstriction syndrome. Magnetic resonance angiography shows generalized vasoconstriction of the anterior and posterior cerebral circulation (arrows). (From Garcia-Reitboeck, 2013, with permission.)

COUNSELING FOR FUTURE PREGNANCIES

As discussed on page 732, defective remodeling of the spiral arteries in some placentations has been posited as the cause of at least one preeclampsia phenotype. Lack of deep placentation has been associated with preeclampsia, placental abruption, fetal-growth restriction, and preterm birth (Wikström, 2011). With this type of “overlap syndrome,” hypertensive disorders may serve as markers for subsequent preterm labor and fetal-growth restriction. For example, even in subsequent nonhypertensive pregnancies, women who had preterm preeclampsia are at increased risk for preterm birth (Connealy, 2013.)

In addition, women who have had either gestational hypertension or preeclampsia are at higher risk to develop hypertension in future pregnancies. Generally, the earlier preeclampsia is diagnosed during the index pregnancy, the greater the likelihood of recurrence. Sibai and colleagues (1986, 1991) found that nulliparas diagnosed with preeclampsia before 30 weeks have a recurrence risk as high as 40 percent during a subsequent pregnancy. In a prospective study of 500 women previously delivered for preeclampsia at 37 weeks, the recurrence rate in a subsequent gestation was 23 percent (Bramham, 2011). These investigators also found an increased risk during subsequent pregnancies for preterm delivery and fetal-growth restriction.
even if these women remained normotensive.

In a study from the Denmark Birth Registry, Lykke and coworkers (2009b) analyzed singleton births in more than 535,000 women who had a first and second delivery. Women whose first pregnancy was complicated by preeclampsia between 32 and 36 weeks had a significant twofold increased incidence of preeclampsia in their second pregnancy—25 versus 14 percent—compared with women who were normotensive during the first pregnancy. Analyzed from another view, they also found that preterm delivery and fetal-growth restriction in the first pregnancy significantly increased the risk for preeclampsia in the second pregnancy.

As probably expected, women with HELLP syndrome have a substantive risk for recurrence in subsequent pregnancies. In two studies the risk ranged from 5 to 26 percent, but the true recurrence risk likely lies between these two extremes (Habli, 2009; Sibai, 1995). Even if HELLP syndrome does not recur with subsequent pregnancies, there is a high incidence of preterm delivery, fetal-growth restriction, placental abruption, and cesarean delivery (Habli, 2009; Hnat, 2002).

LONG-TERM CONSEQUENCES

Over the past 20 years, evidence has accrued that preeclampsia, like fetal-growth disorders and preterm birth, is a marker for subsequent cardiovascular morbidity and mortality. Thus, women with hypertension identified during pregnancy should be evaluated during the first several months postpartum and counseled regarding long-term risks. The Working Group concluded that hypertension attributable to pregnancy should resolve within 12 weeks of delivery (National High Blood Pressure Education Program, 2000). Persistence beyond this time is considered to be chronic hypertension (Chap. 50, p. 1000). The Magpie Trial Follow-Up Collaborative Group (2007) reported that 20 percent of 3375 preeclamptic women seen at a median of 26 months postpartum had hypertension. Importantly, even if hypertension does not persist in the short term, convincing evidence suggests that the risk for long-term cardiovascular morbidity is significantly increased in preeclamptic women.

Cardiovascular and Neurovascular Morbidity

With the advent of national databases, several studies confirm that any hypertension during pregnancy is a marker for an increased risk for morbidity and mortality in later life (American College of Obstetricians and Gynecologists, 2013c). In a case-control study from Iceland Arnadottir and associates (2005) analyzed outcomes for 325 women who had hypertension complicating pregnancy and who were delivered from 1931 through 1947. At a median follow-up of 50 years, 60 percent of women with pregnancy-related hypertension compared with only 53 percent of controls had died. Compared with 629 normotensive pregnant controls, the prevalences of ischemic heart disease—24 versus 15 percent, and stroke—9.5 versus 6.5 percent, were significantly increased in the women who had gestational hypertension. In a Swedish population study of more than 400,000 nulliparas delivered between 1973 and 1982, Wikström and coworkers (2005) also found an increased incidence of ischemic heart disease in women with prior pregnancy-associated hypertension.

Lykke and associates (2009a) cited findings from a Danish registry of more than 780,000 nulliparous women. After a mean follow-up of almost 15 years, the incidence of chronic hypertension was significantly increased 5.2-fold in those who had gestational hypertension, 3.5-fold after mild preeclampsia, and 6.4-fold after severe preeclampsia. After two hypertensive
pregnancies, there was a 5.9-fold increase in the incidence. Importantly, these investigators also reported a significant 3.5-fold increased risk for type 2 diabetes.

Bellamy and coworkers (2007) performed a systematic review and metaanalysis of long-term risks for cardiovascular disease in women with preeclampsia. As shown in Figure 40-25, the risks in later life were increased for hypertension, ischemic heart disease, stroke, venous thromboembolism, and all-cause mortality. As emphasized by several investigators, other cofactors or comorbidities are related to acquisition of these long-term adverse outcomes (Gastrich, 2012; Harskamp, 2007; Hermes, 2012; Spaan, 2012b). These include but are not limited to the metabolic syndrome, diabetes, obesity, dyslipidemia, and atherosclerosis. These conclusions are underscored by the findings of Berends and colleagues (2008), who confirmed shared constitutional risks for long-term vascular-related disorders in preeclamptic women and in their parents. Similar preliminary observations were reported by Smith (2009, 2012) and Stekkinger (2013) and their associates.

![Figure 40-25](image)

**FIGURE 40-25** Long-term cardiovascular consequences of preeclampsia. All differences $p \leq .001$. (Data from Bellamy, 2007.)

At least in some of these women, their hypertensive cardiovascular pathologies appear to have begun near the time of their own births. For example, individuals who are born preterm have increased ventricular mass later in life (Lewandowski, 2013). Women who have preeclampsia and who develop chronic hypertension later in life have an increased ventricular mass index before...
they become hypertensive (Ghossein-Doha, 2013). A similar phenomenon is associated with preterm birth and with fetal-growth disorders.

## Renal Sequelae

Preeclampsia appears to also be a marker for subsequent renal disease. In a preliminary study, the possibility was raised that persistent podocyturia might be a marker for such disease (Garrett, 2013). In a 40-year study of Norwegian birth and end-stage renal disease linked registries, although the absolute risk of renal failure was small, preeclampsia was associated with a fourfold increased risk (Vikse, 2008). Women with recurrent preeclampsia had an even greater risk. These data need to be considered in light of the findings that 15 to 20 percent of women with preeclampsia who undergo renal biopsy have evidence of chronic renal disease (Chesley, 1978). In another long-term follow-up study, Spaan and coworkers (2009) compared formerly preeclamptic women with a cohort of women who were normotensive at delivery. At 20 years following delivery, preeclamptic women were significantly more likely to be chronically hypertensive—55 versus 7 percent—compared with control women. They also had higher peripheral vascular and renovascular resistance and decreased renal blood flow. These data do not permit conclusions as to cause versus effect.

## Neurological Sequelae

Until recently, eclamptic seizures were believed to have no significant long-term sequelae. Findings have now accrued, however, that this is not always the case. Recall that almost all eclamptic women have multifocal areas of perivascular edema, and about a fourth also have areas of cerebral infarction (Zeeman, 2004a).

A Dutch group has reported several long-term follow-up studies in women with severe preeclampsia and eclampsia (Aukes, 2007, 2009, 2012). These investigators found long-term persistence of brain white-matter lesions that were incurred during eclamptic convulsions (Aukes, 2009). When studied with MR imaging at a mean of 7 years, 40 percent of formerly eclamptic women had more numerous and larger aggregate white matter lesions compared with 17 percent of normotensive control women. These investigators later also observed these white-matter lesions in preeclamptic women without convulsions (Aukes, 2012). In studies designed to assess clinical relevance, Aukes and colleagues (2007) reported that formerly eclamptic women had subjectively impaired cognitive functioning. They also reported that women with multiple seizures had impaired sustained attention compared with normotensive controls (Postma, 2009). And recently, Wiegman and associates (2012) described that formerly eclamptic women at approximately 10 years had lower vision-related quality of life compared with control subjects. Because there were no studies done before these women suffered from preeclampsia or eclampsia, the investigators appropriately concluded that cause versus effect of these white-matter lesions remains unknown.

CHAPTER 41

Obstetrical Hemorrhage

GENERAL CONSIDERATIONS

CAUSES OF OBSTETRICAL HEMORRHAGE

uterine atony

uterine inversion

injuries to the birth canal

puerperal hematomas

rupture of the uterus

placental abruption

placenta previa

placenta accrete syndromes

consumptive coagulopathy

management of hemorrhage

Obstetrics is a bloody business.
Dr. Jack Pritchard (1976b)

Obstetrical hemorrhage continues along with hypertension and infections as one of the infamous “triad” of causes of maternal deaths in both developed and underdeveloped countries. It is a leading reason for admission of pregnant women to intensive care units (ICUs) (Crozier, 2011; Small, 2012; Zeeman, 2003; Zwart, 2008). Hemorrhage was a direct cause of nearly 13 percent of 4693 pregnancy-related maternal deaths in the United States documented by the Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention (Berg, 2010). Similarly, Clark and coworkers (2008) reported that 12 percent of maternal deaths recorded in the Hospital Corporation of America database were caused by hemorrhage. In developing countries, its contribution is even more striking. Indeed, hemorrhage is the single most important cause of maternal death worldwide and is responsible for half of all postpartum deaths in developing countries (Lalonde, 2006; McCormick, 2002).
The decreasing maternal mortality rate from hemorrhage in this country has been a major achievement. Decreased deaths from hemorrhage have been a major contributor to the decrease in the maternal mortality rate during the 20th century—from approximately 1000 to only 10 per 100,000 births (Hoyert, 2007). But, as discussed in Chapter 1 (p. 5), probably half of maternal deaths are not reported, and at least a third are considered preventable. It thus seems unlikely that deaths from hemorrhage have reached an irreducible minimum.

Mechanisms of Normal Hemostasis

A major concept in understanding the pathophysiology and management of obstetrical hemorrhage is the mechanism by which hemostasis is achieved after normal delivery. Recall that near term an incredible amount of blood—at least 600 mL/min—flows through the intervillous space (Pates, 2010). As described in Chapter 5 (p. 96), this prodigious flow circulates through the spiral arteries, which average 120 in number. Also recall that these vessels have no muscular layer because of their endotrophoblastic remodeling, which creates a low-pressure system. With placental separation, these vessels at the implantation site are avulsed, and hemostasis is achieved first by myometrial contraction, which compresses this formidable number of relatively large vessels (Chap. 2, p. 26). Contraction are followed by clotting and obliteration of vessel lumens.

If after delivery, the myometrium within and adjacent to the denuded implantation site contracts vigorously, fatal hemorrhage from the placental implantation site is unlikely. Importantly, an intact coagulation system is not necessary for postpartum hemostasis unless there are lacerations in the uterus, birth canal, or perineum. At the same time, however, fatal postpartum hemorrhage can result from uterine atony despite normal coagulation. Adhered placental pieces or large blood clots that prevent effective myometrial contraction will serve to impair hemostasis at the implantation site.

Definition and Incidence

Traditionally, postpartum hemorrhage has been defined as the loss of 500 mL of blood or more after completion of the third stage of labor. This is problematic because almost half of all women delivered vaginally shed that amount of blood or more when losses are measured quantitatively (Pritchard, 1962). These results are depicted in Figure 41-1 and show further that approximately 5 percent of women delivering vaginally lose more than 1000 mL of blood. These studies also showed that estimated blood loss is commonly only approximately half the actual loss. Because of this, estimated blood loss in excess of “average” or 500 mL should alert the obstetrician to possible excessive bleeding. Calibrated delivery-drape markings improve estimation accuracy, but even this technique underestimates blood loss compared with more precise methods (Sosa, 2009; Toledo, 2007).
The blood volume of a pregnant woman with normal pregnancy-induced hypervolemia usually increases by half, but increases range from 30 to 60 percent—1500 to 2000 mL for an average-sized woman (Pritchard, 1965). The equation to calculate blood volume is shown in Table 41-1. It is axiomatic that a normal pregnant woman tolerates, without any decrease in postpartum hematocrit, blood loss at delivery that approaches the volume of blood that she added during pregnancy. Thus, if blood loss is less than the pregnancy-added volume, the hematocrit remains the same acutely and during the first several days. It then increases as nonpregnant plasma volume normalizes during the next week or so. Whenever the postpartum hematocrit is lower than one obtained on admission for delivery, blood loss can be estimated as the sum of the calculated pregnancy-added volume plus 500 mL for each 3 volume percent decrease of the hematocrit. Blood loss in these women can also be calculated using the formula of Hernandez and associates (2012). Briefly, these investigators used admission-to-discharge red cell volumes to compute total blood loss.

**TABLE 41-1. Calculation of Maternal Total Blood Volume**

<table>
<thead>
<tr>
<th>Nonpregnant blood volume:</th>
<th></th>
</tr>
</thead>
</table>
| \[
\frac{[\text{Height (inches)} \times 50] + [\text{Weight (pounds)} \times 25]}{2} = \text{Blood volume (mL)}
\] |

**Pregnancy blood volume:**
Average increase is 30 to 60 percent of calculated nonpregnant volume
Increases across gestational age and plateaus at approximately 34 weeks

Usually larger with low normal-range hematocrit (−30) and smaller with high normal-range hematocrit (−40)

Average increase is 40 to 80 percent with multifetal gestation
Average increase is less with preeclampsia—volumes vary inversely with severity

**Postpartum blood volume with serious hemorrhage:**
Assume acute return to nonpregnant total volume after fluid resuscitation
Pregnancy hypervolemia cannot be restored postpartum

---

*a* Formula arrived at by measuring blood volume and blood loss in more than 100 women using ⁵¹Cr-labeled erythrocytes.
Modified from Hernandez, 2012

---

Excessive blood loss has been estimated by several methods that include measuring loss directly, using a predetermined decline in hematocrit or hemoglobin concentration, or counting the number of women transfused. Of these, direct measurement was performed in a two-center investigation done in Argentina and Uruguay (Sosa, 2009). Specially constructed drapes were used to collect blood at vaginal delivery. These investigators reported that 10.8 percent of women had hemorrhage in excess of 500 mL, whereas 1.9 percent lost > 1000 mL. These estimates likely are too low.

Tita and colleagues (2012) used a 6-volume percent decrease in the postpartum hematocrit to define clinically significant blood loss with vaginal delivery. This decrease easily signifies greater than 1000-mL blood loss in the averaged-sized women. They documented this amount in a fourth of women, which agrees with the findings in Figure 41-1.

A final marker used to estimate the hemorrhage incidence is the transfusion rate. Because of prevailing conservative attitudes toward blood replacement, rates cited more recently are lower than transfusion rates described in older studies. In the study by Tita and colleagues (2012) cited above, more than 6 percent of women delivered vaginally underwent interventional treatment and blood transfusions. In a study of more than 66,000 women delivered at Parkland Hospital from 2002 to 2006, Hernandez and associates (2012) reported that 2.3 percent overall were given blood transfusions for hypovolemia. Half of these women had undergone cesarean delivery. Importantly, for those transfused, these investigators calculated blood loss to average approximately 3500 mL! In a recent study from Australia, 1.6 percent of women delivered in 2010 were transfused (Patterson, 2014). Last, from a registry-based Norwegian study, Skjeldestad and Øian (2012) reported that blood loss exceeded 1250 mL in 2.7 percent of women undergoing cesarean delivery.

Thus, it is apparent that significant blood loss accompanies about a fourth of vaginal deliveries. The amounts and proportions for cesarean delivery are much greater.

When audits of discharge statistics are evaluated, it is apparent that hemorrhage is also underreported. In one example, Bateman and associates (2010) queried the Nationwide Inpatient Sample for 2004 and found a 2.9-percent reported rate of postpartum hemorrhage. Similarly, using a sample of nearly 185,000 delivery outcomes from the National Hospital Discharge Summary database that represented more than 40 million deliveries, Berg and coworkers (2009) reported postpartum hemorrhage incidence of 2.0 and 2.6 percent, for two epochs. In a population-based Canadian study, the incidence of postpartum hemorrhage from atony increased from 3.6 to 4.8
percent from 2001 to 2009 (Mehrabadi, 2013). In contrast, a study encompassing 1999 to 2008 by Kramer and associates (2013) cited a rate of severe postpartum hemorrhage that increased from only 1.9 to 4.2 per 1000 births. At the same time, reported transfusion rates between 1991 and 2003 increased from only 3 to 5 per 1000 deliveries—all rather meager compared with rates in previously cited prospective studies.

**Predisposing Conditions**

There are myriad clinical circumstances in which risks for obstetrical hemorrhage and its consequences are appreciably increased. The imposing list shown in Table 41-2 illustrates that hemorrhage can manifest at any time throughout pregnancy, delivery, and the puerperium. Thus, any description of obstetrical hemorrhage should include gestational age. Use of terms such as *third-trimester bleeding* is not recommended because of imprecision.

| Table 41-2. Obstetrical Hemorrhage: Causes, Predisposing Factors, and Vulnerable Patients |
|-------------------------------------|-------------------------------------|
| Abnormal Placentation               | Uterine Atony                       |
| Placenta previa                     | Uterine overdistention              |
| Placental abruption                 | Large fetus                         |
Importantly, inadequate obstetrical and anesthetic services in some areas contribute to maternal death from hemorrhage. This undoubtedly includes facilities in the United States. It was quantified in the United Kingdom by the 2002 Confidential Enquiry into Maternal and Child Health, which concluded that most maternal deaths from hemorrhage were associated with substandard care (Weindling, 2003). Similar experiences were reported from Japan and from the Netherlands (Nagaya, 2000; Zwart, 2008).

### Timing of Hemorrhage
It is has been traditional to classify obstetrical hemorrhage as \textit{antepartum}—such as with placenta previa or placental abruption, or as \textit{postpartum}—commonly caused by uterine atony or genital tract lacerations. In individual women, however, these terms are nonspecific, and it is reasonable to specify the cause and gestational age as descriptors.

\textbf{Antepartum Hemorrhage}

Bleeding during various times in gestation may give a clue as to its cause. Many aspects of bleeding during the first half of pregnancy from abortion or ectopic pregnancy are discussed in detail in Chapters 18 and 19, respectively. Discussions that follow concern pregnancies with a viable mature living fetus. In these cases, rapid assessment should always consider the deleterious fetal effects of maternal hemorrhage.

Slight vaginal bleeding is common during active labor. This “bloody show” is the consequence of effacement and dilatation of the cervix, with tearing of small vessels. Uterine bleeding, however, coming from above the cervix, is concerning. It may follow some separation of a placenta previa implanted in the immediate vicinity of the cervical canal, or it may be from a placental abruption or uterine tear. Rarely, there may be velamentous insertion of the umbilical cord, and the involved placental vessels may overlie the cervix—\textit{vasa previa}. Fetal hemorrhage follows laceration of these vessels at the time of membrane rupture. In many women near term, the source of uterine bleeding is not identified, symptomless bleeding ceases, and no apparent anatomical cause is found at delivery. In most of these cases, bleeding likely resulted from a slight marginal placental separation. \textit{Despite this, any pregnancy with antepartum bleeding remains at increased risk for an adverse outcome even though bleeding has stopped and placenta previa has been excluded sonographically.}

Several reports address mid- to early third-trimester bleeding. Lipitz and colleagues (1991) reported that a fourth of 65 consecutive women with uterine bleeding between 14 and 26 weeks had placental abruption or previa, and a third of all 65 fetuses ultimately were lost. Similar outcomes were described subsequently (Ajayi, 1992; Leung, 2001). The Canadian Perinatal Network described 806 women with hemorrhage between 22 and 28 weeks’ gestation (Sabourin, 2012). Placental abruption (32 percent), previa (21 percent), and cervical bleeding (6.6 percent) were the most common causes identified, and in a third, no cause was found. Of all women, 44 percent were delivered ≤ 29 weeks. Clearly, second- and third-trimester bleeding are associated with a poor pregnancy prognosis.

\textbf{Postpartum Hemorrhage}

In most cases, the cause of postpartum hemorrhage can and should be determined. Frequent causes are uterine atony with bleeding from the placental implantation site, genital tract trauma, or both (see Table 41-2). Postpartum hemorrhage is usually obvious. Important exceptions are unrecognized intrauterine and intravaginal blood accumulation and uterine rupture with intraperitoneal bleeding. Initial assessment should attempt to differentiate uterine atony from genital tract lacerations. Primary considerations are the predisposing risk factors shown in Table 41-2, lower genital tract examination, and uterine tone assessment. Atony is identified by a boggy, soft uterus during bimanual examination and by expression of clots and hemorrhage during uterine massage.

Persistent bleeding despite a firm, well-contracted uterus suggests that hemorrhage most likely is from lacerations. Bright red blood further suggests arterial bleeding. \textit{To confirm that lacerations are a source of bleeding, careful inspection of the vagina, cervix, and uterus is essential.}

Sometimes bleeding may be caused by both atony and trauma, especially after forceps or
vacuum-assisted vaginal delivery. Importantly, if significant bleeding follows these deliveries, then the cervix and vagina are carefully examined to identify lacerations. This is easier if conduction analgesia was given. If there are no lower genital tract lacerations and the uterus is contracted, yet supracervical bleeding persists, then manual exploration of the uterus is done to exclude a uterine tear. This also is completed routinely after internal podalic version and breech extraction.

Blood Loss Estimation

Estimated blood loss—like beauty—is in the eye of the beholder.

Estimation is notoriously inaccurate, especially with excessive bleeding (p. 781). Instead of sudden massive hemorrhage, postpartum bleeding is frequently steady. If atony persists, bleeding may appear to be only moderate at any given instant but may continue until serious hypovolemia develops. Bleeding from an episiotomy or a vaginal laceration can also appear to be only minimal to moderate. However, constant seepage can lead to enormous blood loss relatively quickly. In some cases, after placental separation, blood may not escape vaginally but instead may collect within the uterine cavity, which can become distended by 1000 mL or more of blood. In others, postpartum uterine massage is applied to a roll of abdominal fat mistaken for the uterus. Thus, monitoring of the uterus immediately postpartum must not be left to an inexperienced person (Chap. 27, p. 547).

All of these factors can lead to an underappreciation of the magnitude of hemorrhage over time. The effects of hemorrhage depend to a considerable degree on the maternal nonpregnant blood volume and the corresponding degree of pregnancy-induced hypervolemia as previously discussed. For this and other reasons, hypovolemia may not be recognized until very late. A treacherous feature of postpartum hemorrhage is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood have been lost. The normotensive woman initially may actually become somewhat hypertensive from catecholamine release in response to hemorrhage. Moreover, women with preeclampsia may become “normotensive” despite remarkable hypovolemia.

Late Postpartum Hemorrhage

Bleeding after the first 24 hours is designated late postpartum hemorrhage. Such bleeding is found in up to 1 percent of women and may be serious (American College of Obstetricians and Gynecologists, 2013b). It is discussed in Chapter 36 (p. 670).

Special Considerations

In certain conditions, a pregnant woman may be particularly susceptible to hemorrhage because her blood volume expansion is less than expected. This situation is most commonly encountered in small women—even those with normal pregnancy-induced hypervolemia. Women with severe preeclampsia or eclampsia are also more vulnerable to hemorrhage because they frequently do not have a normally expanded blood volume. Specifically, Zeeman and associates (2009) documented a mean increase above nonpregnant volume of only 10 percent in eclamptic women (Chap. 40, p. 737). A third example is the moderate to severely curtailed pregnancy-induced volume expansion in women with chronic renal insufficiency (Chap. 53, p. 1061). When excessive hemorrhage is suspected in these high-risk women, crystalloid and blood are promptly administered for suspected hypovolemia.
The most important causes—because of their incidence or consequence—of severe obstetrical hemorrhage and their contribution to maternal mortality rates are shown in Figure 41-2. Fatal hemorrhage is most likely in circumstances in which blood or components are not immediately available. As discussed on page 815, the ability to provide prompt resuscitation of hypovolemia and blood administration is an absolute requirement for acceptable obstetrical care.

![Figure 41-2](image)

**FIGURE 41-2** Contributions to maternal death from various causes of obstetrical hemorrhage. Percentages are approximations because of different classification schemata used. DIC = disseminated intravascular coagulation. (Data from Al-Zirqi, 2008; Berg, 2010; Chichakli, 1999; Zwart, 2008.)

### Uterine Atony

The most frequent cause of obstetrical hemorrhage is failure of the uterus to contract sufficiently after delivery and to arrest bleeding from vessels at the placental implantation site (p. 780). That said, some bleeding is inevitable during third-stage labor as the placenta begins to separate. Blood from the implantation site may escape into the vagina immediately—the Duncan mechanism of placental separation, or it remains concealed behind the placenta and membranes until the placenta is delivered—the Schultze mechanism.

With bleeding during the third stage, the uterus should be massaged if it is not contracted firmly. After the signs of separation, placental descent is indicated by the cord becoming slack. Placental expression should be attempted by manual fundal pressure (Chap. 27, p. 546). If bleeding continues, then manual removal of the placenta may be necessary. Separation and delivery of the placenta by cord traction, especially when the uterus is atonic, may cause uterine inversion, which is discussed on page 787.
Third-Stage Bleeding

If significant bleeding persists after delivery of the infant and while the placenta remains partially or totally attached, then manual placental removal is indicated (Chap. 27, p. 546). For this, adequate analgesia is mandatory, and aseptic surgical technique should be used. As illustrated in Figure 41-3, the placenta is peeled off its uterine attachment by a motion similar to that used in separating the pages of a book. After its removal, trailing membranes are removed by carefully teasing them from the decidua and using ring forceps for this as necessary. Another method is to wipe out the uterine cavity with a gauze-wrapped hand.

**FIGURE 41-3** Manual removal of placenta. **A.** One hand grasps the fundus. The other hand is inserted into the uterine cavity, and the fingers are swept from side to side as they are advanced. **B.** When the placenta has become detached, it is grasped and removed.

Uterine Atony after Placental Delivery

The fundus should always be palpated following placental delivery to confirm that the uterus is well contracted. If it is not firm, then vigorous fundal massage usually prevents postpartum hemorrhage from atony (Hofmeyr, 2008). Simultaneously, 20 units of oxytocin in 1000 mL of crystalloid solution will often be effective given intravenously at 10 mL/min for a dose of 200 mU/min. Higher concentrations are minimally more effective (Tita, 2012). Oxytocin should never be given as an undiluted bolus dose because serious hypotension or cardiac arrhythmias may develop.
Risk Factors

In many women, uterine atony can at least be anticipated well in advance of delivery (see Table 41-2). In one study, however, up to half of women who had atony after cesarean delivery were found to have no risk factors (Rouse, 2006). Thus, the ability to identify which individual woman will experience atony is limited. Risk factors for retained placenta are similar (Endler, 2012).

The magnitude of risk imposed by each of these factors shown in Table 41-2 varies considerably between reports. Primiparity has been cited as a risk factor (Driessen, 2011). High parity is a long-known risk factor for uterine atony. The incidence of postpartum hemorrhage was reported to increase from 0.3 percent in women of low parity to 1.9 percent with parity of 4 or greater. It was 2.7 percent with parity of 7 or greater (Babinszki, 1999). The overdistended uterus is prone to hypotonia after delivery, and thus women with a large fetus, multiple fetuses, or hydramnios are at greater risk. Labor abnormalities predispose to atony and include hyper- or hypotonic labor. Similarly, labor induction or augmentation with either prostaglandins or oxytocin is more likely to be followed by atony (Driessen, 2011). Finally, the woman who has had a prior postpartum hemorrhage is at risk for recurrence with a subsequent delivery.

Evaluation and Management

With immediate postpartum hemorrhage, careful inspection is done to exclude birth canal laceration. Because bleeding can be caused by retained placental fragments, inspection of the placenta after delivery should be routine. If a defect is seen, the uterus should be manually explored, and the fragment removed. Occasionally, retention of a succenturiate lobe may cause postpartum hemorrhage (Chap. 6, p. 117). During examination for lacerations and causes of atony, the uterus is massaged and uterotonic agents are administered.

Uterotonic Agents

There are several compounds that prompt the postpartum uterus to contract (Chap. 27, p. 547). One of these is routinely selected and given to prevent postpartum bleeding by ensuring uterine contractions. Most of these same agents are also used to treat uterine atony with bleeding. Moreover, because many trials combine results from atony prophylaxis and treatment, evaluation of these studies is problematic. For example, oxytocin has been used for more than 50 years, and in most cases, it is infused intravenously or given intramuscularly after placental delivery. Neither route has been shown to be superior (Oladapo, 2012). This or other uterotonins given prophylactically will prevent most cases of uterine atony.

When atony persists despite preventive measures, ergot derivatives have been used for second-line treatment. These include methylergonovine—Methergine—and ergonovine. Only methylergonovine is currently manufactured in the United States. Given parenterally, these drugs rapidly stimulate tetanic uterine contractions and act for approximately 45 minutes (Schimmer, 2011). A common regimen is 0.2 mg of either drug given intramuscularly. A caveat is that ergot agents, especially given intravenously, may cause dangerous hypertension, especially in women with preeclampsia. Severe hypertension is also seen with concomitant use of protease inhibitors given for human immunodeficiency viral (HIV) infection (Chap. 65, p. 1279). These adverse effects notwithstanding, it is speculative whether there are superior therapeutic effects of ergot derivatives compared with oxytocin.

In more recent years, second-line agents for atony have included the E- and F-series prostaglandins. Carboprost tromethamine—Hemabate—is the 15-methyl derivative of
prostaglandin $F_2\alpha$. It was approved more than 25 years ago for uterine atony treatment in a dose of 250 $\mu$g (0.25 mg) given intramuscularly. This dose can be repeated if necessary at 15- to 90-minute intervals up to a maximum of eight doses. Oleen and Mariano (1990) reported its use for postpartum hemorrhage from 12 obstetrical units. Bleeding was controlled in 88 percent of 237 women treated. Another 7 percent required other uterotonics to control hemorrhage, and the remaining 5 percent required surgical intervention. Carboprost causes side effects in approximately 20 percent of women. These include, in descending order of frequency, diarrhea, hypertension, vomiting, fever, flushing, and tachycardia (Oleen, 1990). Another pharmacological effect is pulmonary airway and vascular constriction. Thus, carboprost should not be used for asthmatics and those with suspected amnionic-fluid embolism (p. 812). We have occasionally encountered severe hypertension with carboprost given to women with preeclampsia, and it has also been reported to cause arterial oxygen desaturation that averaged 10 percent (Hankins, 1988).

E-series prostaglandins have been used to prevent or treat atony. Dinoprostone—prostaglandin $E_2$—is given as a 20-mg suppository per rectum or per vaginam every 2 hours. It typically causes diarrhea, which is problematic for the rectal route, whereas vigorous vaginal bleeding may preclude its use per vaginam. Intravenous prostaglandin $E_2$—sulprostone—is used in Europe, but it is not available in this country (Schmitz, 2011).

Misoprostol—Cytotec—is a synthetic prostaglandin $E_1$ analogue that has also been evaluated for both prevention and treatment of atony and postpartum hemorrhage (Abdel-Aleem, 2001; O'Brien, 1998). Most studies have addressed prevention and have conflicting conclusions. In a Cochrane review, Mousa and Alfirevic (2007) reported no added benefits to misoprostol use compared with oxytocin or ergonovine. Derman and coworkers (2006) compared a 600-$\mu$g oral dose given at delivery against placebo. They found that the drug decreased hemorrhage incidence from 12 to 6 percent and that of severe hemorrhage from 1.2 to 0.2 percent. In another study, however, Gerstenfeld and Wing (2001) concluded that 400-$\mu$g misoprostol administered rectally was not more effective than intravenous oxytocin in preventing postpartum hemorrhage. From a systematic review, Villar (2002) found that oxytocin and ergot preparations administered after delivery were more effective than misoprostol for prevention of postpartum hemorrhage (Chap. 27, p. 547).

**Bleeding Unresponsive to Uterotonic Agents**

Hemorrhage that persists despite uterine massage and continued uterotonin administration may be from a yet unrecognized genital tract laceration, for example, uterine rupture. Thus, if bleeding persists after initial measures for atony have been implemented, then the following management steps are performed immediately and simultaneously:

1. Begin bimanual uterine compression, which is easily done and controls most cases of continuing hemorrhage (Fig. 41-4). This technique is not simply fundal massage. The posterior uterine wall is massaged by one hand on the abdomen, while the other hand is made into a fist and placed into the vagina. This fist kneads the anterior uterine wall through the anterior vaginal wall. Concurrently, the uterus is also compressed between the two hands.
2. Immediately mobilize the emergent-care obstetrical team to the delivery room and call for whole blood or packed red cells.
3. Request urgent help from the anesthesia team.
4. Secure at least two large-bore intravenous catheters so that crystalloid with oxytocin is continued simultaneously with blood products. Insert an indwelling Foley catheter for
continuous urine output monitoring.

5. Begin volume resuscitation with rapid intravenous infusion of crystalloid (p. 815).

6. With sedation, analgesia, or anesthesia established and now with optimal exposure, once again manually explore the uterine cavity for retained placental fragments and for uterine abnormalities, including lacerations or rupture.

7. Thoroughly inspect the cervix and vagina again for lacerations that may have escaped attention.

8. If the woman is still unstable or if there is persistent hemorrhage, then blood transfusions are given (p. 815).

**FIGURE 41-4** Bimanual compression for uterine atony. The uterus is positioned with the fist of one hand in the anterior fornix pushing against the anterior wall, which is held in place by the other hand on the abdomen. The abdominal hand is also used for uterine massage.

At this juncture, after causes other than atony have been excluded and after hypovolemia is reversed, several other measures are considered if bleeding continues. Their use depends on several factors such as parity, desire for sterilization, and experience with each method.

**Uterine Packing or Balloon Tamponade.** Uterine packing was popular to treat refractory uterine atony during the first half of the 20th century. It subsequently fell from favor because of concerns regarding concealed bleeding and infection (Hsu, 2003). Newer techniques have been described that alleviate some of these concerns (Zelop, 2011). In one technique, the tip of a 24F Foley catheter with a 30-mL balloon is guided into the uterine cavity and filled with 60 to 80 mL of saline. The open tip permits continuous drainage of blood from the uterus. If bleeding subsides, the catheter is typically removed after 12 to 24 hours. Similar devices that have been used for tamponade include Segstaken-Blakemore and Rusch balloons and condom catheters (Georgiou,
Alternatively, the uterus or pelvis may be packed directly with gauze (Gilstrap, 2002).

Enthusiasm has developed for specially constructed intrauterine balloons to treat hemorrhage from uterine atony and other causes (Barbieri, 2011). A Bakri Postpartum Balloon (Cook Medical) or BT-Cath (Utah Medical Products) may be inserted and inflated to tamponade the endometrial cavity and stop bleeding (Fig. 41-5). Insertion requires two or three team members. The first performs abdominal sonography during the procedure. The second places the deflated balloon into the uterus and stabilizes it. The third member instills fluid to inflate the balloon, rapidly infusing at least 150 mL followed by further instillation over a few minutes for a total of 300 to 500 mL to arrest hemorrhage.

FIGURE 41-5 Intrauterine balloon for postpartum hemorrhage.

There have been few prospective studies with these uterine balloons, and thus data are observational (Aibar, 2013; Grönvall, 2013; Laas, 2012). In all, more than 150 women were managed for postpartum hemorrhage. Perhaps a fourth were caused by uterine atony. For all causes, the success rate was noted to be approximately 85 percent. Combinations of balloon tamponade and uterine compression sutures have also been described (Diemert, 2012; Yoong, 2012). Failures for all of these require various surgical methods including hysterectomy. Well-designed studies are needed before instituting intrauterine balloon tamponade as a second-line treatment for atony.

Surgical Procedures. Several invasive procedures can be used to control hemorrhage from atony. These include uterine compression sutures, pelvic vessel ligation, angiographic embolization, and hysterectomy. These are discussed on page 818.

Uterine Inversion
Puerperal inversion of the uterus is considered to be one of the classic hemorrhagic disasters encountered in obstetrics. Unless promptly recognized and managed appropriately, associated bleeding often is massive. Risk factors include alone or in combination:

1. Fundal placental implantation,
2. Delayed-onset or inadequate uterine contractility after delivery of the fetus, that is, uterine atony,
3. Cord traction applied before placental separation, and
4. Abnormally adhered placentation such as with the accrete syndromes (p. 804).

Depending on which of these factors is contributory, the incidence and severity of uterine inversion varies, with the worst scenario being complete inversion with the uterus protruding from the birth canal as shown in Figure 41-6. There is progressive severity of inversion as shown in Figure 41-7.

**FIGURE 41-6** Maternal death from exsanguination caused by uterine inversion associated with a fundal placenta accreta during a home delivery.
FIGURE 41-7 Progressive degrees of uterine inversion depicted. After the fundus begins and continues to invert (Nos. 1 and 2), it would not be visible externally until it was at the level of the introitus (No. 3) or completely inverted (No. 4).

The incidence of uterine inversion is variable and is usually different for vaginal and for cesarean delivery. Incidences range from approximately 1 in 2000 to 1 in 20,000 deliveries (Baskett, 2002; Ogah, 2011; Rana, 2009; Witteveen, 2013). Our experiences at Parkland Hospital comport with the higher 1:2000 incidence. This is despite our policy to discourage placental delivery by cord traction alone and before certainty of its separation. It is unknown if active management of third-stage labor with cord traction applied ostensibly after signs of placental separation increases the likelihood of uterine inversion (Deneux-Tharaux, 2013; Gülmezoglu, 2012; Peña-Marti, 2007; Prick, 2013).

Recognition and Management
Immediate recognition of uterine inversion improves the chances of a quick resolution and good outcome. That said, inexperienced attendants may have a delayed appreciation for an inverting uterus, especially if it is only partial and thus not protruding through the introitus. In these cases, continued hemorrhage likely will prompt closer examination of the birth canal. Even so, the partially inverted uterus can be mistaken for a uterine myoma, and this can be resolved by sonography (Pauleta, 2010; Rana, 2009). Many cases are associated with immediate life-threatening hemorrhage, and at least half require blood replacement (Baskett, 2002). It was previously taught that associated shock was disproportionate to blood loss because of parasympathetic stimulation from stretching pelvic tissues. This has been refuted (Watson, 1980).

Once any degree of uterine inversion is recognized, several steps must be implemented urgently and simultaneously:

1. Immediate assistance is summoned, including obstetrical and anesthesia personnel.
2. Blood is brought to the delivery suite in case it may be needed.
3. The woman is evaluated for emergency general anesthesia. Large-bore intravenous infusion systems are secured to begin rapid crystalloid infusion to treat hypovolemia while awaiting arrival of blood for transfusion.
4. If the recently inverted uterus has not contracted and retracted completely and if the placenta has already separated, then the uterus may often be replaced simply by pushing up on the inverted fundus with the palm of the hand and fingers in the direction of the long axis of the vagina (Fig. 41-8). Some use two fingers rigidly extended to push the center of the fundus upward. Care is taken not to apply so much pressure as to perforate the uterus with the fingertips.

5. If the placenta is still attached, it is not removed until infusion systems are operational and a uterine relaxant drug administered. Many recommend a trial of an intravenously administered tocolytic drug such as terbutaline, magnesium sulfate, or nitroglycerin for uterine relaxation and repositioning (Hong, 2006; You, 2006). If these fail to provide sufficient relaxation, then a rapidly acting halogenated inhalational agent is administered.

6. After removing the placenta, steady pressure with the fist, palm, or fingers is applied to the inverted fundus in an attempt to push it up into and through the dilated cervix as described in Step 4.

7. Once the uterus is restored to its normal configuration, tocolysis is stopped. Oxytocin is then infused, and other uterotonic drugs may be given as described for atony (p. 785). Meanwhile, the operator maintains the fundus in its normal anatomical position while applying bimanual compression to control further hemorrhage until the uterus is well contracted (see Fig. 41-4). The operator continues to monitor the uterus transvaginally for evidence of subsequent inversion.

**FIGURE 41-8** The incompletely inverted uterus is repositioned by using the abdominal hand for...
palpation of the crater-like depression while gently pushing the inverted fundus up out of the lower segment and to its normal anatomical position.

**Surgical Intervention**

In most cases the inverted uterus can be restored to its normal position by the techniques described above. Occasionally, manual replacement fails. One cause is a dense myometrial constriction ring (Kochenour, 2002). At this point, laparotomy is imperative. The anatomical configuration found at surgery can be confusing as shown in **Figure 41-9**. With agents given for tocolysis, a combined effort is made to reposition the uterus by simultaneously pushing upward from below and pulling upward from above. Application of atraumatic clamps to each round ligament and upward traction may be helpful—the *Huntington procedure*. In some cases, placing a deep traction suture in the inverted fundus or grasping it with tissue forceps may be of aid. However, these may be technically difficult (Robson, 2005). If the constriction ring still prohibits repositioning, a longitudinal surgical cut—*Haultain incision*—is made posteriorly through the ring to expose the fundus and permit reinversion (Sangwan, 2009). After uterine replacement, tocolytics are stopped, oxytocin and other uterotonics are given, and the uterine incision is repaired. Risks of separation of this posterior hysterotomy incision during subsequent pregnancy, labor, and delivery are unknown.

![FIGURE 41-9 Surgical anatomy of a completely inverted uterus viewed from above at laparotomy. The uterine fundus is not visible and the tubes and ovaries have been drawn into the birth canal.](image-url)

In some cases, the uterus will again invert almost immediately after repositioning. If this is a problem, then compression sutures shown on page 819 can be used to prevent another inversion (Matsubara, 2009; Mondal, 2012). Occasionally, chronic puerperal uterine inversion may become
Injuries to the Birth Canal

Childbirth is invariably associated with trauma to the birth canal, which includes the uterus and cervix, vagina, and perineum. Injuries sustained during labor and delivery range from minor mucosal tears to lacerations that create life-threatening hemorrhage or hematomas.

Vulvovaginal Lacerations

Small tears of the anterior vaginal wall near the urethra are relatively common. They are often superficial with little to no bleeding, and their repair is usually not indicated. Minor superficial perineal and vaginal lacerations occasionally require sutures for hemostasis. Those large enough to require extensive repair are typically associated with voiding difficulty, and an indwelling bladder catheter will obviate this.

Deeper perineal lacerations are usually accompanied by varying degrees of injury to the outer third of the vaginal vault. Some extend to involve the anal sphincter or varying depths of the vaginal walls. In more than 87,000 deliveries in the Consortium on Safe Labor database, the frequency of third- or fourth-degree perineal lacerations was 5.7 percent in nulliparas and 0.6 percent in multiparas (Landy, 2011). Bilateral vaginal lacerations are usually unequal in length, and they are separated by a tongue of vaginal tissue. Lacerations involving the middle or upper third of the vaginal vault usually are associated with injuries of the perineum or cervix. These sometimes are missed unless thorough inspection of the upper vagina and cervix is performed. Bleeding despite a firmly contracted uterus is strong evidence of genital tract laceration. Those that extend upward usually are longitudinal. They may follow spontaneous delivery but frequently result from injuries sustained during operative vaginal delivery with forceps or vacuum extractor. Most involve deeper underlying tissues and thus usually cause significant hemorrhage. Bleeding is typically controlled by appropriate suture repair.

Extensive vaginal or cervical tears should prompt a careful search for evidence of retroperitoneal hemorrhage or peritoneal perforation or hemorrhage. If this is strongly suspected, then laparotomy is considered (Rafi, 2010). Extensive vulvovaginal lacerations should also prompt intrauterine exploration for possible uterine tears or rupture. For deep vulvovaginal lacerations, suture repair is usually required, and effective analgesia or anesthesia, vigorous blood replacement, and capable assistance are mandatory. In the study reported by Melamed and colleagues (2009), 1.5 percent of women with these lacerations required blood transfusions. Repair of vulvovaginal lacerations is detailed in Chapter 27 (p. 548).

Levator Sling Injuries

The levator ani muscles, described in Chapter 2 (p. 22), are usually involved with deep vaginal vault lacerations. They also sustain stretch injuries that result from overdistention of the birth canal. Muscle fibers are torn and separated, and their diminished tone may interfere with pelvic diaphragm function to cause pelvic relaxation. If the injuries involve the pubococcygeus muscle, urinary incontinence also may result.

Cervical Lacerations

Superficial lacerations of the cervix can be seen on close inspection in more than half of all vaginal deliveries. Most of these are less than 0.5 cm and seldom require repair (Fahmy, 1991).
Deeper lacerations are less frequent, but even these may be unnoticed. Due to ascertainment bias, variable incidences are described. For example, in the Consortium database, the incidence of cervical lacerations was 1.1 percent in nulliparas and 0.5 percent in multiparas (Landy, 2011). But the overall incidence reported by Melamed and coworkers (2009), in a study of more than 81,000 Israeli women, was only 0.16 percent. Parikh and associates (2007) reported a 0.2-percent incidence of lacerations that needed repair.

Cervical lacerations are not usually problematic unless they cause hemorrhage or extend to the upper third of the vagina. Rarely, the cervix may be entirely or partially avulsed from the vagina—*colporrhaxis*—in the anterior, posterior, or lateral fornices. These injuries sometimes follow difficult forceps rotations or deliveries performed through an incompletely dilated cervix with the forceps blades applied over the cervix. In some women, cervical tears reach into lower uterine segment and involve the uterine artery and its major branches. They occasionally extend into the peritoneal cavity. The more severe lacerations usually manifest as external hemorrhage or as a hematoma, however, they may occasionally be unsuspected. In the large Israeli study reported by Melamed and colleagues (2009), almost 11 percent of women with a cervical laceration required blood transfusions.

Other serious cervical injuries fortunately are uncommon. In one, the edematous anterior cervical lip is caught during labor and compressed between the fetal head and maternal symphysis pubis. If this causes severe ischemia, the anterior lip may undergo necrosis and separate from the rest of the cervix. Another rare injury is when the entire vaginal portion of the cervix is avulsed. Such *annular or circular detachment of the cervix* is seen with difficult deliveries, especially forceps deliveries.

**Diagnosis.** A deep cervical tear should always be suspected in women with profuse hemorrhage during and after third-stage labor, particularly if the uterus is firmly contracted. It is reasonable to inspect the cervix routinely following major operative vaginal deliveries even if there is no third-stage bleeding. Thorough evaluation is necessary, and often the flabby cervix interferes with digital examination. The extent of the injury can be more fully appreciated with adequate exposure and visual inspection. This is best accomplished when an assistant applies firm downward pressure on the uterus while the operator exerts traction on the lips of the cervix with ring forceps. A second assistant can provide even better exposure with right-angle vaginal wall retractors.

**Management.** In general, cervical lacerations of 1 and even 2 cm are not repaired unless they are bleeding. Such tears heal rapidly and are thought to be of no significance. When healed they result in the irregular, sometime stellate appearance of the external cervical os that indicates previous delivery of a viable-size fetus.

Deep cervical tears usually require surgical repair. When the laceration is limited to the cervix or even when it extends somewhat into the vaginal fornix, satisfactory results are obtained by suturing the cervix after bringing it into view at the vulva as depicted in Figure 41-10. While cervical lacerations are repaired, associated vaginal lacerations may be tamponaded with gauze packs to arrest their bleeding. Because hemorrhage usually comes from the upper angle of the wound, the first suture using absorbable material is placed in tissue above the angle. Subsequently, either interrupted or continuous locking sutures are placed outward toward the operator. If lacerations extend to involve the lateral vaginal sulcus, then attempts to restore the normal cervical appearance may lead to subsequent stenosis.
FIGURE 41-10 Repair of cervical laceration with appropriate surgical exposure. Continuous absorbable sutures are placed beginning at the upper angle of the laceration.

Most cervical lacerations are successfully repaired using sutures. However, if there is uterine involvement and continued hemorrhage, some of the methods described on page 818 may be necessary to obtain hemostasis. For example, Lichtenberg (2003) described successful angiographic embolization for a high cervical tear after failed surgical repair.

Puerperal Hematomas

Pelvic hematomas can have several anatomical manifestations following childbirth. They are most often associated with a laceration, episiotomy, or an operative delivery. However, they may develop following rupture of a blood vessel without associated lacerations (Nelson, 2012; Propst, 1998; Ridgway, 1995). In some cases, they are quickly apparent, but in others, hemorrhage may be delayed. Occasionally, they are associated with an underlying coagulopathy. Faulty clotting may be acquired, such as with consumptive coagulopathy from placental abruption or fatty liver failure, or may stem from a congenital bleeding disorder such as von Willebrand disease.

One classification of puerperal hematomas includes vulvar, vulvovaginal, paravaginal, and retroperitoneal hematomas. Vulvar hematomas may involve the vestibular bulb or branches of the
pudendal artery, which are the inferior rectal, perineal, and clitoral arteries (Fig. 41-11). Paravaginal hematomas may involve the descending branch of the uterine artery (Zahn, 1990). In some cases, a torn vessel lies above the pelvic fascia, and a supravelvator hematoma develops. These can extend into the upper portion of the vaginal canal and may almost occlude its lumen. Continued bleeding may dissect retroperitoneally to form a mass palpable above the inguinal ligament. Finally, it may even dissect up behind the ascending colon to the hepatic flexure at the lower margin of the diaphragm (Rafi, 2010).
FIGURE 41-11 Schematic showing types of puerperal hematoma. A. Coronal view showing supravelvator and anterior perineal triangle hematomas on the right. B. Perineal view shows anterior perineal triangle anatomy and an ischioanal fossa hematoma on the left.
Vulvovaginal Hematomas

These may develop rapidly and frequently cause excruciating pain, as did the one shown in Figure 41-12. If bleeding ceases, then small- to moderate-sized hematomas may be absorbed. However, we have encountered a few that rebled up to 2 weeks postpartum. In others, the tissues overlying the hematoma may rupture from pressure necrosis. At this time, profuse hemorrhage may follow, but in other cases, the hematoma drains in the form of large clots and old blood. In those that involve the paravaginal space and extend above the levator sling, retroperitoneal bleeding may be massive and occasionally fatal.

**FIGURE 41-12** Left-sided anterior perineal triangle hematoma associated with a vaginal laceration following spontaneous delivery in a woman with consumptive coagulopathy from acute fatty liver of pregnancy.

**Diagnosis.** A vulvar hematoma is readily diagnosed by severe perineal pain. A tense, fluctuant, and tender swelling of varying size rapidly develops and is eventually covered by discolored skin. A paravaginal hematoma may escape detection temporarily. However, symptoms of pelvic pressure, pain, or inability to void should prompt evaluation with discovery of a round, fluctuant mass encroaching on the vaginal lumen. When there is a supravelator extension, the hematoma extends upward in the paravaginal space and between the leaves of the broad ligament. The hematoma may escape detection until it can be felt on abdominal palpation or until hypovolemia develops. Imaging with sonography or computed tomographic (CT) scanning can be useful to assess hematoma location and extent. As discussed, supravelator hematomas are particularly worrisome because they can lead to hypovolemic shock and death.

**Management.** Vulvovaginal hematomas are managed according to their size, duration since delivery, and expansion. In general, smaller vulvar hematomas identified after the woman leaves the delivery room may be treated expectantly (Propst, 1998). But, if pain is severe or the
hematoma continues to enlarge, then surgical exploration is preferable. An incision is made at the point of maximal distention, blood and clots are evacuated, and bleeding points ligated. The cavity may then be obliterated with absorbable mattress sutures. Often, no sites of bleeding are identified. Nonetheless, the evacuated hematoma cavity is surgically closed, and the vagina is packed for 12 to 24 hours. Supralevator hematomas are more difficult to treat. Although some can be evacuated by vulvar or vaginal incisions, laparotomy is advisable if there is continued hemorrhage.

Blood loss with large puerperal hematomas is nearly always considerably more than the clinical estimate. Hypovolemia is common, and transfusions are frequently required when surgical repair is necessary.

Angiographic embolization as described on page 820 has become popular for management of some puerperal hematomas. Embolization can be used primarily, or more likely secondarily, if surgical attempts at hemostasis have failed or if the hematoma is difficult to access surgically (Distefano, 2013; Ojala, 2005). The use of a Bakri balloon for a paracervical hematoma has also been described (Grönvall, 2013).

### Rupture of the Uterus

Uterine rupture may be primary, defined as occurring in a previously intact or unscarred uterus, or may be secondary and associated with a preexisting myometrial incision, injury, or anomaly. Some of the etiologies associated with uterine rupture are presented in Table 41-3. Importantly, the contribution of each of these underlying causes has changed remarkably during the past 50 years. Specifically, before 1960, when the cesarean delivery rate was much lower than it is currently and when women of great parity were numerous, primary uterine rupture predominated. As the incidence of cesarean delivery increased and especially as a subsequent trial of labor in these women became prevalent through the 1990s, uterine rupture through the cesarean hysterotomy scar became preeminent. As discussed in detail in Chapter 31 (p. 617), along with diminished enthusiasm for trial of labor in women with prior cesarean delivery, the two types of rupture likely now have equivalent incidences. Indeed, in a 2006 study of 41 cases of uterine rupture from the Hospital Corporation of America, half were in women with a prior cesarean delivery (Porreco, 2009).

<td><strong>In addition to the prior cesarean hysterotomy incision already discussed, risks for uterine rupture include other previous operations or manipulations that traumatize the myometrium. Examples are uterine curettage or perforation, endometrial ablation, myomectomy, or hysteroscopy (Kieser, 2002; Pelosi, 1997). In the study by Porreco and colleagues (2009) cited earlier, seven of 21 women without a prior cesarean delivery had undergone prior uterine surgery. In developed countries, the incidence of rupture was cited by Getahun and associates (2012) as 1 in 4800 deliveries. The frequency of primary rupture approximates 1 in 10,000 to 15,000 births (Miller, 1997; Porreco, 2009). One reason is a decreased incidence of women of great parity (Maymon, 1991; Miller, 1997). Another is that excessive or inappropriate uterine stimulation with oxytocin—previously a frequent cause—has mostly disappeared. Anecdotally, however, we have encountered primary uterine rupture in a disparate number of women in whom labor was induced with prostaglandin E1.</strong></td>

extends transversely or obliquely. When the rent is in the portion of the uterus adjacent to the broad ligament, the tear is usually longitudinal. Although these tears develop primarily in the lower uterine segment, it is not unusual for them to extend upward into the active segment or downward through the cervix and into the vagina (Fig. 41-13). In some cases, the bladder may also be lacerated (Rachagan, 1991). If the rupture is of sufficient size, the uterine contents will usually escape into the peritoneal cavity. If the presenting fetal part is firmly engaged, however, then only a portion of the fetus may be extruded from the uterus. Fetal prognosis is largely dependent on the degree of placental separation and magnitude of maternal hemorrhage and hypovolemia. In some cases, the overlying peritoneum remains intact, and this usually is accompanied by hemorrhage that extends into the broad ligament to cause a large retroperitoneal hematoma with extensive blood loss.

![Figure 41-13](image)

**FIGURE 41-13** Supracervical hysterectomy specimen showing uterine rupture during spontaneous labor with a vertical tear at the left lateral edge of lower uterine segment.

Occasionally, there is an inherent weakness in the myometrium in which the rupture takes place. Some examples include anatomical anomalies, adenomyosis, and connective-tissue defects such as Ehlers-Danlos syndrome (Arici, 2013; Nikolaou, 2013).

**Management and Outcomes.** The varied clinical presentations of uterine rupture and its management are discussed in detail in Chapter 31 (p. 617).
In the most recent maternal mortality statistics from the Centers for Disease Control and Prevention, uterine rupture accounted for 14 percent of deaths caused by hemorrhage (Berg, 2010). Maternal morbidity includes hysterectomy that may be necessary to control hemorrhage. There is also considerably increased perinatal morbidity and mortality associated with uterine rupture. A major concern is that surviving infants develop severe neurological impairment (Porreco, 2009).

**Traumatic Uterine Rupture**

Although the distended pregnant uterus is surprisingly resistant to blunt trauma, pregnant women sustaining such trauma to the abdomen should be watched carefully for signs of a ruptured uterus (Chap. 47, p. 954). Even so, blunt trauma is more likely to cause placental abruption as described subsequently. In a study by Miller and Paul (1996), trauma accounted for only three cases of uterine rupture in more than 150 women. Other causes of traumatic rupture that are uncommon today are those due to internal podalic version and extraction, difficult forceps delivery, breech extraction, and unusual fetal enlargement such as with hydrocephaly.

**Placental Abruption**

Separation of the placenta—either partially or totally—from its implantation site before delivery is described by the Latin term *abruptio placentae*. Literally translated, this refers to “rending asunder of the placenta,” which denotes a sudden accident that is a clinical characteristic of most cases. In the purest sense, the cumbersome—and thus seldom used—term *premature separation of the normally implanted placenta* is most descriptive because it excludes separation of a placenta previa implanted over the internal cervical os.

**Etiopathogenesis**

Placental abruption is initiated by hemorrhage into the decidua basalis. The decidua then splits, leaving a thin layer adhered to the myometrium. Consequently, the process begins as a decidual hematoma and expands to cause separation and compression of the adjacent placenta. Inciting causes of many cases are not known, however, several have been posited. The phenomenon of impaired trophoblastic invasion with subsequent atherosis is related in some cases of preeclampsia and abruption (Brosens, 2011). Inflammation or infection may be contributory. Nath and colleagues (2007) found histological evidence of inflammation to be more common in prematurely separated placentas. *Papio* species of baboons develop abruptio placentae similar to humans, and up to half of prematurely separated placentas in these animals demonstrate neutrophilic infiltration (Schenone, 2012; Schlabritz-Loutsevich, 2013a,b).

Abruption likely begins with rupture of a decidual spiral artery to cause a retroplacental hematoma. This can expand to disrupt more vessels and extend placental separation (Fig. 6-3, p. 119). In the early stages of placental abruption, there may be no clinical symptoms. If there is no further separation, the abruption is discovered on examination of the freshly delivered placenta, as a circumscribed depression on the maternal surface. These usually measure a few centimeters in diameter and are covered by dark, clotted blood. Because several minutes are required for these anatomical changes to materialize, a very recently separated placenta may appear totally normal at delivery. Our experiences are like those of Benirschke and associates (2012) in that the “age” of the retroplacental clot cannot be determined exactly. In the example shown in Figure 41-14, a large dark clot is well formed, it has depressed the placental bulk, and it likely is at least several hours old.
Even with continued bleeding and placental separation, placental abruption can still be either total or partial (Fig. 41-15). With either, bleeding typically insinuates itself between the membranes and uterus, ultimately escaping through the cervix to cause external hemorrhage. Less often, the blood is retained between the detached placenta and the uterus, leading to concealed hemorrhage and delayed diagnosis (Chang, 2001). The delay translates into much greater maternal and fetal hazards. With concealed hemorrhage, the likelihood of consumptive coagulopathy also is greater. This is because increased pressure within the intervillous space caused by the expanding retroplacental clot forces more placental thromboplastin into the maternal circulation (p. 797).
Chronic Abruption. Some cases of chronic placental separation begin early in pregnancy. Dugoff and coworkers (2004) observed an association between some abnormally elevated maternal serum aneuploidy markers and subsequent abruption. Ananth (2006) and Weiss (2004) and their associates have also correlated first- and second-trimester bleeding with third-trimester placental abruption. In some cases of a chronic abruption, subsequent oligohydramnios develops—chronic abruption-oligohydramnios sequence—CAOS (Elliott, 1998). Even later in pregnancy, hemorrhage with retroplacental hematoma formation is occasionally arrested completely without delivery. These women may have abnormally elevated serum levels of alpha-fetoprotein (Ngai, 2012). We documented a chronic abruption in a woman with suggestive findings by labeling her red cells with radiochromium. Her symptoms abated, and at delivery 3 weeks later, a 400-mL clot found within the uterus contained no radiochromium, whereas peripheral blood at that time did. Thus, red cells in the clot had accumulated before they were labeled with the radioisotope 3 weeks before delivery.

Traumatic Abruption. External trauma—usually from motor vehicle accidents or aggravated...
assault—can cause placental separation. The frequency of abruption caused by trauma varies and may be dependent on whether these women are cared for in a major trauma unit. Kettel (1988) and Stafford (1988) and their coworkers have appropriately stressed that abruption can be caused by relatively minor trauma. The clinical presentation and sequelae of these abruptions are somewhat different from spontaneous cases. For example, associated fetomaternal hemorrhage, while seldom clinically significant with most spontaneous abruptions, is more common with trauma because of concomitant placental tears or “fractures” (Fig. 47-11, p. 954). Fetal bleeding that averaged 12 mL was noted in a third of women with a traumatic abruption reported by Pearlman (1990). In eight women cared for at Parkland Hospital, we found fetal-to-maternal hemorrhage of 80 to 100 mL in three of eight cases of traumatic placental abruption (Stettler, 1992). Importantly, in some cases of trauma, a nonreassuring fetal heart rate tracing may not be accompanied by other evidence of placental separation. A sinusoidal tracing is one example (Fig. 24-13, p. 482). Traumatic abruption is considered in more detail in Chapter 47 (p. 953).

**Fetal-to-Maternal Hemorrhage.** Most blood in the retroplacental hematoma in a nontraumatic placental abruption is maternal. This is because hemorrhage is caused by separation within the maternal decidua, and placental villi are usually initially intact. In 78 women at Parkland Hospital with a nontraumatic placental abruption, fetal-to-maternal hemorrhage was documented in only 20 percent—and all of these had < 10 mL fetal blood loss (Stettler, 1992). As discussed above, significant fetal bleeding is much more likely with a traumatic abruption that results from a concomitant placental tear.

**Frequency**
The reported incidence of placental abruption varies because of different criteria used. That said, its frequency averages 0.5 percent or 1 in 200 deliveries. In the National Center for Health Statistics database of 15 million deliveries, Salihu and colleagues (2005) reported an incidence of 0.6 percent or 1 in 165 births. From the National Hospital Discharge Summary database from 1999 through 2001, the incidence of placental abruption was found to be 1 percent (Ananth, 2005). From a Maternal-Fetal Medicine Units Network study of approximately 10,000 nulliparous women, the incidence was 0.6 percent (Roberts, 2010). In nearly 366,000 deliveries at Parkland Hospital from 1988 through 2012, the incidence of placental abruption averaged 0.35 percent or 1 in 290 (Fig. 41-16).
According to Ananth (2001b, 2005), the frequency of placental abruption has increased in this country from 0.8 percent in 1981 to 1.0 percent in 2001. Most of this increase was in black women. At Parkland Hospital, however, both the incidence and severity have decreased. With placental abruption so extensive as to kill the fetus, the incidence was 0.24 percent or 1 in 420 births from 1956 through 1967 (Pritchard, 1967). As the number of high-parity women giving birth decreased along with improved availability of prenatal care and emergency transportation, the frequency of abruption causing fetal death decreased to 0.12 percent or 1 in 830 births through 1989. Thereafter and through 2003, it decreased further to 0.06 percent or 1 in 1600, and most recently through 2012, it declined to 0.048 percent or 1 in 2060.

Perinatal Morbidity and Mortality

Major fetal congenital anomalies have an increased association with placental abruption (Riihimäki, 2013). Overall, perinatal outcomes are influenced by gestational age, and the frequency of placental abruption increases across the third trimester up to term. As seen in Figure 41-17, more than half of the placental abruptions at Parkland Hospital developed at $\geq 37$ weeks. Perinatal mortality and morbidity, however, are more common with earlier abruptions. Perinatal deaths caused by abruptions can be assessed by their contribution to mortality or as an actual mortality ratio. Looked at the first way, although the rates of fetal death have declined, the contribution of abruption as a cause of stillbirths remains prominent because other causes have also decreased. For example, since the early 1990s, 10 to 12 percent of all third-trimester stillbirths at Parkland Hospital have been the consequence of placental abruption. This is similar to the rate reported by Fretts and Usher (1997) for the Royal Victoria Hospital in Montreal during the 18-year period ending in 1995 (Chap. 35, p. 662).
Looked at the other way, several investigators have documented high perinatal mortality rates caused by placental abruption. Salihu and colleagues (2005) analyzed more than 15 million singleton births in the United States between 1995 and 1998. The perinatal mortality rate associated with placental abruption was 119 per 1000 births compared with 8 per 1000 for the general obstetrical population. They emphasized that the high rate was due not just to placental abruption, but also to the associated increases in preterm delivery and fetal-growth restriction. Of the two, preterm birth has been reported to be the most important (Nath, 2008).

Perinatal morbidity—often severe—is common in survivors. An early study by Abdella and associates (1984) documented significant neurological deficits within the first year of life in 15 percent of survivors. Two subsequent studies by Matsuda and coworkers (2003, 2013) reported that 20 percent of survivors developed cerebral palsy. These observations are similar to ours from Parkland Hospital. Notably, 20 percent of liveborn neonates of women with an abruption had severe acidemia, defined by a pH < 7.0 or base deficit of ≥ 12 mmol/L. Importantly, 15 percent of liveborn neonates subsequently died.

Predisposing Factors

Demographic Factors. Several predisposing factors may increase the risk for placental abruption, and some are listed in Table 41-4. First, the incidence of abruption increases with maternal age (see Fig. 41-16). In the First- and Second-Trimester Evaluation of Risk (FASTER) trial, women older than 40 years were 2.3 times more likely to experience abruption compared with those 35 years or younger (Cleary-Goldman, 2005). There are conflicting data regarding women of great parity (Pritchard, 1991; Toohey, 1995). Race or ethnicity also appears to be important. In almost 366,000 deliveries at Parkland Hospital, abruption severe enough to kill the fetus was most common in African-American and white women—1 in 200—less so in Asian women—1 in 300—and least in Latin-American women—1 in 350 (Pritchard, 1991). A familial association was found in an analysis of a Norwegian population-based registry that included almost 378,000 sisters with more than 767,000 pregnancies (Rasmussen, 2009). If a woman had a severe abruption, then the risk for her sister was doubled, and the heritability risk was estimated to be 16 percent. The
control group of their sisters-in-law had a risk similar to that for the general obstetrical population.

NA = not available.

**Hypertension and Preeclampsia.** Some form of hypertension is the most frequent condition associated with placental abruption. This includes gestational hypertension, preeclampsia, chronic hypertension, or a combination thereof. In the report by Pritchard and colleagues (1991) that described 408 women with placental abruption and fetal demise cared for at Parkland Hospital, hypertension was apparent in half once hypovolemia was corrected. Half of these women—a fourth of all 408—had chronic hypertension. Looked at another way, a Network study reported that 1.5 percent of pregnant women with chronic hypertension suffered placental abruption (Sibai, 1998). Risk estimates by Zetterstrom and associates (2005) included a twofold increased incidence of abruption in women with chronic hypertension compared with normotensive women—an incidence of 1.1 versus 0.5 percent.

Chronic hypertension with superimposed preeclampsia or fetal-growth restriction confers an ever greater increased risk (Ananth, 2007). Even so, the severity of hypertension does not necessarily correlate with abruption incidence (Zetterstrom, 2005). The long-term effects of these associations are apparent from the significantly increased cardiovascular mortality risk in affected women (Pariente, 2013). Observations from the Magpie Trial Collaborative Group (2002) suggest that women with preeclampsia given magnesium sulfate may have a reduced risk for abruption.

**Preterm Prematurely Ruptured Membranes.** There is no doubt that there is a substantially
increased risk for abruption when the membranes rupture before term. Major and colleagues (1995) reported that 5 percent of 756 women with ruptured membranes between 20 and 36 weeks developed an abruption. Kramer and coworkers (1997) found an incidence of 3.1 percent if membranes were ruptured for longer than 24 hours. Ananth and associates (2004) reported that the threefold risk of abruption with preterm rupture was further increased with infection. This same group has suggested that inflammation and infection as well as preterm delivery may be the primary causes leading to abruption (Nath, 2007, 2008).

Cigarette Smoking. Given other vascular diseases caused by smoking, it is not surprising that studies from the Collaborative Perinatal Project linked this to an increased risk for abruption (Misra, 1999; Naeye, 1980). Results of metaanalyses of 1.6 million pregnancies included a twofold risk for abruption in smokers (Ananth, 1999b). This risk increased to five- to eightfold if smokers had chronic hypertension, severe preeclampsia, or both. Similar findings have been reported by Mortensen (2001), Hogberg (2007), Kaminsky (2007), and all their coworkers.

Cocaine Abuse. Women who use cocaine can have an alarming frequency of placental abruption. Bingol and colleagues (1987) described 50 women who abused cocaine during pregnancy—eight had a stillbirth caused by placental abruption. In a systematic review, Addis and associates (2001) reported that placental abruption was more common in women who used cocaine than in those who did not.

Lupus Anticoagulant and Thrombophilias. Women affected by some of these have higher associated rates of thromboembolic disorders during pregnancy. However, the link with placental abruption is less clear (American College of Obstetricians and Gynecologists, 2012a, 2013a). Lupus anticoagulant is associated with maternal floor infarction of the placenta, but is less so with typical abruptions. There is no convincing evidence that thrombophilias—for example, factor V Leiden or prothrombin gene mutation—are associated with placental abruption. These have been reviewed by Kenny and coworkers (2014) and are discussed further in Chapters 52 (p. 1029) and 59 (p. 1174).

Uterine Leiomyomas. Especially if located near the mucosal surface behind the placental implantation site, uterine myomas can predispose to abortion or later to placental abruption (Chaps. 18, p. 360 and 63, p. 1225).

Recurrent Abruption. Because many of the predisposing factors are chronic and therefore repetitive, it would be reasonable to conclude that placental abruption would have a high recurrence rate. In fact, the woman who has suffered an abruption—especially one that caused fetal death—has an extraordinarily high risk for recurrence. In these women, Pritchard and associates (1970) identified a recurrence rate of 12 percent—and half of these caused another fetal death. Furuhashi and colleagues (2002) reported a 22-percent recurrence rate—half recurred at a gestational age 1 to 3 weeks earlier than the first abruption. Looked at a second way, Tikkanen and coworkers (2006) found that of 114 parous women who experienced an abruption, 9 percent had a prior abruption. A third perspective is provided by a population-based study of 767,000 pregnancies completed by Rasmussen and Irgens (2009). They reported a 6.5-fold increased risk for recurrence of a “mild” abruption and 11.5-fold risk for a “severe” abruption. For women who had two severe abruptions, the risk for a third was increased 50-fold.

Management of a pregnancy subsequent to an abruption is difficult because another separation may suddenly occur, even remote from term. In many of these recurrences, fetal well-being is
Clinical Findings and Diagnosis

Most women with a placental abruption have sudden-onset abdominal pain, vaginal bleeding, and uterine tenderness. In a prospective study, Hurd and colleagues (1983) reported that 78 percent with placental abruption had vaginal bleeding, 66 percent had uterine tenderness or back pain, and 60 percent had a nonreassuring fetal status. Other findings included frequent contractions and persistent hypertonus. In a fifth of these women, preterm labor was diagnosed, and abruption was not suspected until fetal distress or death ensued.

Importantly, the signs and symptoms of placental abruption can vary considerably. In some women, external bleeding can be profuse, yet placental separation may not be so extensive as to compromise the fetus. In others, there may be no external bleeding, but the placenta is sufficiently sheared off that the fetus is dead—a concealed abruption. In one unusual case, a multiparous woman cared for at Parkland Hospital presented with a nosebleed. She had no abdominal or uterine pain, tenderness, or vaginal bleeding. Her fetus was dead, however, and her blood did not clot. The plasma fibrinogen level was 25 mg/dL. Labor was induced, and a total abruption was confirmed at delivery.

Differential Diagnosis. With severe placental abruption, the diagnosis generally is obvious. From the previous discussion, it follows that less severe, more common forms of abruption cannot always be recognized with certainty. Thus, the diagnosis is one of exclusion. Unfortunately, there are no laboratory tests or other diagnostic methods to accurately confirm lesser degrees of placental separation. Sonography has limited use because the placenta and fresh clots may have similar imaging characteristics. In an early study, Sholl (1987) confirmed the clinical diagnosis with sonography in only 25 percent of women. In a later study, Glantz and Purnell (2002) reported only 24-percent sensitivity in 149 consecutive women with a suspected placental abruption. Importantly, negative findings with sonographic examination do not exclude placental abruption. Conversely, magnetic resonance (MR) imaging is highly sensitive for placental abruption, and if knowledge of this would change management, then it should be considered (Masselli, 2011).

With abruption, intravascular coagulation is almost universal. Thus, elevated serum levels of D-dimers may be suggestive, but this has not been adequately tested. Ngai and associates (2012) have provided preliminary data that serum levels of alpha-fetoprotein > 280 μg/L have a positive-predictive value of 97 percent.

Thus, in the woman with vaginal bleeding and a live fetus, it is often necessary to exclude placenta previa and other causes of bleeding by clinical and sonographic evaluation. It has long been taught—perhaps with some justification—that painful uterine bleeding signifies placental abruption, whereas painless uterine bleeding is indicative of placenta previa. The differential diagnosis is usually not this straightforward, and labor accompanying previa may cause pain suggestive of placental abruption. On the other hand, pain from abruption may mimic normal labor, or it may be painless, especially with a posterior placenta. At times, the cause of the vaginal bleeding remains obscure even after delivery.

Hypovolemic Shock. Placental abruption is one of several notable obstetrical entities that may be complicated by massive and sometimes torrential hemorrhage. Hypovolemic shock is caused by maternal blood loss. In an earlier report from Parkland Hospital, Pritchard and Brekken (1967)
described 141 women with abruption so severe as to kill the fetus. Blood loss in these women often amounted to at least half of their pregnant blood volume. Importantly, massive blood loss and shock can develop with a concealed abruption. Prompt treatment of hypotension with crystalloid and blood infusion will restore vital signs to normal and reverse oliguria from inadequate renal perfusion. In the past, placental abruption was an all-too-common cause of acute kidney injury requiring dialysis (Chap. 53, p. 1063).

Consumptive Coagulopathy. Obstetrical events—mainly placental abruption and amniotic-fluid embolism—led to the initial recognition of defibrination syndrome, which is currently referred to as consumptive coagulopathy or disseminated intravascular coagulation. The major mechanism causing procoagulant consumption is intravascular activation of clotting. Abruption is the most common cause of clinically significant consumptive coagulopathy in obstetrics—and indeed, probably in all of medicine. There are significant amounts of procoagulants in the retroplacental clots, but these cannot account for all missing fibrinogen (Pritchard, 1967). We and others have observed that the levels of fibrin degradation products are higher in serum from peripheral blood compared with that found in serum from blood contained in the uterine cavity (Bonnar, 1969). The reverse would be anticipated in the absence of significant intravascular coagulation.

An important consequence of intravascular coagulation is the activation of plasminogen to plasmin, which lyses fibrin microemboli to maintain microcirculatory patency. With placental abruption severe enough to kill the fetus, there are always pathological levels of fibrinogen–fibrin degradation products and D-dimers in maternal serum.

Most women with placental abruption will have some degree of intravascular coagulation. However, in a third of those with an abruption severe enough to kill the fetus, the plasma fibrinogen level will be < 150 mg/dL. These clinically significant levels may cause troublesome surgical bleeding. Elevated serum levels of fibrinogen-fibrin degradation products, including D-dimers, are also found, but their quantification is not clinically useful. Serum levels of several other coagulation factors are also variably decreased. Thrombocytopenia, sometimes profound, may accompany severe hypofibrinogenemia initially and becomes common after repeated blood transfusions.

Consumptive coagulopathy is more likely with a concealed abruption because intrauterine pressure is higher, thus forcing more thromboplastin into the large veins draining the implantation site. With a partial abruption and a live fetus, severe coagulation defects are seen less commonly. Our experience has been that if serious coagulopathy develops, it is usually evident by the time abruption symptoms appear. Disseminated intravascular coagulation is discussed in more detail on page 808.

Couvelaire Uterus. At the time of cesarean delivery, it is not uncommon to find widespread extravasation of blood into the uterine musculature and beneath the serosa (Fig. 41-18). It is named after Couvelaire, who in the early 1900s termed it uteroplacental apoplexy. Effusions of blood are also seen beneath the tubal serosa, between the leaves of the broad ligaments, in the substance of the ovaries, and free in the peritoneal cavity. These myometrial hemorrhages seldom cause uterine atony, and alone they are not an indication for hysterectomy.
Acute Kidney Injury. Previously known as acute renal failure, acute kidney injury is a general term describing renal dysfunction from many causes (Chap. 53, p. 1063). In obstetrics, it is most commonly seen in cases of severe placental abruption in which treatment of hypovolemia is delayed or incomplete. Even when abruption is complicated by severe intravascular coagulation, however, prompt and vigorous treatment of hemorrhage with blood and crystalloid solution usually prevents clinically significant renal dysfunction. It is unclear what contributory role abruption occupies in the increasing incidence of obstetric-related acute kidney injury in this country (Bateman, 2010; Kuklina, 2009). Undoubtedly, the risk for renal injury with abruption is magnified when preeclampsia coexists (Drakeley, 2002; Hauth, 1999). Currently, most cases of acute kidney injury are reversible and not so severe as to require dialysis. That said, irreversible acute cortical necrosis encountered in pregnancy is most often associated with abruption. In past years, a third of all patients admitted to renal units for chronic dialysis were women who had suffered an abruption (Grünfeld, 1987; Lindheimer, 2007).

Sheehan Syndrome. Rarely, severe intrapartum or early postpartum hemorrhage is followed by pituitary failure—Sheehan syndrome. The exact pathogenesis is not well understood, especially since endocrine abnormalities are infrequent even in women who suffer catastrophic hemorrhage. Findings include failure of lactation, amenorrhea, breast atrophy, loss of pubic and axillary hair, hypothyroidism, and adrenal cortical insufficiency. In some women, there may be varying degrees of anterior pituitary necrosis and impaired secretion of one or more trophic hormones (Matsuwaki,
Management

Treatment of the woman with a placental abruption varies depending primarily on her clinical condition, the gestational age, and the amount of associated hemorrhage. With a living viable-size fetus and with vaginal delivery not imminent, emergency cesarean delivery is chosen by most. In some women, fetal compromise will be evident (Figs. 41-19 and 41-20). When evaluating fetal status, sonographic confirmation of fetal heart activity may be necessary because sometimes an electrode applied directly to a dead fetus will provide misleading information by recording the maternal heart rate. If the fetus has died or if it is not considered mature enough to live outside the uterus, then vaginal delivery is preferable. In either case, prompt and intensive resuscitation with blood plus crystalloid is begun to replace blood lost from retroplacental and external hemorrhage. These measures are lifesaving for the mother and hopefully for her fetus. If the diagnosis of abruption is uncertain and the fetus is alive and without evidence of compromise, then close observation may be warranted provided that immediate intervention is available.

FIGURE 41-19 Placental abruption with fetal compromise. Lower panel: Uterine hypertonus with a baseline pressure of 20 to 25 mm Hg and frequent contractions peaking at approximately 75 mm Hg. Upper panel: The fetal heart rate demonstrates baseline bradycardia with repetitive late decelerations.
Intrapartum placental abruption with acute onset of fetal compromise prompted emergent cesarean delivery. An infant with 1- and 5-minute Apgar scores of 4 and 7, respectively, was delivered.

A major hazard to cesarean delivery is imposed by clinically significant consumptive coagulopathy. As discussed on page 797, this likelihood is lessened if the fetus is still alive—and thus the abruption “less severe.” Preparations include assessment of coagulability—especially fibrinogen content—and plans for blood and component replacement.

Cesarean Delivery. The compromised fetus is usually best served by cesarean delivery, and the speed of response is an important factor in perinatal outcomes (see Fig. 41-20). Kayani and coworkers (2003) studied this relationship in 33 singleton pregnancies with a clinically overt placental abruption and fetal bradycardia. Of the 22 neurologically intact survivors, 15 were delivered within a 20-minute decision-to-delivery interval. However, eight of 11 infants who died or developed cerebral palsy were delivered with an interval > 20 minutes.

Vaginal Delivery. If the fetus has died, then vaginal delivery is usually preferred. As reviewed on page 780, hemostasis at the placental implantation site depends primarily on myometrial contraction and not blood coagulability. Thus, after vaginal delivery, uterotonic agents and uterine massage are used to stimulate myometrial contractions. Fibers compress placental site vessels and prompt hemostasis even if coagulation is defective.

There are exceptions for which vaginal delivery may not be preferable even if the fetus is dead. For example, in some cases, hemorrhage is so brisk that it cannot be successfully managed even by vigorous blood replacement. Obstetrical complications that prohibit vaginal delivery such as a term fetus with a transverse lie are another example. Women with a prior high-risk hysterotomy incision, that is, a prior vertical or classical cesarean delivery, pose a complex situation.

Labor with extensive placental abruption tends to be rapid because the uterus is usually persistently hypertonic. This can magnify fetal compromise (see Fig. 41-19). In some cases, baseline intraamnionic pressures reach 50 mm Hg or higher, and rhythmic increases reach more than 100 mm Hg with contractions.

Early amniotomy has long been championed in the management of placental abruption. This ostensibly achieves better spiral artery compression that might decrease implantation site bleeding.
and reduce thromboplastin infusion into the maternal vascular system. Although evidence supporting this theory is lacking, membrane rupture may hasten delivery. However, if the fetus is small, the intact sac may be more efficient in promoting cervical dilatation. If rhythmic uterine contractions are not superimposed on baseline hypertonus, then oxytocin is given in standard doses. There are no data indicating that oxytocin enhances thromboplastin escape into the maternal circulation to worsen coagulopathy (Clark, 1995; Pritchard, 1967).

In the past, some had set arbitrary time limits to permit vaginal delivery. Instead, experiences indicate that maternal outcome depends on the diligence with which adequate fluid and blood replacement therapy are pursued rather than on the interval to delivery. Observations from Parkland Hospital described by Pritchard and Brekken (1967) are similar to those from the University of Virginia reported by Brame and associates (1968). Specifically, women with severe abruption who were transfused during 18 hours or more before delivery had similar outcomes to those in whom delivery was accomplished sooner.

**Expectant Management with Preterm Fetus.** Delaying delivery may prove beneficial when the fetus is immature. Bond and colleagues (1989) expectantly managed 43 women with placental abruption before 35 weeks’ gestation, and 31 of them were given tocolytic therapy. The mean interval-to-delivery for all 43 was approximately 12 days. Cesarean delivery was performed in 75 percent, and there were no stillbirths. As discussed on page 794, women with a very early abruption frequently develop chronic abruption-oligohydramnios sequence—CAOS. In one report, Elliott and coworkers (1998) described four women with an abruption at a mean gestation of 20 weeks who developed oligohydramnios and delivered at an average gestational age of 28 weeks. In a description of 256 women with an abruption ≤ 28 weeks, Sabourin and colleagues (2012) reported that a mean of 1.6 weeks was gained. Of the group, 65 percent were delivered < 29 weeks, and half of all women underwent emergent cesarean delivery.

Unfortunately, even continuous fetal heart rate monitoring does not guarantee universally good outcomes. For example, a normal tracing may precede sudden further separation with instant fetal compromise as shown in Figure 41-20. In some of these, if the separation is sufficient, the fetus will die before it can be delivered. Tocolysis is advocated by some for suspected abruption if the fetus does not display compromise. One drawback reported in the early study by Hurd (1983) was that abruption went unrecognized for dangerously long periods if tocolysis was initiated. Subsequent studies were more optimistic and observed that tocolysis improved outcomes in a highly selected cohort of women with preterm pregnancies (Bond, 1989; Combs, 1992; Sholl, 1987). In another study, Towers and coworkers (1999) administered magnesium sulfate, terbutaline, or both to 95 of 131 women with abruption diagnosed before 36 weeks. The perinatal mortality rate was 5 percent in both groups with or without tocolysis. We are of the view that until a randomized trial is done, a clinically evident abruption contraindicates tocolytic therapy. This does not preclude magnesium sulfate given for severe gestational hypertension.

---

**Placenta Previa**

The Latin *previa* means going before—and in this sense, the placenta goes before the fetus into the birth canal. In obstetrics, placenta previa describes a placenta that is implanted somewhere in the lower uterine segment, either over or very near the internal cervical os. Because these anatomical relationships cannot always be precisely defined, and because they frequently change across pregnancy, terminology can sometimes be confusing.
Placental Migration

With the frequent use of sonography in obstetrics, the term *placental migration* was used to describe the apparent movement of the placenta away from the internal os (King, 1973). Obviously, the placenta does not move per se, and the mechanism of *apparent* movement is not completely understood. To begin with, *migration* is clearly a misnomer, because decidual invasion by chorionic villi on either side of the cervical os persists. Several explanations are likely additive. First, apparent movement of the low-lying placenta relative to the internal os is related to the imprecision of two-dimensional sonography in defining this relationship. Second, there is differential growth of the lower and upper uterine segments as pregnancy progresses. With greater upper uterine blood flow, placental growth more likely will be toward the fundus—*trophotropism*. Many of those placentas that “migrate” most likely never were circumferentially implanted with true villous invasion that reached the internal cervical os. *Finally, a low-lying placenta is less likely to “migrate” within a uterus with a prior cesarean hysterotomy scar.* Of interest, at the time of delivery there are an equal number of anterior and posterior placentas (Young, 2013).

Placental migration has been quantified in several studies. Sanderson and Milton (1991) studied 4300 women at midpregnancy and found that 12 percent had a low-lying placenta. Of those not covering the internal os, previa did not persist, and none subsequently had placental hemorrhage. Conversely, approximately 40 percent of placentas that covered the os at midpregnancy continued to do so until delivery. Thus, placentas that lie close to but not over the internal os up to the early third trimester are unlikely to persist as a previa by term (Dashe, 2002; Laughon, 2005; Robinson, 2012). Still, Bohrer and associates (2012) reported that a second-trimester low-lying placenta was associated with antepartum admission for hemorrhage and increased blood loss at delivery.

The likelihood that placenta previa persists after being identified sonographically at given epochs before 28 weeks’ gestation is shown in Figure 41-21. Similar findings for twin pregnancies are reported until 23 weeks, after which the previa persistence rate is much higher (Kohari, 2012). A prior uterine incision also has an obvious effect. Stafford and coworkers (2010), but not Trudell and colleagues (2013), found that a previa and a third-trimester cervical length < 30 mm increased the risk for hemorrhage, uterine activity, and preterm birth. Friszer and associates (2013) showed that women admitted for bleeding had a greater chance of delivery by 7 days with the cervix < 25 mm, although Trudell and colleagues (2013) did not confirm this.
FIGURE 41-21 Likelihood of persistence of placenta previa or low-lying placenta at delivery. These are shown as a function of sonographic diagnosis at three pregnancy epochs of a previa or placental edges 1 to 5 mm from the cervical internal os. CD = cesarean delivery. (Data from Oyelese, 2006.)

As indicated and discussed subsequently, persistent previa is more common in women who have had a prior cesarean delivery. In the absence of any other indication, sonography need not be frequently repeated simply to document placental position. Moreover, restriction of activity is not necessary unless a previa persists beyond 28 weeks or if clinical findings such as bleeding or contractions develop before this time.

Classification
Terminology for placenta previa has been confusing. In a recent Fetal Imaging Workshop sponsored by the National Institutes of Health (Dashe, 2013), the following classification was recommended:

- **Placenta previa**—the internal os is covered partially or completely by placenta. In the past, these were further classified as either total or partial previa (Figs. 41-22 and 41-23).
- **Low-lying placenta**—implantation in the lower uterine segment is such that the placental edge does not reach the internal os and remains outside a 2-cm wide perimeter around the os. A previously used term, *marginal previa*, described a placenta that was at the edge of the internal os but did not overlie it.
FIGURE 41-22 Total placenta previa showing that copious hemorrhage could be anticipated with any cervical dilatation.
Clearly, the classification of some cases of previa will depend on cervical dilatation at the time of assessment (Dashe, 2013). For example, a low-lying placenta previa at 2-cm dilatation may become a partial placenta previa at 4-cm dilatation because the cervix has dilated to expose the placental edge (see Fig. 41-23). Conversely, a placenta previa that appears to be total before cervical dilatation may become partial at 4-cm dilatation because the cervical opening now extends beyond the edge of the placenta. *Digital palpation in an attempt to ascertain these changing relations between the placental edge and internal os as the cervix dilates usually causes severe hemorrhage!*

With both total and partial placenta previa, a certain degree of spontaneous placental separation is an inevitable consequence of lower uterine segment remodeling and cervical dilatation.
Although this frequently causes bleeding, and thus technically constitutes a placental abruption, this term is usually not applied in these instances. Somewhat but not always related is *vasa previa*, in which fetal vessels course through membranes and present at the cervical os (Bronsteen, 2013). This is discussed in Chapter 6 (p. 123).

**Incidence and Associated Factors**

Reported incidences for placenta previa average 0.3 percent or 1 case per 300 to 400 deliveries. It was reported to be almost 1 in 300 deliveries in the United States in 2003 (Martin, 2005). The frequency at Parkland Hospital from 1988 through 2012 was approximately 1 in 360 for nearly 366,000 births. Similar frequencies have been reported from Canada, England, and Israel, but it was only 1 in 700 deliveries from a Japanese study (Crane, 1999; Gurol-Urganci, 2011; Matsuda, 2011; Rosenberg, 2011). Except for the last study, these reported frequencies are remarkably similar considering the lack of precision in definition and classification discussed above.

Several factors increase the risk for placenta previa. One of these—multifetal gestation—seems intuitive because of the larger placental area. And indeed, the incidence of associated previa with twin pregnancy is increased by 30 to 40 percent compared with that of singletons (Ananth, 2003a; Weis, 2012). Many of the other associated factors are less intuitive.

**Maternal Age.** The frequency of placenta previa increases with maternal age (Biro, 2012). At Parkland Hospital, this incidence increased from a low rate of approximately 1 in 1660 for women 19 years or younger to almost 1 in 100 for women older than 35 (see Fig. 41-16). Coincidental with increasing maternal age in the United States and Australia, the overall incidence of previa has increased substantively (Frederiksen, 1999; Roberts, 2012). The FASTER Trial, which included more than 36,000 women, cited the frequency of previa to be 0.5 percent for women younger than 35 years compared with 1.1 percent in those older than 35 years (Cleary-Goldman, 2005).

**Multiparity.** The risk for previa increases with parity. The obvious effects of advancing maternal age and parity are confounding. Still, Babinszki and colleagues (1999) reported that the 2.2-percent incidence in women with parity of 5 or greater was increased significantly compared with that of women with lower parity.

**Prior Cesarean Delivery.** The cumulative risks for placenta previa that accrue with the increasing number of cesarean deliveries are extraordinary. In a Network study of 30,132 women undergoing cesarean delivery, Silver and associates (2006) reported an incidence of 1.3 percent for those with only one prior cesarean delivery, but it was 3.4 percent if there were six or more prior cesarean deliveries. In a retrospective cohort of nearly 400,000 women who were delivered of two consecutive singletons, those with a cesarean delivery for the first pregnancy had a significant 1.6-fold increased risk for previa in the second pregnancy (Gurol-Urganci, 2011). These same investigators reported a 1.5-fold increased risk from six similar population-based cohort studies. Gesteland (2004) and Gilliam (2002) and their coworkers calculated that the likelihood of previa was increased more than eightfold in women with parity greater than 4 and who had more than four prior cesarean deliveries.

Importantly, women with a prior uterine incision and placenta previa have an increased likelihood that cesarean hysterectomy will be necessary for hemostasis because of an associated accrete syndrome (p. 804). In the study by Frederiksen and colleagues (1999), 6 percent of women who had a primary cesarean delivery for previa required a hysterectomy. This rate was 25 percent
Cigarette Smoking. The relative risk of placenta previa is increased at least twofold in women who smoke (Ananth, 2003a; Usta, 2005). It has been postulated that carbon monoxide hypoxemia causes compensatory placental hypertrophy and more surface area. Smoking may also be related to decidual vasculopathy that has been implicated in the genesis of previa.

Elevated Prenatal Screening MSAFP Levels. Women who have otherwise unexplained abnormally elevated prenatal screening levels of maternal serum alpha-fetoprotein (MSAFP) are at increased risk for previa and a host of other abnormalities as discussed on page 806. Moreover, women with a previa who also had a MSAFP level ≥ 2.0 MoM at 16 weeks’ gestation were at increased risk for late-pregnancy bleeding and preterm birth. Screening with MSAFP is considered in detail in Chapter 14 (p. 284).

Clinical Features
Painless bleeding is the most characteristic event with placenta previa. Bleeding usually does not appear until near the end of the second trimester or later, but it can begin even before midpregnancy. And undoubtedly, some late abortions are caused by an abnormally located placenta. Bleeding from a previa usually begins without warning and without pain or contractions in a woman who has had an uneventful prenatal course. This so-called sentinel bleed is rarely so profuse as to prove fatal. Usually it ceases, only to recur. In perhaps 10 percent of women, particularly those with a placenta implanted near but not over the cervical os, there is no bleeding until labor onset. Bleeding at this time varies from slight to profuse, and it may clinically mimic placental abruption.

A specific sequence of events leads to bleeding in cases in which the placenta is located over the internal os. First, the uterine body remodels to form the lower uterine segment. With this, the internal os dilates, and some of the implanted placenta inevitably separates. Bleeding that ensues is augmented by the inherent inability of myometrial fibers in the lower uterine segment to contract and thereby constrict avulsed vessels. Similarly, bleeding from the lower segment implantation site also frequently continues after placental delivery. Last, there may be lacerations in the friable cervix and lower segment. This may be especially problematic following manual removal of a somewhat adhered placenta.

Abnormally Implanted Placenta. A frequent and serious complication associated with placenta previa arises from its abnormally firm placental attachment. This is anticipated because of poorly developed decidua that lines the lower uterine segment. Biswas and coworkers (1999) performed placental bed biopsies in 50 women with a previa and in 50 control women. Trophoblastic giant-cell infiltration of spiral arterioles—rather than endovascular trophoblast—was found in half of previa specimens. However, only 20 percent from normally implanted placentas had these changes.

Placenta accrete syndromes arise from abnormal placental implantation and adherence and are classified according to the depth of placental ingrowth into the uterine wall. These include placenta accreta, increta, and percreta (p. 804). In a study of 514 cases of previa reported by Frederiksen and associates (1999), abnormal placental attachment was identified in 7 percent. As discussed above, previa overlying a prior cesarean incision conveys a particularly high risk for accreta.

Coagulation Defects. Placenta previa is rarely complicated by coagulopathy even when there is
extensive implantation site separation (Wing, 1996b). Placental thromboplastin, which incites the intravascular coagulation seen with placental abruption, is presumed to readily escape through the cervical canal rather than be forced into the maternal circulation. The paucity of large myometrial veins in this area may also be protective.

**Diagnosis**

Whenever there is uterine bleeding after midpregnancy, placenta previa or abruption should always be considered. In the Canadian Perinatal Network study discussed on page 783, placenta previa accounted for 21 percent of women admitted from 22 to 28 weeks’ gestation with vaginal bleeding (Sabourin, 2012). Previa should not be excluded until sonographic evaluation has clearly proved its absence. Diagnosis by clinical examination is done using the *double set-up* technique because it requires that a finger be passed through the cervix and the placenta palpated. A digital examination should not be performed unless delivery is planned. *A cervical digital examination is done with the woman in an operating room and with preparations for immediate cesarean delivery. Even the gentlest examination can cause torrential hemorrhage.* Fortunately, double set-up examination is rarely necessary because placental location can almost always be ascertained sonographically.

**Sonographic Placental Localization.** Quick and accurate localization can be accomplished using standard sonographic techniques (Dashe, 2013). In many cases, *transabdominal sonography* is confirmatory, as shown in Figure 41-24A, and an average accuracy of 96 percent has been reported (Laing, 1996). Imprecise results may be caused by bladder distention, so doubtful cases should be confirmed after bladder emptying. Moreover, sometimes a large fundal placenta is not appreciated to extend down to the internal cervical os. *Transvaginal sonography* is safe, and the results are superior as shown in Figures 41-24B and 41-25. In a comparative study by Farine and associates (1988), the internal os was visualized in all cases using transvaginal sonography but was seen in only 70 percent using transabdominal sonography. Transperineal sonography is also accurate to localize placenta previa (Hertzberg, 1992). In a study by Rani and colleagues (2007), placenta previa was correctly identified in 69 of 70 women and was confirmed at delivery. They reported the positive-predictive value to be 98 percent, whereas the negative-predictive value was 100 percent.
FIGURE 41-24 Total placenta previa. A. Transabdominal sonogram shows placenta (white arrowheads) covering the cervix (black arrows). B. Transvaginal sonogram shows placenta (arrows), lying between the cervix and fetal head.
FIGURE 41-25 Transvaginal sonogram of an anterior placenta previa at 36 weeks’ gestation. The placental margin (red arrow) extends downward toward the cervix. The internal os (yellow arrow) and cervical canal (short white arrows) are marked to show their relationship to the leading edge of the placenta.

Magnetic Resonance Imaging. Although several investigators have reported excellent results using MR imaging to visualize placental abnormalities, it is unlikely that this technique will replace sonography for routine evaluation anytime soon. That said, MR imaging has proved useful for evaluation of placenta accreta (p. 807).

Management of Placenta Previa

Women with a previa are managed depending on their individual clinical circumstances. The three factors that usually are considered include fetal age and thus maturity; labor; and bleeding and its severity.

If the fetus is preterm and there is no persistent active bleeding, management favors close observation in an obstetrical unit. Data are sparse regarding tocolytic administration for uterine contractions. Although good randomized trials are lacking, Bose and colleagues (2011) recommend that if tocolytics are given, they be limited to 48 hours of administration. We categorically recommend against their use in this setting. After bleeding has ceased for about 2 days and the fetus is judged to be healthy, the woman can usually be discharged home. Importantly, the woman and her family must fully appreciate the possibility of recurrent bleeding and be prepared for immediate transport back to the hospital. In other cases, prolonged hospitalization may be ideal.

In properly selected patients, there appear to be no benefits to inpatient compared with
outpatient management (Mouer, 1994; Neilson, 2003). In a randomized study by Wing and colleagues (1996a), no differences in maternal or fetal morbidity were noted with either management method. This trial of inpatient versus home management included 53 women who had a bleeding previa at 24 to 36 weeks’ gestation. Of these 53 women, 60 percent had recurrent bleeding. Also, of all 53 women, half eventually required expeditious cesarean delivery. Home management is more economical. In one study, hospital stay length and costs for mother-infant care were reduced by half with outpatient management (Drost, 1994).

For women who are near term and who are not bleeding, plans are made for scheduled cesarean delivery. Timing is important to maximize fetal growth but to minimize the possibility of antepartum hemorrhage. A National Institutes of Health workshop concluded that women with a previa are best served by elective delivery at 36 to 37 completed weeks (Spong, 2011). With suspected placenta accrete syndromes, delivery was recommended at 34 to 35 completed weeks. At Parkland Hospital, we prefer to wait until 37 to 38 weeks before delivery (p. 807).

Delivery

Practically all women with placenta previa undergo cesarean delivery. Many surgeons recommend a vertical skin incision. Cesarean delivery is emergently performed in more than half because of hemorrhage, for which about a fourth require blood transfusion (Boyle, 2009; Sabourin, 2012). Although a low transverse hysterotomy is usually possible, this may cause fetal bleeding if there is an anterior placenta and the placenta is cut through. In such cases, fetal delivery should be expeditious. Thus, a vertical uterine incision may be preferable in some instances. That said, even when the incision extends through the placenta, maternal or fetal outcomes are rarely compromised.

Following placental removal, there may be uncontrollable hemorrhage because of poorly contracted smooth muscle of the lower uterine segment. When hemostasis at the placental implantation site cannot be obtained by pressure, the implantation site can be oversewn with 0-chromic sutures. Cho and associates (1991) described interrupted 0-chromic sutures at 1-cm intervals to form a circle around the bleeding portion of the lower segment to control hemorrhage in all eight women in whom it was employed. Huissoud and coworkers (2012) also described use of circular sutures. Kayem (2011) and Penotti (2012) and their colleagues reported that only 2 of 33 women with a previa and no accreta who had anterior-posterior uterine compression sutures required hysterectomy. Kumru and associates (2013) reported success with the Bakri balloon in 22 of 25 cases. Diemert and coworkers (2012) described good results with combined use of a Bakri balloon and compression sutures. Albayrak and colleagues (2011) described Foley balloon tamponade. Druzin (1989) proposed tightly packing the lower uterine segment with gauze, and the pack was removed transvaginally 12 hours later. Law and coworkers (2010) reported successful use of hemostatic gel. Other methods include bilateral uterine or internal iliac artery ligation as described on page 819. Finally, pelvic artery embolization as described on page 820 has also gained acceptance.

If these more conservative methods fail and bleeding is brisk, then hysterectomy is necessary. Placenta previa—especially with abnormally adhered placental variations—currently is the most frequent indication for peripartum hysterectomy at Parkland Hospital and from other reports (Wong, 2011). It is not possible to accurately estimate the impact on hysterectomy from previa alone without considering the associated accrete syndromes. Again, for women whose placenta previa is implanted anteriorly at the site of a prior uterine incision, there is an increased likelihood of associated placenta accrete syndrome and need for hysterectomy. In a study of 318 peripartum hysterectomies from in the United Kingdom, 40 percent were done for abnormally...
implanted placentation (Knight, 2007). At Parkland Hospital, 44 percent of cesarean
hysterectomies were done for bleeding placenta previa or placenta accrete syndrome. In an
Australian study of emergency peripartum hysterectomy, 19 percent were done for placenta previa,
and another 55 percent for a morbidly adhered placenta (Awan, 2011). The technique for
peripartum hysterectomy is described in Chapter 30 (p. 599).

**Maternal and Perinatal Outcomes**

A marked reduction in maternal mortality rates from placenta previa was achieved during the last
half of the 20th century. Still, as shown in Figure 41-2, placenta previa and coexistent accrete
syndromes both contribute substantively to maternal morbidity and mortality. In one review, there
was a threefold increased maternal mortality ratio of 30 per 100,000 for women with previa
(Oyelese, 2006). In another report of 4693 maternal deaths in the United States, placenta previa
and accrete syndromes accounted for 17 percent of deaths from hemorrhage (Berg, 2010).

The report from the Consortium on Safe Labor emphasizes the ongoing perinatal morbidity with
placenta previa (Lai, 2012). Preterm delivery continues to be a major cause of perinatal death
(NØrgaard, 2012). For the United States in 1997, Salihu and associates (2003) reported a
threefold increased neonatal mortality rate with placenta previa that was caused primarily from
preterm delivery. Ananth and colleagues (2003b) reported a comparably increased risk of neonatal
death even for fetuses delivered at term. This is at least partially related to fetal anomalies, which
are increased two- to threefold in pregnancies with placenta previa (Crane, 1999).

The association of fetal-growth restriction with placenta previa is likely minimal after
controlling for gestational age (Crane, 1999). In a population-based cohort of more than 500,000
singleton births, Ananth and associates (2001a) found that most low-birthweight infants associated
with placenta previa resulted from preterm birth. Harper and coworkers (2010) reported similar
findings from a cohort of nearly 58,000 women who underwent routine second-trimester
sonographic evaluation at their institution.

### Placenta Accrete Syndromes

These syndromes describe the abnormally implanted, invasive, or adhered placenta. Derivation of
accrete comes from the Latin ac- + crescere—to grow from adhesion or coalescence, to adhere,
or to become attached to (Benirschke, 2012). Accrete syndromes thus include any placental
implantation with abnormally firm adherence to myometrium because of partial or total absence of
the decidua basalis and imperfect development of the fibrinoid or Nitabuch layer. If the decidual
spongy layer is lacking either partially or totally, then the physiological line of cleavage is absent,
and some or all cotyledons are densely anchored. The surface area of the implantation site
involved and the depth of trophoblastic tissue ingrowth are variable between women, but all
affected placentas can potentially cause significant hemorrhage.

Accrete syndromes have evolved into one of the most serious problems in obstetrics. As
subsequently discussed, the likelihood of placenta accrete syndrome is closely linked to prior
uterine surgery. Thus, related to the increasing and current all-time high rate of cesarean delivery
in the United States, the frequency of placenta accrete syndromes has reached seemingly epidemic
proportions. And, at least until recently, there seems to be no consensus for management (Wright,
2013). To better codify some of the serious consequences associated with accrete syndromes, the
American College of Obstetricians and Gynecologists (2012b) and the Society for Maternal-Fetal
Medicine (2010) have taken the lead to address management problems. Accrete syndromes have
also been the subject of recent reviews (Rao, 2012; Wortman, 2013a).
Etiopathogenesis

Microscopically, placental villi are anchored to muscle fibers rather than to decidual cells. Decidual deficiency then prevents normal placental separation after delivery. Intuitive thinking and now substantiated data suggest that accrete syndromes are not solely caused by an anatomical layer deficiency (Tantbirojn, 2008). Evidence indicates that the cytotrophoblasts may control decidual invasion through factors such as angiogenesis and growth expression (Cohen, 2010; Duzyj, 2013; Wehrum, 2011). Indeed, accrete syndrome tissue specimens have shown evidence for “hyperinvasiveness” compared with otherwise uncomplicated previa specimens (Pri-Paz, 2012). The distribution of large vessels is different than that seen with nonaccrete placentas (Chantraine, 2012). As described by Benirschke and colleagues (2012), there is an antecedent “constitutional endometrial defect” in most cases. The increased risk conveyed by previous uterine trauma—for example, cesarean delivery—may be partially explained by an increased vulnerability of the decidua to trophoblast invasion following incision into the decidua (Garmi, 2012).

Classification

Variants of placenta accrete syndrome are classified by the depth of trophoblastic growth (Fig. 41-26). Placenta accreta indicates that villi are attached to the myometrium. With placenta increta, villi actually invade the myometrium, and placenta percreta defines villi that penetrate through the myometrium and to or through the serosa. In clinical practice, these three variants are encountered in an approximate ratio of 80:15:5, respectively (Wong, 2008). In all three varieties, abnormal adherence may involve all lobules—total placenta accreta (Fig. 41-27). If all or part of a single lobule is abnormally attached, it is described as a focal placenta accreta. Histological diagnosis cannot be made from the placenta alone, and the uterus or curettings with myometrium are necessary for histopathological confirmation (Benirschke, 2012).
percreta.

Black arrows show the invading line of the placenta through the myometrium. (Photograph courtesy of Dr. Thomas R. Dowd). **B.** Hysterectomy specimen containing a partial placenta previa with placenta percreta that invaded the lateral fundal region to cause hemoperitoneum.

**Incidence and Associated Conditions**

The increased frequency of accrete syndromes during the past 50 years stems from the liberalized use of cesarean delivery. In 1924, Polak and Phelan presented their data from Long Island College Hospital, which had one case of placenta accreta complicating 6000 deliveries. In a 1951 review, a maternal mortality rate of up to 65 percent was cited (McKeogh, 1951). In 1971, in the 14th edition of *Williams Obstetrics*, Hellman and Pritchard described placenta accreta as the subject of case reports. In a review several years later, Breen and coworkers (1977) cited a reported average incidence of 1 in 7000 deliveries.

Since these reports, however, the incidence of accrete syndromes has increased remarkably, in direct relationship to the increasing cesarean delivery rate (Chap. 31, p. 618). The incidence of placenta accrete syndrome was cited as 1 in 2500 in the 1980s, and currently, the American College of Obstetricians and Gynecologists (2012b) cites it to be as high as 1 in 533 deliveries. Because of this increasing frequency, accrete syndromes are now one of the most serious problems in obstetrics. In addition to their significant contribution to maternal morbidity and mortality, accrete syndromes are a leading cause of intractable postpartum hemorrhage and emergency peripartum hysterectomy (Awan, 2011; Eller, 2011; Rossi, 2010). Their contribution as a cause of maternal deaths from hemorrhage is shown in Figure 41-2. In *their review of nearly 10,000 pregnancy-related maternal deaths in the United States*, Berg and associates (2010) reported that 8 percent of deaths due to hemorrhage were caused by accrete syndromes.
Risk Factors

These are similar in many aspects to those for placenta previa (p. 801). That said, the two most important risk factors are an associated previa, a prior cesarean delivery, and more likely a combination of the two. In one study, an accrete placenta more likely followed emergency compared with elective cesarean delivery (Kamara, 2013). A classical hysterotomy incision has a higher risk for a subsequent accrete placenta (Gyamfi-Bannerman, 2012). Decidual formation may be defective over a previous hysterotomy scar, and it also may follow any type of myometrial trauma such as curettage (Benirschke, 2012). Myomectomy apparently confers a low risk (Gyamfi-Bannerman, 2012). In one study, 10 percent of women with a previa had an associated accrete placenta. In another study, almost half of women with a prior cesarean delivery had myometrial fibers seen microscopically adhered to the placenta (Hardardottir, 1996; Zaki, 1998). Findings from a Maternal-Fetal Medicine Units Network study by Silver and colleagues (2006) of women with one or more prior cesarean deliveries who also had a placenta previa are shown in Figure 41-28. The astonishing increase in frequency of associated accrete syndromes is apparent.

Another risk factor became apparent with widespread use of MSAFP and human chorionic gonadotropin (hCG) screening for neural-tube defects and aneuploidies (Chap. 14, p. 285). In a study reported by Hung (1999) of more than 9300 women screened at 14 to 22 weeks, the risk for accrete syndromes was increased eightfold with MSAFP levels > 2.5 MoM, and it was increased fourfold when maternal free β-hCG levels were > 2.5 MoM.

Cesarean-Scar Pregnancy. In some women with an accrete placenta, there may be adverse outcomes before fetal viability. One presentation generally referred to as a cesarean scar pregnancy clinically is similar to that of an ectopic pregnancy. Its frequency has been reported to...
be approximately 1 in 2000 pregnancies (Ash, 2007; Rotas, 2006). Timor-Tritsch (2012) provided a scholarly review of 751 such cases, and the subject is discussed in detail in Chapter 19 (p. 391).

Clinical Presentation and Diagnosis

In cases of first- and second-trimester accrete syndromes, there is usually hemorrhage that is the consequence of coexisting placenta previa. Such bleeding will usually prompt evaluation and management. In some women who do not have an associated previa, accreta may not be identified until third-stage labor when an adhered placenta is encountered.

Ideally, abnormal placental ingrowth is identified antepartum, usually by sonography (Chantraine, 2013; Tam Tam, 2012). For gray-scale transvaginal sonography, the American College of Obstetricians and Gynecologists (2012b) cites a sensitivity of 77 to 87 percent, specificity of 96 to 98 percent, and a positive- and negative-predictive value of 65 to 93 and 98 percent, respectively. Individual studies have reported similar findings (Chalubinski, 2013; Elhawary, 2013; Maher, 2013). Although controversial, at Parkland Hospital, we have found that the addition of Doppler color flow mapping is highly predictive of myometrial invasion (Fig. 41-29). This is suspected if the distance between the uterine serosa-bladder wall interface and the retroplacental vessels is < 1 mm and if there are large intraplacental lacunae (Twickler, 2000). Similarly, Cali and associates (2013) reported that hypervascularity of the uterine serosa-bladder wall interface had the highest positive- and negative-predictive values for placenta percreta.

FIGURE 41-29 Transvaginal sonogram of placental invasion with accrete syndrome. Retroplacental vessels (white arrows) invade the myometrium and obscure the bladder-serosal interface. Abnormal intraplacental venous lakes (black arrowheads) are commonly seen in this setting.

MR imaging can be used as an adjunct to sonography to define anatomy, degree of invasion, and possible ureteral or bladder involvement (Chalubinski, 2013; Palacios Jaraquemada, 2005). La
and coworkers (2007) identified three MR imaging findings that suggested accreta. These include uterine bulging, heterogeneous signal intensity within the placenta, and dark intraplacental bands on T2-weighted imaging. Some suggest MR imaging when sonography results are inconclusive or there is a posterior previa (American College of Obstetricians and Gynecologists, 2012b Elhawary, 2013).

Management

Preoperative assessment should begin at the time of recognition during prenatal care (Fitzpatrick, 2014; Sentilhes, 2013). A major decision concerns the ideal institution for delivery. Exigencies to be considered are appropriate surgical, anesthesia, and blood banking capabilities. An obstetrical surgeon or gynecological oncologist as well as surgical, urological, and interventional radiological consultants should all be available (Eller, 2011; Stafford, 2008). The American College of Obstetricians and Gynecologists (2012b) and the Society for Maternal-Fetal Medicine (2010) recommend planned delivery in a tertiary-care facility. In some of these, especially designed teams have been assembled and are on call (Walker, 2013). Women who refuse blood or its derivatives pose especially difficult management decisions (Barth, 2011). If possible, delivery is best scheduled for peak availability of all resources and team members. However, emergency contingent plans should also be in place.

Timing of Delivery. To accomplish scheduled surgical intervention, preterm delivery is necessary and justified given the serious adverse maternal consequences of emergency cesarean delivery. The American College of Obstetricians and Gynecologists (2012b) recommends individualization of delivery timing. It cites a decision-analysis study that justifies elective delivery without fetal lung maturity testing after 34 completed weeks (Robinson, 2010). The results of two recent surveys indicate that most practitioners do not deliver these women until 36 weeks or later (Esakoff, 2012; Wright, 2013). At Parkland Hospital, we generally schedule these procedures after 36 completed weeks but are prepared also to manage them in nonelective situations.

Preoperative Arterial Catheterization. There has been enthusiasm for placement of intraarterial catheters to mitigate blood loss and to enhance surgical visibility. Balloon-tipped catheters advanced into the internal iliac arteries are inflated after delivery to occlude pelvic blood flow to aid placental removal and hysterectomy (Ballas, 2012; Desai, 2012). Alternatively, the catheters can be used to embolize bleeding arterial sites. Others have concluded that these procedures offer borderline efficacy and have serious risks (Sentilhes, 2009; Yu, 2009). Complications have included thromboses of the common and left iliac arteries (Bishop, 2011; Greenberg, 2007). At this time, we agree with the American College of Obstetricians and Gynecologists (2012b) that a firm recommendation cannot be made for or against their use.

Cesarean Delivery and Hysterectomy. Before commencing with delivery, the risk of hysterectomy to prevent exsanguination should be estimated. Confirmation of a percreta or increta almost always mandates hysterectomy. However, some of these abnormal placentations, especially if partial, may be amenable to placental delivery with hemostatic suture placement. Because the scope of invasion may not be apparent before delivery of the fetus, we usually attempt to create a wide bladder flap before making the hysterotomy incision. The round ligaments are divided, and the lateral edges of the peritoneal reflection are dissected downward. If possible, these incisions are extended to encircle the entire placental implantation site that visibly occupies the prevesical space and posterior bladder wall. Following this, a classical hysterotomy incision is made to avoid the placenta and profuse hemorrhage before fetal delivery. Some advocate a transverse
fundal incision if the placenta occupies the entire anterior wall (Kotsuji, 2013).

After fetal delivery, the extent of placental invasion is assessed without attempts at manual placental removal. In a report from the United Kingdom, attempts for partial or total placental removal prior to hysterectomy were associated with twice as much blood loss (Fitzpatrick, 2014). Generally speaking, with obvious percreta or increta, hysterectomy is usually the best course, and the placenta is left in situ. As discussed in Chapter 36 (p. 670), a focal partial accreta may avulse easily and later emerge as a placental polyp (Benirschke, 2012). With more extensive placental ingrowth—even with total accreta—there may be little or no bleeding until manual placental removal is attempted. Unless there is spontaneous separation with bleeding that mandates emergency hysterectomy, the operation begins after full assessment is made. With bleeding, successful treatment depends on immediate blood replacement therapy and other measures that include uterine or internal iliac artery ligation, balloon occlusion, or embolization. Various case reports have described argon beam coagulation and hemostatic combat gauze (Karam, 2003; Schmid, 2012).

Leaving the Placenta in Situ. In a few cases, after the fetus has been delivered, it may be possible to trim the umbilical cord and repair the hysterotomy incision but leave the placenta in situ. This may be wise for women in whom abnormal placentation was not suspected before cesarean delivery and in whom uterine closure stops bleeding. After this, she can be transferred to a higher-level facility for definitive management. Another consideration is the woman with a strong desire for fertility and who has received extensive counseling. In some cases, the placenta spontaneously resorbs. In others, a subsequent hysterectomy—either planned or prompted by bleeding or infection—is performed weeks postpartum when blood loss might be lessened (Hays, 2008; Kayem, 2002; Lee, 2008; Timmermans, 2007). Of 26 women treated this way, 21 percent ultimately required hysterectomy. Of the remainder, most required additional medical and surgical interventions for bleeding and infection (Bretelle, 2007). Evidence that treatment with methotrexate aids resorption is lacking. We agree with the American College of Obstetricians and Gynecologists (2012b) that this method of management is seldom indicated. For women in whom the placenta is left in situ, serial serum β-hCG measurements are not informative, and serial sonographic or MR imaging is recommended (Timmermans, 2007; Worley, 2008).

Pregnancy Outcomes

Reports describing outcomes with accrete syndromes have limited numbers of patients. That said, two large series provide data from which some basic observations can be made. First, these syndromes can have disastrous outcomes for both mother and fetus. Although the depth of placental invasion does not correspond with perinatal outcome, it is of paramount maternal significance (Seet, 2012). Shown in Table 41-5 are outcomes from three reports of women from tertiary-care hospitals and in whom the diagnosis of accrete placenta was made preoperatively. Despite these advantages, a litany of complications included hemorrhage, urinary tract injury, ICU admission, and secondary surgical procedures. These reports chronicled outcomes in a second cohort of women in whom care was not given at a tertiary-care facility or in whom the diagnosis of accrete placenta was not made until delivery, or both. In these cohorts, morbidity was higher, and there was one maternal death.

<table>

</tr>
</thead>
</table>

Second, in the Utah experiences, attempts at placental removal increased morbidity significantly—67 versus 36 percent—compared with no attempts at removal before hysterectomy. They also found that preoperative bilateral ureteral stenting reduced morbidity. However, no benefits accrued from internal iliac artery ligation (Eller, 2011; Po, 2012). Our management at Parkland Hospital is similar, however, the final decision for hysterectomy is not made until assessment at delivery. Also, we do not routinely perform preoperative ureteral stent placement. We have at times inserted stents transvesically if indicated intraoperatively. As discussed on page 820, preoperative arterial catheterization may be beneficial (Desai, 2012).

### Subsequent Pregnancy

There is some evidence that women with accrete syndromes have an increased risks for recurrence, uterine rupture, hysterectomy, and previa (Eshkoli, 2013).

### CONSUMPTIVE COAGULOPATHY

Obstetrical syndromes commonly termed *consumptive coagulopathy* or *disseminated intravascular coagulation (DIC)* were described in the 1901 report by DeLee in which “temporary hemophilia” developed with placental abruption or with a long-dead macerated fetus.
In ensuing decades, similar—but frequently less intense—coagulopathic syndromes have been described for almost all areas of medicine (Levi, 2010b; Montagnana, 2010).

Disseminated Intravascular Coagulation in Pregnancy

Because of many definitions used and its variable severity, citing an accurate incidence for consumptive coagulopathy is not possible in pregnant women. For example, as will be discussed, some degree of significant coagulopathy is found with most cases of placental abruption and amniotic-fluid embolism. Other instances in which frequently occurring but insignificant degrees of coagulation activation can be found include sepsis, thrombotic microangiopathies, acute kidney injury, and preeclampsia and HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndromes (Rattray, 2012; Su, 2012). Although profound consumptive coagulopathy can be associated with fatty liver disease of pregnancy, diminished hepatic synthesis of procoagulants makes a significant contribution (Nelson, 2013).

When consumptive coagulopathy is severe, the likelihood of maternal and perinatal morbidity and mortality is increased. Rattray and colleagues (2012) described 49 cases from Nova Scotia during a 30-year period. Antecedent causes included placental abruption, obstetrical hemorrhage, preeclampsia and HELLP syndromes, acute fatty liver, sepsis, and amniotic-fluid embolism. Of these, 59 percent received blood transfusions, 18 percent underwent hysterectomy, 6 percent were dialyzed, and there were three maternal deaths. The perinatal mortality rate was 30 percent.

Pregnancy-Induced Coagulation Changes

Several changes in coagulation and fibrinolysis can be documented during normal pregnancy. Some of these include appreciable increases in the plasma concentrations of factors I (fibrinogen), VII, VIII, IX, and X. A partial list of these normal values can be found in the Appendix (p. 1288) and in Chapter 4 (p. 57). At the same time, plasminogen levels are increased considerably, but levels of plasminogen activator inhibitor-1 and -2 (PAI-1 and PAI-2) also increase. Thus, plasmin activity usually decreases until after delivery (Hale, 2012; Hui, 2012). The mean platelet count decreases by 10 percent during pregnancy, and there is increased platelet activation (Kenny, 2014).

The net results of these changes include increased levels of fibrinopeptide A, β-thromboglobulin, platelet factor 4, and fibrinogen-fibrin degradation products, which includes d-dimers. Along with decreased concentrations of anticoagulant protein S, hypercoagulability, and decreased fibrinolysis, there is augmented—yet compensated—intravascular coagulation that may function to maintain the uteroplacental interface.

Pathological Activation of Coagulation

Normal coagulation and fibrinolysis can be pathologically activated via two pathways. The extrinsic pathway is active by thromboplastin from tissue destruction, whereas the intrinsic pathway is initiated by collagen and other tissue components that become exposed with loss of endothelial integrity (Fig. 41-30). Tissue factor III is an integral membrane protein. It is released by endothelial cells to complex with factor VII, which in turn activates tenase (factor IX) and prothrombinase (factor X) complexes. Uncontrolled thrombin generation converts fibrinogen to fibrin, which polymerizes to deposit in small vessels of virtually every organ system. This seldom causes organ failure, because these vessels are protected by enhanced fibrinolysis stimulated by fibrin monomers released by coagulation. These monomers combine with tissue plasminogen
activator and plasminogen to release plasmin, which lyses fibrinogen and fibrin monomers and polymers. The products form a series of fibrinogen-fibrin derivatives that are measured by immunoassay. These are the fibrin degradation products or fibrin-split products, which include \( \alpha \)-dimers (see Fig. 41-30). There may also be evidence for microangiopathic hemolysis from mechanical trauma to the red cell membrane by fibrin strands in small vessels. This is likely a contributing cause of hemolysis in women with preeclampsia and HELLP syndromes (Pritchard 1976a).

**FIGURE 41-30** Mechanisms of coagulation and fibrinolysis.

The pathologically activated cycle of coagulation and fibrinolysis becomes clinically important when coagulation factors and platelets are sufficiently depleted to cause bleeding—hence, consumptive coagulopathy. Several obstetrical conditions are accompanied by release of potent
inciting factors for clinically significant consumptive coagulation. The best known and most common, and therefore most serious, results from thromboplastin release with placental abruption. Also, unique to obstetrics is the immediate and profound coagulation factor depletion that can follow entry of amniotic fluid into the maternal circulation. This causes activation of factor X by abundant mucin in fetal squames. Other causes include activation by release of endotoxins from gram-negative bacteria and exotoxins from gram-positive bacteria.

**Diagnosis**

The International Society on Thrombosis and Haemostasis has promulgated a DIC score to aid identification and prognosis prediction (Taylor, 2001). This algorithm, shown in Table 41-6, has not been applied in obstetrical conditions but can serve as a rough guideline to identify a pregnant woman with consumptive coagulopathy. Again, although not including obstetrical patients, the Prowess Trial evaluated 840 subjects with severe sepsis. The mortality rate increased from approximately 25 percent with a DIC score of 3 to 70 percent with a score of 7 (Dhainaut, 2004).

**Evaluation and Management**

Obstetrical causes of consumptive coagulopathy are almost always due to an identifiable, underlying pathological process that must be eliminated to halt ongoing defibrination. Thus, prompt
Identification and removal of the source of the coagulopathy is given priority. With surgical incisions or extensive lacerations accompanied by severe hemorrhage, rapid replacement of procoagulants is usually indicated. Vigorous restoration and maintenance of the circulation to treat hypovolemia cannot be overemphasized. With adequate perfusion, activated coagulation factors, fibrin, and fibrin degradation products are promptly removed by the reticuloendothelial system, along with restoration of hepatic and endothelial synthesis of procoagulants.

Some treatments for intravascular coagulation have been conceived by armchair theorists and are mentioned here only to be condemned. For example, in years past, some recommended heparin administration to block consumption of procoagulants. Others recommended epsilon-aminocaproic acid to inhibit fibrinolysis by blocking plasminogen conversion to plasmin. The dangers of giving heparin to an actively bleeding woman are obvious. Fibrinolysis inhibition is probably not quite as dangerous, but any putative benefits remain unproven.

**Identification of Defective Hemostasis.** Bioassay is an excellent method to detect or suspect clinically significant coagulopathy. *Excessive bleeding at sites of modest trauma characterizes defective hemostasis.* Examples include persistent bleeding from venipuncture sites, nicks from shaving the perineum or abdomen, trauma from bladder catheterization, and spontaneous bleeding from the gums, nose, or gastrointestinal tract. Purpuric areas at pressure sites such as sphygmomanometer cuffs or tourniquets suggest significant thrombocytopenia. As discussed, any surgical procedure provides the ultimate bioassay and elicits generalized oozing from the skin, subcutaneous and fascial tissues, the retroperitoneal space, the episiotomy, or incisions and dissections for cesarean delivery or hysterectomy.

**Fibrinogen and Degradation Products.** In late pregnancy, plasma fibrinogen levels typically have increased to 300 to 600 mg/dL. Even with severe consumptive coagulopathy, levels may sometimes be high enough to protect against clinically significant hypofibrinogenemia. For example, defibrination caused by a placental abruption might lower an initial fibrinogen level of 600 mg/dL to 250 mg/dL. Although this would indicate massive fibrinogen consumption, there are still adequate levels to promote clinical coagulation—usually about 150 mg/dL. If serious hypofibrinogenemia—less than 50 mg/dL—is present, the clot formed from whole blood in a glass tube may initially be soft but not necessarily remarkably reduced in volume. Then, over the next half hour or so, as platelet-induced clot retraction develops, the clot becomes quite small. When many of the erythrocytes are extruded, the volume of liquid in the tube clearly exceeds that of clot.

Fibrinolysis cleaves fibrin and fibrinogen into various fibrin degradation products that are detected by several sensitive test systems. There are many fragment types, and monoclonal antibodies in assay kits usually measure d-dimers specific for that assay. These values are always abnormally high with clinically significant consumptive coagulopathy. At least in obstetrical disorders, quantification has not been correlated with outcomes, although “moderate” to “strong” increases constitute part of the diagnostic algorithm shown in Table 41-6.

**Thrombocytopenia**

Seriously low platelet concentrations are likely if petechiae are abundant or if clotted blood fails to retract within an hour or so. Confirmation is provided by a platelet count. If there is associated severe preeclampsia syndrome, there may also be qualitative platelet dysfunction (Chap. 40, p. 738).
Prothrombin and Partial Thromboplastin Times

Prolongation of these standard coagulation tests may result from appreciable reductions in procoagulants essential for generating thrombin, from very low fibrinogen concentrations, or from appreciable amounts of circulating fibrinogen-fibrin degradation products. Prolongation of the prothrombin time and partial thromboplastin time need not be the consequence of consumptive coagulopathy.

### Placental Abruption

This is the most common cause of severe consumptive coagulopathy in obstetrics and is discussed on page 793.

### Preeclampsia Syndrome

Endothelial activation or injury is a hallmark of preeclampsia, eclampsia, and HELLP syndrome. In general, the clinical severity of preeclampsia is directly correlated with thrombocytopenia and fibrinogen-fibrin degradation products (Levi, 2010b; Kenny, 2014). That said, intravascular coagulation is seldom clinically worrisome. Delivery reverses these changes, and treatment until then is supportive. These syndromes are discussed in detail in Chapter 40.

### Fetal Death and Delayed Delivery

Consumptive coagulopathy associated with prolonged retention of a dead fetus is unusual today because fetal death can be easily confirmed and there are highly effective methods for labor induction. Currently, the syndrome is only occasionally encountered when there is one dead twin fetus and an ongoing pregnancy. With singleton pregnancies, if the dead fetus is undelivered, most women enter spontaneous labor within 2 weeks. Gross disruption of maternal coagulation rarely develops before 4 weeks (Pritchard, 1959, 1973). After 1 month, however, almost a fourth will develop consumptive coagulopathy.

The pathogenesis of coagulopathy appears to be mediated by thromboplastin released by the dead fetus and the placenta (Jimenez, 1968; Lerner, 1967). Typically, the fibrinogen concentration falls during 6 weeks or more to levels that are normal for nonpregnant adults, but in some cases, this declines to < 100 mg/dL. Simultaneously, fibrin degradation product and d-dimer levels become elevated in serum, and moderate thrombocytopenia develops (Pritchard, 1973). If enough time elapses to seal the placental-decidual interface, these coagulation defects may correct spontaneously before evacuation (Pritchard, 1959).

### Discordant Fetal Death in Multifetal Gestation

Obvious coagulation derangement occasionally develops in a multifetal pregnancy in which there is at least one fetal death and survival of another (Chescheir, 1988; Landy, 1989). This situation is uncommon, and in one study of 22 such pregnancies, none developed a coagulopathy (Petersen, 1999). Most cases are seen in monochorionic twins with shared circulations, which are described in Chapter 45 (p. 904). The course in such a woman cared for at Parkland Hospital is shown in Figure 41-31. In this case, the coagulopathy ceased spontaneously, and the surviving healthy twin was delivered near term. The placenta of the long-dead fetus was filled with fibrin.
FIGURE 41-31 A. Following the confirmed death of one twin at 28 weeks’ gestation, serial studies demonstrated decreasing plasma fibrinogen concentrations and elevated serum fibrin-degradation products that reached a nadir 4 weeks later. After this, fibrinogen concentrations increased and fibrin degradation product levels decreased in mirror-like fashion. B. When delivered at 36 weeks, the fibrin-filled placenta (clear arrow) of the long-dead fetus (asterisk) is apparent. The liveborn cotwin was healthy and had normal coagulation studies and a normal-appearing placenta (blue arrow).

Amnionic-Fluid Embolism

This uniquely obstetrical syndrome was described in 1941 by Steiner and Lushbaugh and became classically characterized by the abrupt onset of hypotension, hypoxia, and severe consumptive coagulopathy. Even so, amnionic-fluid embolism has great individual variation in its clinical manifestation. For example, only one of these three clinical hallmarks predominates in some affected women.

Despite variations in the reported incidence of this uncommon but extremely important complication, many reports describe a similar frequency. A study that included 3 million births in the United States cited an estimated frequency of 7.7 cases per 100,000 births (Abenhaim, 2008). The United Kingdom Obstetric Surveillance System reported an incidence of 2.0 per 100,000 births (Knight, 2010). And review of more than 4 million births in Canada yielded an incidence of 2.5 per 100,000 births (Kramer, 2012). Another review of data from five high-resource countries cites frequencies from 1.9 to 6.1 per 100,000 deliveries. The case-fatality rates in all of these studies ranged from 11 to 43 percent. From another perspective, amnionic-fluid embolism was the cause of 10 to 15 percent of all pregnancy-related deaths in the United States and Canada (Berg, 2003; 2010; Clark, 2008; Kramer, 2012).

Predisposing conditions are rapid labor, meconium-stained amnionic fluid, and tears into uterine and other large pelvic veins. Other risk factors commonly cited include older maternal age; postterm pregnancy; labor induction or augmentation; eclampsia; cesarean, forceps, or vacuum delivery; placental abruption or previa; and hydramnios (Knight, 2010, 2012; Kramer, 2012). The association of uterine hypertonus appears to be the effect rather than the cause of amnionic-fluid embolism. This is likely because uterine blood flow ceases when intrauterine pressures exceed 35 to 40 mm Hg. Thus, a hypertonic contraction would be the least likely circumstance for amnionic fluid and other debris to enter uterine veins (Clark, 1995). Because of this, there is also no association between this disorder and hypertonus from oxytocin.

In obvious cases of amnionic-fluid embolism, the clinical picture is unquestionably dramatic. The classic example is that of a woman in the late stages of labor or immediately postpartum who begins gasping for air and then rapidly suffers seizures or cardiorespiratory arrest complicated by massive hemorrhage from consumptive coagulopathy. It has become apparent that there is a variation in the clinical manifestations of this condition. For example, we and others have managed several women in whom otherwise uncomplicated vaginal or cesarean delivery was followed by severe acute consumptive coagulopathy without overt cardiorespiratory difficulties. In those women, consumptive coagulopathy appears to be the forme fruste of amnionic-fluid embolism (Kramer, 2012; Porter, 1996).
Etiopathogenesis

Some amnionic fluid commonly enters the maternal circulation at the time of normal delivery through a minor breach in the physiological barrier between maternal and fetal compartments. Thus, it is fortunate that infused amnionic fluid is generally innocuous, even in large amounts (Adamsons, 1971; Stolte, 1967). At delivery, squames, other cellular elements of fetal origin, and trophoblasts can be identified in maternal peripheral blood (Clark, 1986; Lee, 1986). These are presumed to enter venous channels from the placental implantation site or from small lacerations that inevitably develop in the lower uterine segment or cervix with delivery. Although these events are usually innocuous, amnionic fluid constituents in some women initiate a complex series of pathophysiological sequelae shown in Table 41-7. The wide range of clinical manifestations underscores the subjective nature of diagnosis of many of these women.

Author data presents number of affected women. Denominators reflect circumstances in which the whole cohort was not evaluated for a particular finding.

ARDS = acute respiratory distress syndrome; NS = not stated.

Considering the wide spectrum of cardiovascular pathophysiological aberrations and sometimes profound coagulopathy, one can reasonably conclude that amnionic fluid and its constituents have a multitude of actions. For example, tissue factor in amnionic fluid presumably activates factor X to incite coagulation (Ecker, 2012; Levi, 2013). Others that have been described include endothelin-1 expressed by fetal squames, phosphatidylserine expressed by amnion, and complement activators (Khong, 1998; Zhou, 2009). An anaphylactoid reaction with complement activation has been postulated because serum levels of tryptase and histamine are also elevated (Benson, 2001; Clark, 1995).

Pathophysiology

Animal studies in primates and goats have provided important insights into central hemodynamic aberrations caused by amnionic fluid infused intravenously (Adamsons, 1971; Hankins, 1993). In general, evidence for fetal debris embolization and toxicity increases with the volume infused and the amount of meconium contamination (Hankins, 2002). If a response is evoked, its initial phase
consists of pulmonary and systemic hypertension. A similar response was reported in a woman in whom transesophageal echocardiography was performed within minutes of collapse. Findings included a massively dilated akinetic right ventricle and a small, vigorously contracting, cavity-obliterated left ventricle (Stanten, 2003). Profound oxygen desaturation is often seen in the initial phase, and this is the cause of neurological injury in most survivors (Harvey, 1996). All of these observations are consistent with failure to transfer blood from the right to the left heart because of severe and unrelenting pulmonary vasoconstriction. This initial phase is probably followed by decreased systemic vascular resistance and diminished cardiac output (Clark, 1988). Women who survive beyond these first two phases invariably have a consumptive coagulopathy and usually lung and brain injury.

Postmortem Findings. Histopathological findings may be dramatic in fatal cases of amnionic-fluid embolism such as the one shown in Figure 41-32. The detection of such debris, however, may require special staining, and even then, it may not be seen. In one study, fetal elements were detected in 75 percent of autopsies and in 50 percent of specimens prepared from concentrated buffy coat aspirates taken antemortem from a pulmonary artery catheter (Clark, 1995). Several other studies, however, have demonstrated that fetal squamous cells, trophoblasts, and other debris of fetal origin may commonly be found in the central circulation of women with conditions other than amnionic-fluid embolism. Thus, the diagnosis is generally made by identifying clinically characteristic signs and symptoms and excluding other causes.
FIGURE 41-32 Fatal amnionic-fluid embolism. A. Lung findings at autopsy: fetal squames (arrows) packed into a small pulmonary artery. Most of the empty spaces within the vessel were demonstrated by special lipid stains to be filled with vernix caseosa. B. Laboratory findings from the same woman demonstrated acute defibrination with decreased levels of fibrinogen and platelets along with increased levels of fibrinogen-fibrin degradation products.

Management and Clinical Outcomes
Immediate resuscitative actions are necessary to interdict the high mortality rate. As discussed, the initial period of systemic and pulmonary hypertension that frequently heralds amniotic-fluid embolism is transient. Tracheal intubation, cardiopulmonary resuscitation, and other supportive measures must be instituted without delay. Treatment is directed at oxygenation and support of the failing myocardium, along with circulatory support that includes rapid blood and component replacement. That said, there are no data indicating that any type of intervention improves maternal or fetal prognosis. In undelivered women undergoing cardiopulmonary resuscitation, consideration should be given to emergency cesarean delivery to perhaps optimize these efforts and improve newborn outcome. Decision making for perimortem cesarean delivery is more complex in a woman who is hemodynamically unstable but who has not suffered cardiac arrest (Chap. 47, p. 956).

Most reports describe dismal outcomes with amniotic-fluid embolism. However, this is likely influenced by underdiagnosis and reporting biases that favor the most severe cases, which are recognized but also have the greatest mortality rates. Several reports are illustrative. From a California database of 1.1 million deliveries, there was a 60-percent mortality rate with amniotic-fluid embolism (Gilbert, 1999). In a report from the Suzhou region of China, 90 percent of mothers died (Weiwen, 2000). This latter report emphasizes that death can be amazingly rapid because 12 of the 34 women who died did so within 30 minutes. The mortality rate was less dismal in the largest study from a Canadian database. Of 120 women with an amniotic-fluid embolism, only a fourth died. In many reports, survivors commonly have profound neurological impairment. Clark (1995) observed that only 8 percent of women who lived despite cardiac arrest survived neurologically intact.

As perhaps expected, perinatal outcomes are also poor and are inversely related to the maternal cardiac arrest-to-delivery interval. Even so, neonatal survival rate is 70 percent, but unfortunately, up to half of survivors suffer residual neurological impairment. In the Canadian study, 28 percent of infants were considered to be asphyxiated at birth (Kramer, 2012).

**Sepsis Syndrome**

Various infections that are accompanied by endo- or exotoxin release can result in sepsis syndrome in pregnant women. Although a feature of this syndrome includes activation of coagulation, seldom does sepsis alone cause massive procoagulant consumption. *Escherichia coli* bacteremia is frequently seen with antepartum pyelonephritis and puerperal infections, however, accompanying consumptive coagulopathy is usually not severe. Some notable exceptions are septicemia associated with puerperal infection or septic abortion caused by exotoxins released from infecting organisms such as group A *Streptococcus pyogenes*, *Staphylococcus aureus*, or *Clostridium perfringens* or *sordellii*. Treatment of sepsis syndrome and septic shock is discussed in Chapter 47 (p. 946).

**Purpura Fulminans**

This severe—often lethal—form of consumptive coagulopathy is caused by microthrombi in small blood vessels leading to skin necrosis and sometimes vasculitis. Debridement of large areas of skin over the extremities and buttocks frequently requires treatment in a burn unit. Purpura fulminans usually complicates sepsis in women with heterozygous protein C deficiency and low protein C serum levels (Levi, 2010b). Recall that homozygous protein C deficiency results in fatal neonatal purpura fulminans (Chap. 52, p. 1031).
Abortion

Septic abortion—especially associated with the organisms discussed above—can incite coagulation and worsen hemorrhage, especially with midtrimester abortions. Indeed, sepsis syndrome accompanied by intravascular coagulation accounts for 25 percent of abortion-related deaths (Saraiya, 1999). In the past, especially with illegal abortions, infections with *Clostridium perfringens* were a frequent cause of intense intravascular hemolysis at Parkland Hospital (Pritchard, 1971). More recently, however, septic abortions from infection with *Clostridium sordellii* have emerged as important causes (Chap 18, p. 357).

Second-trimester induced abortions can stimulate intravascular coagulation even in the absence of sepsis. Ben-Ami and associates (2012) described a 1.6-percent incidence in 1249 late second-trimester pregnancies terminated by dilatation and evacuation. Two thirds were done for fetal demise, which may have been contributory to coagulopathy. Another source of intense coagulation is from instillation of hypertonic solutions to effect midtrimester abortions. These are not commonly performed currently for pregnancy terminations (Chap. 18, p. 369). The mechanism is thought to initiate coagulation by thromboplastin release into maternal circulation from placenta, fetus, and the decidua by the necrobiotic effect of the hypertonic solutions (Burkman, 1977).

**Management of Hemorrhage**

One of the most crucial elements of obstetrical hemorrhage management is recognition of its severity. As discussed on page 781, visual estimation of blood loss, especially when excessive, is notoriously inaccurate, and true blood loss is often two to three times the clinical estimates. Consider also that in obstetrics, part and sometimes even all of the lost blood may be concealed. Estimation is further complicated in that peripartum hemorrhage—when most severe cases are encountered—also includes the pregnancy-induced increased blood volume. If pregnancy hypervolemia is not a factor, then following blood loss of 1000 mL, the hematocrit typically falls only 3 to 5 volume percent within an hour. The hematocrit nadir depends on the speed of resuscitation using infused intravenous crystalloids. Recall that with abnormally increased acute blood loss, the real-time hematocrit is at its maximum whenever measured in the delivery, operating, or recovery room.

A prudent rule is that any time blood loss is considered more than average by an experienced team member, then the hematocrit is determined and plans are made for close observation for physiological deterioration. Urine output is one of the most important “vital signs” with which to monitor the woman with obstetrical hemorrhage. Renal blood flow is especially sensitive to changes in blood volume. Unless diuretic agents are given—and these are seldom indicated with active bleeding—accurately measured urine flow reflects renal perfusion, which in turn reflects perfusion of other vital organs. Urine flow of at least 30 mL, and preferably 60 mL, per hour or more should be maintained. With potentially serious hemorrhage, an indwelling bladder catheter is inserted to measure hourly urine flow.

**Hypovolemic Shock**

Shock from hemorrhage evolves through several stages. Early in the course of massive bleeding, there are decreases in mean arterial pressure, stroke volume, cardiac output, central venous pressure, and pulmonary capillary wedge pressure. Increases in arteriovenous oxygen content
difference reflect a relative increase in tissue oxygen extraction, although overall oxygen consumption falls.

Blood flow to capillary beds in various organs is controlled by arterioles. These are resistance vessels that are partially controlled by the central nervous system. However, approximately 70 percent of total blood volume is contained in venules, which are passive resistance vessels controlled by humoral factors. Catecholamine release during hemorrhage causes a generalized increase in venular tone that provides an autotransfusion from this capacitance reservoir (Barber, 1999). This is accompanied by compensatory increases in heart rate, systemic and pulmonary vascular resistance, and myocardial contractility. In addition, there is redistribution of cardiac output and blood volume by selective, centrally mediated arteriolar constriction or relaxation—autoregulation. Thus, although perfusion to the kidneys, splanchnic beds, muscles, skin, and uterus is diminished, relatively more blood flow is maintained to the heart, brain, and adrenal glands.

When the blood volume deficit exceeds approximately 25 percent, compensatory mechanisms usually are inadequate to maintain cardiac output and blood pressure. Importantly, additional small losses of blood will now cause rapid clinical deterioration. Following an initial increased total oxygen extraction by maternal tissue, maldistribution of blood flow results in local tissue hypoxia and metabolic acidosis. This creates a vicious cycle of vasoconstriction, organ ischemia, and cellular death. Another important clinical effect of hemorrhage is activation of lymphocytes and monocytes, which in turn cause endothelial cell activation and platelet aggregation. These cause release of vasoactive mediators with small vessel occlusion and further impairment of microcirculatory perfusion. Other common obstetrical syndromes—preeclampsia and sepsis—also lead to loss of capillary endothelial integrity, additional loss of intravascular volume into the extracellular space, and platelet aggregation (Chaps. 40, p. 734 and 47, p. 947).

The pathophysiological events just described lead to the important but often overlooked extracellular fluid and electrolyte shifts involved in both the genesis and successful treatment of hypovolemic shock. These include changes in the cellular transport of various ions such as sodium and water into skeletal muscle and potassium loss. Replacement of extracellular fluid and intravascular volume are both necessary. Survival is enhanced in acute hemorrhagic shock if blood plus crystalloid solution is given compared with blood transfusions alone.

Immediate Management and Resuscitation

Whenever there is suggestion of excessive blood loss in a pregnant woman, steps are simultaneously taken to identify the source of bleeding and to begin resuscitation. If she is undelivered, restoration of blood volume is beneficial to mother and fetus, and it also prepares for emergent delivery. If she is postpartum, it is essential to immediately identify uterine atony, retained placental fragments, or genital tract lacerations. At least one and preferably more large-bore intravenous infusion systems are established promptly with rapid administration of crystalloid solutions, while blood is made available. An operating room, surgical team, and anesthesia providers are assembled immediately. Specific management of hemorrhage is further dependent on its etiology. For example, antepartum bleeding from placenta previa is approached somewhat differently than that from postpartum atony.

Fluid Resuscitation

It cannot be overemphasized that treatment of serious hemorrhage demands prompt and adequate refilling of the intravascular compartment with crystalloid solutions. These rapidly equilibrate into
the extravascular space, and only 20 percent of crystalloid remains intravascularly in critically ill patients after 1 hour (Zuckerbraun, 2010). Because of this, initial fluid is infused in a volume three times the estimated blood loss.

Resuscitation of hypovolemic shock with colloid versus crystalloid solutions is debated. In a Cochrane review of resuscitation of nonpregnant critically ill patients, Perel and Roberts (2007) found equivalent benefits but concluded that colloid solutions were more expensive. Similar results were found in the Saline versus Albumin Fluid Evaluation (SAFE) randomized trial of almost 7000 nonpregnant patients (Finfer, 2004). We concur with Zuckerbraun and colleagues (2010) that acute volume resuscitation is preferably done with crystalloid and blood.

**Blood Replacement**

There is considerable debate regarding the hematocrit level or hemoglobin concentration that mandates blood transfusion. Cardiac output does not substantively decrease until the hemoglobin concentration falls to approximately 7 g/dL or hematocrit of 20 volume percent. At this level the Society of Thoracic Surgeons (2011) recommends consideration for red-cell transfusions. Also, Military Combat Trauma Units in Iraq used a target hematocrit of 21 volume percent (Barbieri, 2007). In general, with ongoing obstetrical hemorrhage, we recommend rapid blood infusion when the hematocrit is < 25 volume percent. This decision is dependent on whether the fetus has been delivered, surgery is imminent or ongoing operative blood loss is expected, or acute hypoxia, vascular collapse, or other factors are present.

Scant clinical data elucidate these issues. In a study from the Canadian Critical Care Trial! Group, nonpregnant patients were randomly assigned to restrictive red cell transfusions to maintain hemoglobin concentration > 7 g/dL or to liberal transfusions to maintain the hemoglobin level at 10 to 12 g/dL. The 30-day mortality rate was similar—19 versus 23 percent in the restrictive versus liberal groups, respectively (Hebert, 1999). In a subanalysis of patients who were less ill, the 30-day mortality rate was significantly lower in the restrictive group—9 versus 26 percent. In a study of women who had suffered postpartum hemorrhage and who were now isovolemic and not actively bleeding, there were no benefits of red cell transfusions when the hematocrit was between 18 and 25 volume percent (Morrison, 1991). The number of units transfused in a given woman to reach a target hematocrit depends on her body mass and on expectations of additional blood loss.

**Blood Component Products.** Contents and effects of transfusion of various blood components are shown in Table 41-8. Compatible whole blood is ideal for treatment of hypovolemia from catastrophic hemorrhage. It has a shelf life of 40 days, and 70 percent of the transfused red cells function for at least 24 hours following transfusion. One unit raises the hematocrit by 3 to 4 volume percent. Whole blood replaces many coagulation factors—which is important in obstetrics—especially fibrinogen—and its plasma treats hypovolemia. A collateral derivative is that women with severe hemorrhage are resuscitated with fewer blood donor exposures than with packed red cells and components (Shaz, 2009).

| TABLE 41-8. Blood Products Commonly Transfused in Obstetrical Hemorrhage |
There are reports that support the preferable use of whole blood for massive hemorrhage, including our experiences at Parkland Hospital (Alexander, 2009; Hernandez, 2012). Of more than 66,000 deliveries, women with obstetrical hemorrhage treated with whole blood had significantly decreased incidences of renal failure, acute respiratory distress syndrome, pulmonary edema, hypofibrinogenemia, ICU admissions, and maternal death compared with those given packed red cells and component therapy. Freshly donated whole blood has also been used successfully for life-threatening massive hemorrhage at combat support hospitals in Iraq (Spinella, 2008).

It is problematic that in most institutions today, whole blood is rarely available. Thus, most women with obstetrical hemorrhage and ongoing massive blood loss are given packed red cells and crystalloid in 2:1 or 3:1 proportions. In these instances, there are no data to support a 1:1 red cell:plasma transfusion ratio. Many institutions use massive transfusion protocols designed to anticipate all facets of obstetrical hemorrhage defined as massive. These “recipes” commonly contain a combination of red cells, plasma, cryoprecipitate, and platelets (Pacheco, 2011; Shields, 2011). If time permits, we usually prefer to await results of emergently performed hematological laboratory assessments to treat deficiencies of fibrinogen or platelets. If time does not permit this, however, the massive transfusion protocol is activated.

**Dilutional Coagulopathy.** A major drawback of treatment for massive hemorrhage with crystalloid solutions and packed red blood cells is depletion of platelets and clotting factors. As discussed on page 808, this can lead to a dilutional coagulopathy clinically indistinguishable from disseminated intravascular coagulation (Hossain, 2013). In some cases, impaired hemostasis further contributes to blood loss.

**Thrombocytopenia** is the most frequent coagulation defect found with blood loss and multiple transfusions (Counts, 1979). In addition, packed red cells have very small amounts of soluble clotting factors, and stored whole blood is deficient in platelets and in factors V, VIII, and XI. Massive replacement with red cells only and without factor replacement can also cause
hypofibrinogenemia and prolongation of the prothrombin and partial thromboplastin times. Because many causes of obstetrical hemorrhage also cause consumptive coagulopathy, the distinction between dilutional and consumptive coagulopathy can be confusing. Fortunately, treatment for both is similar.

A few studies have assessed the relationship between massive transfusion and resultant coagulopathy in civilian trauma units and military combat hospitals (Bochicchio, 2008; Borgman, 2007; Gonzalez, 2007; Johansson, 2007). Patients undergoing massive transfusion—defined as 10 or more units of blood—had much higher survival rates as the ratio of plasma to red cell units was near 1.4, that is, one unit of plasma given for each 1.4 units of packed red cells. By way of contrast, the highest mortality group had a 1:8 ratio. Most of these studies found that component replacement is rarely necessary with acute replacement of 5 to 10 units of packed red cells.

From the foregoing, when red cell replacement exceeds five units or so, a reasonable practice is to evaluate the platelet count, clotting studies, and plasma fibrinogen concentration. In the woman with obstetrical hemorrhage, the platelet count should be maintained above 50,000/μL by the infusion of platelet concentrates. A fibrinogen level < 100 mg/dL or a sufficiently prolonged prothrombin or partial thromboplastin time in a woman with surgical bleeding is an indication for replacement. Fresh-frozen plasma is administered in doses of 10 to 15 mL/kg, or alternatively, cryoprecipitate is infused (see Table 41-8).

**Type and Screen versus Crossmatch.** A blood type and antibody screen should be performed for any woman at significant risk for hemorrhage. Screening involves mixing maternal serum with standard reagent red cells that carry antigens to which most of the common clinically significant antibodies react. Crossmatching involves the use of actual donor erythrocytes rather than the standardized red cells. Clinical results show that the type-and-screen procedure is amazingly efficient. Indeed, only 0.03 to 0.07 percent of patients identified to have no antibodies are subsequently found to have antibodies by crossmatch (Boral, 1979). Importantly, administration of screened blood rarely results in adverse clinical sequelae.

**Packed Red Blood Cells.** One unit of packed erythrocytes is derived from one unit of whole blood to have a hematocrit of 55 to 80 volume percent, depending on the length of gentle centrifugation. Thus one unit contains the same volume of erythrocytes as one whole blood unit. It will increase the hematocrit by 3 to 4 volume percent depending on patient size. Packed red blood cell and crystalloid infusion are the mainstays of transfusion therapy for most cases of obstetrical hemorrhage.

**Platelets.** With operative delivery or with lacerations, platelet transfusions are considered with ongoing obstetrical hemorrhage when the platelet count falls below 50,000/μL (Kenny, 2014). In the nonsurgical patient, bleeding is rarely encountered if the platelet count is 10,000/μL or higher (Murphy, 2010). The preferable source of platelets is a bag obtained by single-donor apheresis. This is the equivalent of six units from six individual donors. Depending on maternal size, each single-donor apheresis bag raises the platelet count by approximately 20,000/μL (Schlicter, 2010). If these bags are not available, then individual-donor platelet units are used. One unit contains about $5.5 \times 10^{10}$ platelets, and six to eight such units are generally transfused.

Importantly, the donor plasma in platelet units must be compatible with recipient erythrocytes. Further, because some red blood cells are invariably transfused along with the platelets, only units from D-negative donors should be given to D-negative recipients. If necessary, however, adverse sequelae are unlikely. For example, transfusion of ABO-nonidentical platelets in nonpregnant
patients undergoing cardiovascular surgery had no clinical effects (Lin, 2002).

**Fresh-Frozen Plasma.** This component is prepared by separating plasma from whole blood and then freezing it. Approximately 30 minutes are required for frozen plasma to thaw. It is a source of all stable and labile clotting factors, including fibrinogen. Thus, it is often used for treatment of women with consumptive or dilutional coagulopathy. *Plasma is not appropriate for use as a volume expander in the absence of specific clotting factor deficiencies.* It should be considered in a bleeding woman with a fibrinogen level < 100 mg/dL or with an abnormal prothrombin or partial thromboplastin time.

An alternative to frozen plasma is *liquid plasma (LQP).* This never-frozen plasma is stored at 1 to 6°C for up to 26 days, and in vitro, it appears to be superior to thawed plasma (Matijevic, 2013).

**Cryoprecipitate and Fibrinogen Concentrate.** Each unit of cryoprecipitate is prepared from one unit of fresh-frozen plasma. Each 10- to 15-mL unit contains at least 200 mg of fibrinogen, factor VIII:C, factor VIII:von Willebrand factor, factor XIII, and fibronectin (American Association of Blood Banks, 2002). It is usually given as a “pool” or “bag” using an aliquot of fibrinogen concentrate taken from 8 to 120 donors. Cryoprecipitate is an ideal source of fibrinogen when levels are dangerously low and there is oozing from surgical incisions. Another alternative is virus-inactivated fibrinogen concentrate. Each gram of this raises the plasma fibrinogen level approximately 40 mg/dL (Ahmed, 2012; Kikuchi, 2013). Either is used to replace fibrinogen. However, there are no advantages to these compared with fresh-frozen plasma for general clotting factor replacement. Exceptions are general factor deficiency replacement for women in whom volume overload may be a problem—an unusual situation in obstetrics—and for those with a specific factor deficiency.

**Recombinant Activated Factor VII (rFVIIa).** This synthetic vitamin K-dependent protein is available as *NovoSeven.* It binds to exposed tissue factor at the site of injury to generate thrombin that activates platelets and the coagulation cascade. Since its introduction, rFVIIa has been used to help control hemorrhage from surgery, trauma, and many other causes (Mannucci, 2007). More than three fourths of Level I trauma centers include it in their massive transfusion protocols (Pacheco, 2011). It is included in the massive transfusion protocol at Parkland Hospital.

One major concern with rFVIIa use is arterial—and to a lesser degree venous—thrombosis. In a review of 35 randomized trials with nearly 4500 subjects, arterial thromboembolism developed in 55 percent (Levi, 2010a). A second concern is that it was found to be only marginally effective in most of these studies (Pacheco, 2011). In obstetrics, recombinant FVIIa has also been used to control severe hemorrhage in women with and without hemophilia (Alfirevic, 2007; Franchini, 2007). It has been used with uterine atony, lacerations, and placental abruption or previa. In approximately a third of cases, hysterectomy was required. Importantly, rFVIIa will not be effective if the plasma fibrinogen level is < 50 mg/dL or the platelet count is < 30,000/μL.

**Topical Hemostatic Agents.** Several agents can be used to control persistent oozing. These were recently reviewed by dos Santos and Menzin (2012). In general, these are rarely used in obstetrical hemorrhage.

**Autologous Transfusion.** Patient phlebotomy and autologous blood storage for transfusion has been disappointing. Exceptions are women with a rare blood type or with unusual antibodies. In one report, three fourths of women who began such a program in the third trimester donated only
Complications with Transfusions. During the past several decades, substantial advances have been achieved in blood transfusion safety. Although many risks are avoided or mitigated, the most serious known risks that remain include errors leading to ABO-incompatible blood transfusion, transfusion-related acute lung injury (TRALI), and bacterial and viral transmission (Lerner, 2010).

The transfusion of an incompatible blood component may result in acute hemolysis. If severe, this can cause disseminated intravascular coagulation, acute kidney injury, and death. Preventable errors responsible for most of such reactions frequently include mislabeling of a specimen or transfusing an incorrect patient. Although the rate of such errors in the United States has been estimated to be 1 in 14,000 units, these are likely underreported (Lerner, 2010; Linden, 2001). A transfusion reaction is characterized by fever, hypotension, tachycardia, dyspnea, chest or back pain, flushing, severe anxiety, and hemoglobinuria. Immediate supportive measures include stopping the transfusion, treating hypotension and hyperkalemia, provoking diuresis, and alkalinizing the urine. Assays for urine and plasma hemoglobin concentration and an antibody screen help confirm the diagnosis.

The syndrome of transfusion-related acute lung injury (TRALI) can be a life-threatening complication. It is characterized by severe dyspnea, hypoxia, and noncardiogenic pulmonary edema that develop within 6 hours of transfusion (Triulzi, 2009). TRALI is estimated to complicate at least 1 in 5000 transfusions. Although the pathogenesis is incompletely understood, injury to the pulmonary capillaries may arise from anti-human leukocyte antigen (HLA) antibodies in donor plasma (Lerner, 2010; Schubert, 2013). These antibodies bind to leukocytes that aggregate in pulmonary capillaries and release inflammatory mediators. A delayed form of TRALI syndrome has been reported to have an onset 6 to 72 hours following transfusion (Marik, 2008). Management is with supportive therapy that may include mechanical ventilation (Chap. 47, p. 944).

Bacterial infection from transfusion of a contaminated blood component is unusual because bacterial growth is discouraged by refrigeration. The most often implicated contaminant of red cells include Yersinia, Pseudomonas, Serratia, Acinetobacter, and Escherichia species. The more important risk is from bacterial contamination of platelets, which are stored at room temperature. Current estimates are that 1 in 1000 to 2000 platelet units are contaminated. Death from transfusion-related sepsis is 1 per 17,000 for single-door platelets and 1 per 61,000 for apheresis-donor packs (Lerner, 2010).

Risks from many transfusion-related viral infections have been curtailed. Fortunately, the most feared infection—HIV—is the least common. With current screening methods using nucleic acid amplification, the risk of HIV or hepatitis C virus infection in screened blood is estimated to be 1 case per 1 to 2 million units transfused (Stramer, 2004). The risk for HIV-2 infection is less.

Other viral infections include hepatitis B transmission, which is estimated to be < 1 per...
100,000 transfused units (Jackson, 2003). Choosing donors who have been vaccinated will lower this incidence. Because of its high prevalence, cytomegalovirus-infected leukocytes are necessarily often transfused. Thus, precautions are taken for immunosuppressed recipients, keeping in mind that this includes the fetus (Chap. 15, p. 310). Finally, there are slight risks for transmitting West Nile virus, human T-lymphotropic virus Type I, and parvovirus B19 (American Association of Blood Banks, 2013).

**Red Cell Substitutes.** Use of these artificial carriers of oxygen has been abandoned (Ness, 2007; Spiess, 2009). Three that have been studied include perfluorocarbons, liposome-encapsulated hemoglobin, and hemoglobin-based oxygen carriers.

### Adjunctive Surgical Procedures to Treat Hemorrhage

#### Uterine Artery Ligation

Several surgical procedures may be helpful to arrest of obstetrical hemorrhage. Of these, the technique for unilateral or bilateral uterine artery ligation is used primarily for lacerations at the lateral part of a hysterotomy incision ([Fig. 41-33](#41-33)). In our experiences, this procedure is less helpful for hemorrhage from uterine atony.

**FIGURE 41-33** Uterine artery ligation. The suture goes through the lateral uterine wall anteriorly,
curves around posteriorly, then re-enters anteriorly. When tied, it encompasses the uterine artery.

**Uterine Compression Sutures.** Almost 20 years ago a surgical technique to arrest hemorrhage for severe postpartum atony was introduced by B-Lynch and coworkers (1997). The procedure involves placement of a No. 2-chromic suture to compress the anterior and posterior uterine walls together. Because they give the appearance of suspenders, they are also called *braces* (Fig. 41-34). Several modifications of the B-Lynch technique have been described (Cho, 2000; Hayman, 2002; Matsubara, 2013b; Nelson, 2007). Indications vary for its application, and this will affect the success rate. For example, B-Lynch (2005) cited 948 cases with only seven failures. Conversely, Kayem and associates (2011) described 211 women in whom compression sutures were employed. The overall failure rate of 25 percent did not differ between B-Lynch sutures and their modifications. Our experiences at Parkland Hospital are not nearly so successful. The technique has been effective in perhaps half of cases in which it is used.
FIGURE 41-34 Uterine compression suture or “brace.” The B-Lynch suture technique is illustrated from an anterior view of the uterus in Figures A, B, and D and a posterior view in Figure C. The numbers denote the sequential path of the suture and are shown in more than one figure. Step 1. Beginning below the incision, the needle pierces the lower uterine segment to enter the uterine cavity. Step 2. The needle exits the cavity above the incision. The suture then loops up and around the fundus to the posterior uterine surface. Step 3. The needle pierces the posterior uterine wall to reenter the uterine cavity. The suture then traverses from left to right within the cavity. Step 4. The needle exits the uterine cavity through the posterior uterine wall. From the back of the uterus, the suture loops up and around the fundus to the front of the uterus. Step 5. The needle pierces the myometrium above the incision to reenter the uterine cavity. Step 6. The needle exits below the incision and the sutures at points 1 and 6 are tied below the incision. The hysterotomy incision is then closed in the usual fashion.

There are complications with compression sutures, and some are unique (Matsubara, 2013b). Their precise frequency is unknown, but it is likely low. The most common involve variations of uterine ischemic necrosis with peritonitis (Gottlieb, 2008; Joshi, 2004; Ochoa, 2002; Treloar, 2006). Total uterine necrosis was described by Friederich and associates (2007) in a woman in whom B-Lynch sutures were placed along with bilateral ligation of uterine, uteroovarian, and round ligament arteries. In most cases, subsequent pregnancies are uneventful if compression sutures are placed. A few women, however, with B-Lynch or Cho sutures have been reported to have defects in the uterine wall (Akoury, 2008; An, 2013). Another long-term complication is uterine cavity synechiae, which may develop in 20 to 50 percent of these women by 3 months (Alouini, 2011; Ibrahim, 2013; Poujade, 2011).

**Internal Iliac Artery Ligation**

Ligation of one or both internal iliac arteries has been used for many years to reduce hemorrhage from pelvic vessels (Allahbadia, 1993; Joshi, 2007). Drawbacks are that the procedure may be technically difficult and is only successful half of the time (American College of Obstetricians and Gynecologists, 2012b). It is not particularly helpful to abate hemorrhage with postpartum atony (Clark, 1985; Joshi, 2007).

Adequate exposure is obtained by opening the peritoneum over the common iliac artery and dissecting down to the bifurcation of the external and internal iliac arteries (Fig. 41-35). Branches distal to the external iliac arteries are palpated to verify pulsations at or below the inguinal area. Ligation of the internal iliac artery 5 cm distal to the common iliac bifurcation will usually avoid the posterior division branches (Bleich, 2007). The areolar sheath of the artery is incised longitudinally, and a right-angle clamp is carefully passed just beneath the artery from lateral to medial. Care must be taken not to perforate contiguous large veins, especially the internal iliac vein. Suture—usually nonabsorbable—is passed under the artery with a clamp, and the vessel is then securely ligated.
Following ligation, pulsations in and distal to the external iliac artery are again confirmed. If not, pulsations must be identified after arterial hypotension has been successfully treated to ensure that the artery has not been compromised. The most important mechanism of action with internal iliac artery ligation is an 85-percent reduction in pulse pressure in those arteries distal to the ligation (Burchell, 1968). This converts an arterial pressure system into one with pressures approaching those in the venous circulation. This creates vessels more amenable to hemostasis via pressure and clot formation.

Even bilateral internal iliac artery ligation does not appear to interfere with subsequent reproduction. Nizard and colleagues (2003) reported follow-up in 17 women who had bilateral artery ligation. From a total of 21 pregnancies, 13 were normal, three ended with miscarriage, three were terminated, and there were two ectopic pregnancies.
Angiographic Embolization

This tool is now used for many causes of intractable hemorrhage when surgical access is difficult. In more than 500 women reported, embolization was 90-percent effective (Bodner, 2006; Lee, 2012; Poujade, 2012; Sentilhes, 2009). Rouse (2013) recently reviewed the subject and concluded that embolization can be used to arrest refractory postpartum hemorrhage. However, the author cautioned that the procedure is less effective with placenta percreta or with concurrent coagulopathy. Other reports have been less enthusiastic, and the American College of Obstetricians and Gynecologists (2012b) describes its efficacy as “unclear.” Fertility is not impaired, and many subsequent successful pregnancies have been reported (Chauleur, 2008; Fiori, 2009; Kolomeyevskaya, 2009). There are limited data describing its antepartum use. Embolization in a 20-week pregnant woman was reported for a large lower uterine segment arteriovenous malformation (Rebarber, 2009). It has also been used for renal hemorrhage (Wortman, 2013b).

Complications of embolization are relatively uncommon, but they can be severe. Uterine ischemic necrosis has been described (Coulange, 2009; Katakam, 2009; Sentilhes, 2009). Uterine infection has been reported (Nakash, 2012). Finally, Al-Thunyan and coworkers (2012) described a woman with massive buttock necrosis and paraplegia following bilateral internal iliac artery embolization.

Preoperative Pelvic Arterial Catheter Placement

There are a few instances in which massive blood loss and difficult surgical dissection is anticipated. For these, investigators have described use of balloon-tipped catheters inserted into the iliac or uterine arteries preoperatively. Catheters can then be inflated or embolization performed to mitigate heavy blood loss if it develops (Desai, 2012; Matsubara, 2013a). These techniques are used more commonly in cases of accrete syndromes (p. 804), and they have also been described for abdominal pregnancy (Chap. 19, p. 388). The reported success rates have been variable, and these techniques are not universally recommended (Angstmann, 2012; Pacheco, 2011, 2013; Zacharias, 2003). Again the American College of Obstetricians and Gynecologists (2012b) considers the use and efficacy of these techniques to be “unclear.” Adverse effects are uncommon, but postoperative iliac and popliteal artery thrombosis and stenosis have been reported (Greenberg, 2007; Hoffman, 2010; Sewell, 2006).

Pelvic Umbrella Pack

The umbrella or parachute pack was described by Logothetopulos (1926) to arrest intractable pelvic hemorrhage following hysterectomy. Although seldom used today, it can be lifesaving if all other measures have failed. The pack is constructed of a sterile x-ray cassette bag that is filled with gauze rolls knotted together to provide enough volume to fill the pelvis (Fig. 41-36). The pack is introduced transabdominally with the stalk exiting the vagina. Mild traction is applied by tying the stalk to a 1-liter fluid bag, which is hung over the foot of the bed. An indwelling urinary catheter is placed to prevent urinary obstruction and to monitor urinary output. Percutaneous pelvic drains can be placed to monitor ongoing bleeding within the peritoneal cavity. Broad-spectrum antimicrobials are given, and the umbrella pack is removed vaginally after 24 hours.
FIGURE 41-36 Assembly of a pelvic pressure pack to control hemorrhage. A sterile x-ray cassette cover drape (plastic bag) is filled with gauze rolls tied end-to-end. The length of gauze is then folded into a ball (A) and placed within the cassette bag in such a way that the gauze can be unwound eventually with traction on the tail (D). Intravenous tubing (E) is tied to the exiting part of the neck (C) and connected to a 1-liter bag or other suitable weight (F). Once in place, the gauze pack (A) fills the pelvis to tamponade vessels, and the narrow upper neck (B) passes to exit the vagina (C). The IV bag is suspended off the foot of the bed to sustain pressure of the gauze pack on bleeding sites.

Dildy and colleagues (2006) described use of the pelvic pack to arrest hemorrhage following hysterectomy in 11 women. These women were given seven to 77 units of red cells, and the pack successfully stopped bleeding in all but two women. Over the years, we have had mixed results with this technique, but we can recommend it as a “last-ditch” attempt when exsanguination is inevitable, especially in “low-resource” areas.

Low birthweight defines neonates who are born too small. Preterm or premature births are terms used to describe neonates who are born too early. With respect to gestational age, a newborn may be preterm, term, or postterm. With respect to size, a newborn may be normally grown and appropriate for gestational age; undersized, thus, small for gestational age; or overgrown and consequently, large for gestational age. In recent years, the term small for gestational age has been widely used to categorize newborns whose birthweight is usually < 10th percentile for gestational age. Other frequently used terms have included fetal-growth restriction or intrauterine growth restriction. The term large for gestational age has been widely used to categorize newborns whose birthweight is > 90th percentile for gestational age. The term appropriate for gestational age designates newborns whose weight is between the 10th and 90th percentiles.

Thus, infants born before term can be small or large for gestational age but still fit the definition of preterm. Low birthweight refers to neonates weighing 1500 to 2500 g; very low birthweight
refers to those between 500 and 1500 g; and extremely low birthweight refers to those between 500 and 1000 g. In 1960, a neonate weighing 1000 g had a 95-percent risk of death. Today, a neonate with the same birthweight has a 95-percent chance of surviving (Ingelfinger, 2007). This remarkable improvement in survival is due to the widespread application of neonatal intensive care in the early 1970s.

DEFINITION OF PRETERM

Up until the 15th edition of this textbook (1976), a preterm or premature infant was defined by birthweight < 2500 g. Beginning with the 15th edition, preterm infants were those delivered before 37 completed weeks, that is, ≤ 36\(\frac{6}{7}\) weeks. This definition, which has now been in use for almost 40 years, was first promulgated in 1976 by the World Health Organization (WHO) and the International Federation of Gynecology and Obstetrics (FIGO). This definition was based on statistical analysis of gestational age distribution at birth (Steer, 2005). It lacks a specific functional basis and should be clearly distinguished from the concept of prematurity. Prematurity represents incomplete development of various organ systems at birth. The lungs are particularly affected, leading to the respiratory distress syndrome.

Beginning in 2005, in recognition that infants born between 34\(\frac{0}{7}\) weeks and 36\(\frac{6}{7}\) weeks experience morbidities and mortality characteristic of premature infants, preterm births were subdivided. Those before 33\(\frac{6}{7}\) weeks are labeled—early preterm, and those occurring between 34 and 36 completed weeks—late preterm. Most recently, Spong (2013) observed, “it has become apparent that infants born between 37 weeks 0 days and 38 weeks 6 days gestation experience morbidities that are associated with prematurity compared to births at 39 weeks 0 days through 40 weeks 6 days when infant mortality is lower than at any other time in human gestation.” Those births 37\(\frac{0}{7}\) weeks through 38\(\frac{6}{7}\) weeks are now defined as early term and those 39 weeks 0 days through 40 weeks 6 days are defined as term.

In the United States in 2011, 23,910 infants died in their first year of life (Hamilton, 2012). Preterm birth, defined as delivery before 37 completed weeks, has been implicated in approximately two thirds of these deaths (Mathews, 2013). As shown in Table 42-1, late preterm births, defined as those 34 to 36 weeks’ gestation, comprised approximately 70 percent of all births before 37 completed weeks. The data in Table 42-1 suggest the possibility of redefining births attributed to short gestation to be those before 39 weeks. Surprisingly, 40 percent of live births in the United States in 2009 were associated with a shortened period of gestation when births 39 to 41 weeks are taken as the reference standard. Moreover, these 40 percent of live births with shortened gestation contributed 80 percent of the infant deaths. Another implication of these data is that only 55 percent of births in the United States occurred during the optimal 39 to 41 weeks’ gestation. Put yet another way, only 55 percent of births were “normal” based on infant outcomes. Does this mean that almost half of pregnancies resulting in live births are “abnormal”? Alternatively, perhaps the adjectives “normal” and “abnormal” should be abandoned and replaced with the realization that fetal maturation in humans is a continuum that is completed later in human pregnancy than previously appreciated.

TABLE 42-1. Infant Mortality Rates in the United States in 2009
Steer (2005) observed that signs of immaturity at birth and shorter than average gestational length have an unusually high incidence in *Homo sapiens* compared with other mammals. This has been attributed to the development of a narrow pelvis for bipedal gait, coupled with evolution toward a large brain and head that is associated with language and social skill acquisition. It is hypothesized that this combination results in a relatively high incidence of obstructed labor, which favors an evolutionary trend toward shorter gestation and thus an earlier birth.

As previously noted, if infant mortality rates are used as the outcome of interest, the data in Table 42-1 suggest that optimal pregnancy outcomes vis-à-vis prematurity are achieved at 39 weeks’ gestation. Is the 39-week threshold correct for defining pathologically shortened human gestation? For example, if neonatal death is used as the outcome of interest, delivery at 38\(^{0/7}\) through 38\(^{6/7}\) weeks is equivalent to delivery at 39 weeks (McIntire, 2008). Similarly, if respiratory morbidity is used as the outcome of interest, 38\(^{0/7}\) through 38\(^{6/7}\) weeks is equivalent to 39 weeks (Consortium on Safe Labor, 2010). These examples suggest that shortened human gestation with regard to prematurity is birth before 38\(^{0/7}\) weeks rather than before 39\(^{0/7}\) weeks.

A consequence of defining optimal pregnancy outcomes to occur at 39 weeks has been the concern that some births before 39 weeks may be unnecessary, that is, intentional deliveries not based on medical indications. Indeed, Bailit (2012) observed, “The dangers of delivering a newborn before 39 weeks for nonmedical reasons have become increasingly clear.” The evidence that unnecessary deliveries are occurring before 39 weeks in the United States is not robust. Martin (2009b) used birth certificate data to analyze late preterm births between 1990 and 2006. The rate of infants born late preterm increased 20 percent during this time period. Moreover, the percentage of late preterm births for which labor was induced more than doubled between 1990 and 2006, climbing from 7.5 to 17.3 percent. The percentage of late preterm births delivered by cesarean also rose substantially, from 23.5 to 34.3 percent. Such increases in obstetrical interventions inevitably raise the specter of medically unnecessary interventions.

Reddy (2009) used 2001 United States birth certificate data to examine delivery indications for late preterm birth. A total of 23 percent of late preterm births had no recorded indication for delivery. Some of the factors significantly increasing the chance of no recorded indication were

older maternal age, non-Hispanic white mother, and ≥ 13 years of education. Factors such as these raised the possibility that patient factors—as opposed to medical factors—were playing a role in late preterm births without a specified medical indication in the birth certificate. But Bailit (2012) has described the complexities of ascertaining the indications for delivery.

In contrast, an analysis of the indications for delivery of 21,771 late preterm births at Parkland Hospital using a research data set showed that 99.8 percent of such births were indicated and that 80 percent were due to idiopathic preterm labor or preterm spontaneously ruptured membranes. Indeed, and as shown in Figure 42-1, medically indicated preterm births are largely responsible for the increase in preterm births in the United States.

FIGURE 42-1 Rates of births < 37 weeks in the United States from 1989 to 2001. (Redrawn from Ananth, 2005, with permission.)

Undoubtedly, unnecessary obstetrical interventions are occurring before 38 or 39 weeks’ gestation, but the magnitude of this problem is unclear at this time. Caution is urged before assuming that obstetrical interventions before 38 or 39 weeks are unnecessary. For example,
Koopmans and colleagues (2009) randomized women with mild preeclampsia or gestational hypertension at 36 weeks' gestation to induction of labor versus expectant management. This trial showed that delivery at 37 weeks was better for women and their newborns compared with later delivery. The American College of Obstetricians and Gynecologists (2013b) also recommends caution before withholding indicated intervention.

TRENDS IN PRETERM BIRTH RATES

The percentage of preterm births increased 36 percent from 9.4 percent in 1984 to a high of 12.8 percent in 2006 (Mathews, 2013). Since 2006, however, the trend has reversed, and the percentage of preterm births declined to 11.7 percent in 2011 (Figure 42-2). This decline in the percentage of preterm births occurred for both the early—less than 34 weeks—and later preterm periods (Hamilton, 2012). Although the lowest level in more than a decade, the 2011 preterm birth rate is still higher than rates reported during the 1980s and most of the 1990s.

Is the decrease in preterm births shown in Figure 42-2 real? It could be argued that the decrease since 2006 is a result of changes in the birth certificate that is used to compute United States preterm birth rates. In 2003, a revised birth certificate intended to expand the collection of clinical
information was introduced in the United States. Implementation depends on the rapidity with which the various states transitioned to the new version. For example, by 2008, the revised birth certificate had been implemented in 27 states representing 65 percent of all 2008 births (Osterman, 2011). This “trickle in” implementation coincides with the decline in preterm births shown in Figure 42-2.

Importantly, the 2003 version of the birth certificate introduced use of a clinical estimate of gestational age rather than primarily the last menstrual period, which was used in the previous 1989 version of the birth certificate. Joseph and associates (2007) noticed that preterm birth rates were much higher in the United States compared with Canada. This difference, however, was reduced when the United States rate was based on the clinical estimate of gestational age rather than menstrual dating. For example, the preterm birth rate in the United States in 2002 was 12.3 percent if computed using menstrual dating compared with 10.1 percent when a clinical estimate was used. The decrease in preterm births shown in Figure 42-2 from 12.8 percent in 2006 to 11.7 percent in 2011 is well within the range of change to be expected if the change was attributable to the method used for determining gestational age for the 2003 birth certificate.

A disturbing aspect of the trend in preterm birth rates in the United States is the persistence of racial and ethnic disparity (Fig. 42-3). Indeed, 77 percent of the race/ethnicity-related disparity in infant mortality rates in the United States in 2009 was associated with preterm birth (Mathews, 2013). Some investigators attribute this disparity to socioeconomic circumstances (Collins, 2007). Rates of preterm birth in the United States are also higher compared with those in other industrialized countries (Ananth, 2009; Joseph, 2007). For example, the preterm birth rate was 12.3 percent in the United States in 2003 compared with 7.7 percent in Canada. Indeed, similar differences have been noted in the preterm delivery rates between the United States and virtually all the other industrialized countries.

![Preterm births in the United States in 2011 according to maternal race and ethnicity. (Redrawn from Hamilton, 2012.)](image-url)
Various morbidities, largely due to organ system immaturity, are significantly increased in infants born before 37 weeks’ gestation compared with those delivered at term (Table 42-2). For approximately 40 years, complications in infants born before 34 weeks have been the primary focus. Only recently (2005) have late preterm infants—34 to 36 weeks—gained attention because of their increased morbidity. Attention has also been given to increasingly small preterm infants—very low birthweight and extremely low birthweight. These very small infants suffer disproportionately not only the immediate complications of prematurity but also long-term sequelae such as neurodevelopmental disability. Indeed, live births once considered “abortuses” because they weighed < 500 g are now classified as live births. Indeed, there were 6331 live births between 400 and 500 g recorded in the United States in 2009 (Martin, 2011). Remarkable strides have been made in neonatal survival for infants born preterm. This is especially true for those born after 28 weeks. Shown in Figure 42-4 are survival rates for more than 18,000 infants born between 400 and 1500 g or between 22 and 32 weeks’ gestation. Importantly, the results are shown as a function of both birthweight and gestational age. After achieving a birthweight of ≥ 1000 g or a gestational age of 28 weeks for females or 30 weeks for males, survival rates reach 95 percent.

Data from Eichenwald, 2008.
FIGURE 42-4 Mortality rates by birthweight, gestational age, and gender. The limits of the colored area indicate the upper 95th and lower 5th percentiles of birthweight for each gestational age. The curved lines indicate combinations of birthweight and gestational age with the same estimated probability of mortality from 10 to 90 percent. The gradation of color denotes the change in estimated probability of death. Green indicates infants of lower gestational age and birthweight who are more likely to die, whereas yellow indicates infants of higher gestational age and birthweight who are less likely to die. The methods used underestimate mortality rates in those at 22 and 23 weeks with a birthweight up to 600 g. (Redrawn from Fanaroff, 2007, with permission.)

Resources used to care for low-birthweight infants are a measure of the societal burden of preterm birth. The annual cost of preterm birth in the United States in 2006 was estimated to be $26.2 billion, or $51,000 per premature infant (Institute of Medicine, 2007). The economic consequences of preterm birth that reach beyond the newborn period into infancy, adolescence, and adulthood are difficult to estimate. However, they must be enormous when the effects of adult
Mortality and Morbidity at the Extremes of Prematurity

The tremendous advances in the perinatal and neonatal care of the preterm infant have been found predominantly in those infants delivered at ≤ 33 weeks. With survival of increasingly very immature infants in the 1990s, there has been uncertainty and controversy as to the lower limit of fetal maturation compatible with extrauterine survival. This has resulted in continual reassessment of the threshold of viability.

Threshold of Viability

Births before 26 weeks are generally considered at the current threshold of viability, and these preterm infants pose various complex medical, social, and ethical considerations. For example, Sidney Miller is a child who was born at 23 weeks, weighed 615 g, and survived but developed severe physical and mental impairment (Annas, 2004). At age 7 years, she was described as a child who “could not walk, talk, feed herself, or sit up on her own … was legally blind, suffered from severe mental retardation, cerebral palsy, seizures, and spastic quadriplegia in her limbs.” An important issue for her family was the need for a lifetime of medical care estimated to cost tens of millions of dollars.

Infants now considered to be at the threshold of viability are those born at 22, 23, 24, or 25 weeks (American College of Obstetricians and Gynecologists, 2012a,b). These infants have been described as fragile and vulnerable because of their immature organ systems. Moreover, they are at high risk for brain injury from hypoxic-ischemic injury and sepsis. In this setting, hypoxia and sepsis start a cascade of events that lead to brain hemorrhage, white-matter injury that causes periventricular leukomalacia, and poor subsequent brain growth eventuating in neurodevelopmental impairment (Chap. 34, p. 656). Because active brain development normally occurs throughout the second and third trimesters, those infants born at 22 to 25 weeks are believed especially vulnerable to brain injury.

Until recently, discussion of clinical management and ethical and economic considerations of extremely premature infants were hampered by data compromised by ascertainment bias (American College of Obstetricians and Gynecologists, 2012a,b). For example, the mean survival rate was 45 percent if the denominator was all live births compared with 72 percent if the denominator used was only infants admitted to neonatal intensive care (Guillen, 2011). Another source of ascertainment bias was use of multicenter datasets. There were considerable center differences in obstetrical and early neonatal interventions, particularly at 22 and 23 weeks (Stoll, 2010).

A remarkable report on infants born before 27 weeks was recently published (Serenius, 2013). This report is unique in that it details a national population-based prospective study of all infants born alive or stillborn before 27 weeks in Sweden. This country is a uniform society without extreme poverty, and antenatal care is easily accessible and used by almost 100 percent of mothers. All citizens are covered by health insurance including 480 days of parental leave after childbirth and additional benefits for severely sick children. Active perinatal care in Sweden includes early and free access to specialist perinatal care, centralization of extremely preterm births to level III hospitals, a low threshold to provide life support at birth, and near universal admission of infants born at 23 to 26 weeks for neonatal intensive care. Thus, this report likely describes infant outcomes at the threshold of viability under optimal circumstances.

Shown in Table 42-3 are the survival and disability rates for 707 infants born alive from 22 to
26 weeks between 2004 and 2007 in Sweden. The proportion of children with mild or no disabilities increased from 40 percent at 22 weeks to 83 percent at 26 weeks. Conversely, the number of infants with moderate or severe disabilities decreased with advancing gestational age at birth. Moderate or severe disabilities were found in 31 percent of preterm boys compared with 23 percent of preterm girls. No differences in overall outcomes were noted if singletons and multiple births were compared.

The most recent report from the United States concerning survival and morbidity rates for births at 22 to 26 weeks is from the National Institute of Child Health and Human Development (NICHD) Neonatal Network. This dataset includes 5736 live births delivered between 2003 and 2007 at 20 medical centers across the United States. Rates of survival and survival without morbidity in the neonatal period are shown in Table 42-4.

### TABLE 42-4. Survival and Disability Rates for 5736 Live Births Born between 22 and 26 Weeks’ Gestation at 20 Medical Centers in the United States During 2003–2007
Cesarean delivery at the threshold of viability is controversial. For example, if the fetus-infant is perceived to be too immature for aggressive support, then cesarean delivery for common indications such as breech presentation or nonreassuring fetal heart rate patterns might be preempted. This aside, national data clearly show a high frequency of cesarean delivery for these small infants (Fig. 42-5). Determining the optimal delivery mode for newborns at the threshold of viability is virtually impossible given that randomizing the delivery route has extreme ethical considerations. That said, retrospective, nonrandomized studies have consistently failed to document a benefit of cesarean delivery for the extremely preterm fetus (American College of Obstetricians and Gynecologists, 2012a). Reddy (2012) analyzed 2906 singleton live births between 24\(^{0/7}\) and 31\(^{6/7}\) weeks selected because they were eligible for attempted vaginal birth after excluding those cases with fetal distress, placenta previa, placental abruption, and anomalies. Attempted vaginal delivery for cephalic presenting fetuses had a high success rate (84 percent), and there was no difference in the neonatal mortality rate compared with that with planned cesarean delivery. For breech presentations, however, there was a threefold increased relative risk in mortality when vaginal delivery was attempted. Werner (2013) analyzed 20,231 preterm infants at 24 to 34 weeks born in New York City between 1995 and 2003. Cesarean delivery was not protective against poor outcomes such as neonatal death, intraventricular hemorrhage, seizures, respiratory distress, and subdural hemorrhage.

Threshold of Viability at Parkland Hospital

Policies were developed in conjunction with the Neonatology Service. We must emphasize that the decision not to perform cesarean delivery does not necessarily imply that the fetus is “nonviable” or “written off.” Neonatologists are consulted before delivery, and there is discussion of survival and morbidity with the woman and her family. A neonatologist attends each delivery and determines subsequent management.

From an obstetrical standpoint, all fetal indications for cesarean delivery in more advanced pregnancies are practiced in women at 25 weeks. Cesarean delivery is not offered for fetal indications at 23 weeks. At 24 weeks, cesarean delivery is not offered unless fetal weight is estimated at 750 g or greater. Aggressive obstetrical management is practiced in cases of growth restriction.

Late Preterm Birth

As shown in Figure 42-6, infants between 34 and 36 weeks account for more than 70 percent of all preterm births. These are the fastest increasing and largest proportion of singleton preterm births in the United States (Raju, 2006). Thus, increased attention is being given to determining optimal obstetrical and neonatal management of late preterm birth.
To estimate the risks associated with late preterm births, we analyzed neonatal mortality and morbidity rates at 34, 35, and 36 weeks compared with those of births at term between 1988 and 2005 at Parkland Hospital (McIntire, 2008). We were particularly interested in obstetrical complications during this time, because if modified, rates of late preterm birth can possibly be decreased. Approximately 3 percent of all births during the study period occurred between 24 and 32 weeks, and 9 percent were during the late preterm weeks. Thus, late preterm births accounted for three fourths of all preterm births. Approximately 80 percent of these were due to idiopathic spontaneous preterm labor or prematurely ruptured membranes (Fig. 42-7). Complications such as hypertension or placental accidents were implicated in the other 20 percent of cases.
Neonatal mortality rates were significantly increased in each late preterm week compared with those at 39 weeks as the referent and as shown in Figure 42-8. Similarly, Tomashek (2007) analyzed all United States births between 1995 and 2002 and also found higher neonatal mortality rates for late preterm infants. Importantly, indices of neonatal morbidity shown in Table 42-5 are increased in these late preterm infants born at Parkland. Fuchs (2008) reported similar results regarding respiratory morbidity in 722 infants. Specifically, the frequency of respiratory morbidity decreased by approximately 50 percent per week from 34 to 37 completed weeks. Increased rates of adverse neurodevelopment have also been found in late preterm infants compared with term newborns (Petrini, 2009).

**TABLE 42-5.** Neonatal Morbidity Rates at Parkland Hospital in Live Births Delivered Late Preterm Compared with 39 Weeks
These findings suggest that the health-care focus on prematurity should be expanded to include late preterm births. Even so, because approximately 80 percent of these women begin labor spontaneously—similar to births before 34 weeks—attempts to interrupt preterm labor have not been satisfactory. Specifically, the Institute of Medicine (2007) report, *Preterm Birth: Causes, Consequences, and Prevention*, acknowledges that treatment of preterm labor has not prevented preterm birth. Thus, we are of the view that a national strategy aimed at prevention of late preterm births is unlikely to provide discernible benefit without new developments in the prevention and management of preterm labor. In the meantime, the Maternal-Fetal Medicine Units (MFMU) Network is studying the efficacy of corticosteroids in late preterm births. The American College of Obstetricians and Gynecologists (2013b) has emphasized that intentional late preterm deliveries should occur only when an accepted maternal or fetal indication for delivery exists.

### CAUSES OF PRETERM DELIVERY

There are four main direct reasons for preterm births in the United States. These include: (1) spontaneous unexplained preterm labor with intact membranes, (2) idiopathic preterm premature...
rupture of membranes (PPROM), (3) delivery for maternal or fetal indications, and (4) twins and higher-order multifetal births. Of all preterm births, 30 to 35 percent are indicated, 40 to 45 percent are due to spontaneous preterm labor, and 30 to 35 percent follow preterm membrane rupture (Goldenberg, 2008). Indeed, much of the increase in the singleton preterm birth rate in the United States is explained by rising numbers of indicated preterm births (Ananth, 2005).

Reasons for preterm birth have multiple, often interacting, antecedents and contributing factors. This complexity has greatly confounded efforts to prevent and manage this complication. This is particularly true for preterm ruptured membranes and spontaneous preterm labor, which together lead to 70 to 80 percent of preterm births. Last, according to data from Martin (2006), approximately one in six preterm births in the United States is from twins or higher-order multifetal pregnancies (Chap. 45, p. 891). For example, in 2004, there were 508,356 preterm births, and of these, 86,116 or 17 percent were from multifetal pregnancies. Many of these pregnancies were achieved using ovulation-inducing drugs and assisted reproductive technologies (ART).

Analogous to other complex disease processes, multiple coexistent genetic alterations and environment may lead to preterm birth (Esplin, 2005; Ward, 2008). There are polymorphisms in genes associated with inflammation and infection and in those associated with collagen turnover (Velez, 2008). Inherited mutations in genes regulating collagen assembly may predispose individuals to cervical insufficiency or prematurely ruptured membranes (Anum, 2009; Wang, 2006; Warren, 2007).

Basic Science of Spontaneous Preterm Labor

For both clinical and research purposes, pregnancies with intact fetal membranes and spontaneous preterm labor must be distinguished from those complicated by preterm prematurely ruptured membranes. Even so, those with spontaneous preterm labor do not constitute a homogeneous group characterized singularly by early initiation of parturition (American College of Obstetricians and Gynecologists, 2012b). This certainly is one reason why preventative therapies and clinical tools to assess the risks for preterm birth have been difficult to identify. Among the more common associated findings are multifetal pregnancy, intrauterine infection, bleeding, placental infarction, premature cervical dilatation, cervical insufficiency, hydramnios, uterine fundal abnormalities, and fetal anomalies. Severe maternal illness as a result of infections, autoimmune diseases, and gestational hypertension also increases preterm labor risks.

Although there are unique aspects to each cause of preterm labor, these diverse processes culminate in a common end point, which is premature cervical dilatation and effacement and premature activation of uterine contractions. It seems important to emphasize that the actual process of preterm labor should be considered a final step—one that results from progressive or acute changes that could be initiated days or even weeks before labor onset. Indeed, many forms of spontaneous preterm labor that result from premature initiation of phase 2 of parturition may be viewed in this light (Chap. 21, p. 410). Although the end result in preterm birth is the same as at term, namely cervical ripening and myometrial activation, recent studies in animal models support the idea that preterm birth is not always an acceleration of the normal process. Diverse pathways to instigate parturition exist and are dependent on the etiology of preterm birth. Identification of both common and uncommon factors has begun to explain the physiological processes of human parturition at term and preterm. Four major causes of spontaneous preterm labor include uterine distention, maternal–fetal stress, premature cervical changes, and infection.
Uterine Distention

There is no doubt that multifetal pregnancy and hydramnios lead to an increased risk of preterm birth (Chap. 45, p. 913). It is likely that early uterine distention acts to initiate expression of contraction-associated proteins (CAPs) in the myometrium. The CAP genes that are influenced by stretch include those coding for gap-junction proteins such as connexin 43, for oxytocin receptors, and for prostaglandin synthase (Korita, 2002; Lyall, 2002; Sooranna, 2004). Recent reports suggest that gastrin-releasing peptides (GRPs) are increased with stretch to promote myometrial contractility and that GRP antagonists can inhibit uterine contractility (Tattershall, 2012). There is also a stretch-induced potassium channel—TREK-1—that is upregulated during gestation and downregulated in labor. This pattern of expression is consistent with a potential role in uterine relaxation during pregnancy (Buxton, 2010). Expression of TREK-1 splice variants that block function of the full-length TREK-1 have been recently identified in myometrium from women with preterm labor. This further implicates a role for TREK-1 in uterine quiescence (Wu, 2012).

Although these and other regulatory factors remain to be validated, it is clear that excessive uterine stretch causes premature loss of myometrial quiescence.

Excessive uterine stretch also leads to early activation of the placental–fetal endocrine cascade shown in Figure 21-17 (p. 425). The resulting early rise in maternal corticotropin-releasing hormone and estrogen levels can further enhance the expression of myometrial CAP genes (Warren, 1990; Wolfe, 1988). Finally, the influence of uterine stretch should be considered with regard to the cervix. For example, cervical length is an important risk factor for preterm birth in multifetal pregnancies (Goldenberg, 1996). Prematurely increased stretch and endocrine activity may initiate events that shift the timing of uterine activation, including premature cervical ripening.

Maternal–Fetal Stress

Stress is defined as a condition or adverse circumstance that disturbs the normal physiological or psychological functioning of an individual. But the complexities of measuring “stress” are what cause difficulty in defining its exact role (Lobel, 1994). That said, considerable evidence shows a correlation between some sort of maternal stress and preterm birth (Hedegaard, 1993; Hobel, 2003; Ruiz, 2003). Moreover, there is a correlation between maternal psychological stress and the placental–adrenal endocrine axis that provides a potential mechanism for stress-induced preterm birth (Lockwood, 1999; Petraglia, 2010; Wadhwa, 2001).

As discussed earlier, the last trimester is marked by rising maternal serum levels of placental-derived corticotropin-releasing hormone (CRH). This hormone works with adrenocorticotropic hormone (ACTH) to increase adult and fetal adrenal steroid hormone production, including the initiation of fetal cortisol biosynthesis. Rising levels of maternal and fetal cortisol further increase placental CRH secretion, which develops a feed-forward endocrine cascade that does not end until delivery (Fig. 21-17, p. 425). Rising levels of CRH further stimulate fetal adrenal dehydroepiandrosterone sulfate (DHEA-S) biosynthesis, which acts as substrate to increase maternal plasma estrogens, particularly estriol.

It has been hypothesized that a premature rise in cortisol and estrogens results in an early loss of uterine quiescence. A number of studies have reported that spontaneous preterm labor is associated with an early rise in maternal CRH levels and that CRH determination may be a useful biomarker for preterm birth risk assessment (Holzman, 2001; McGrath, 2002; McLean, 1995; Moawad, 2002). Because of large variations in CRH levels among pregnant women, however, a single CRH measurement has low sensitivity (Leung, 2001; McGrath, 2002). It may be that the rate of increase in maternal CRH levels is possibly a more accurate predictor of preterm birth. Confounding factors include CRH variability among ethnic groups. Another is that placental CRH...
enters the fetal circulation—albeit at lower levels than in the maternal circulation. In vitro studies have shown that CRH can directly stimulate fetal adrenal production of DHEA-S and cortisol (Parker, 1999; Smith, 1998). Thus, current studies do not support the idea that CRH levels alone have a positive-predictive value for preterm birth risk.

If preterm delivery is associated with early activation of the fetal adrenal–placental endocrine cascade, maternal estrogen levels would likely be prematurely elevated. This is indeed the case. An early rise in serum estriol concentrations is noted in women with subsequent preterm labor (Heine, 2000; McGregor, 1995). Physiologically, this premature rise in estrogen levels may alter myometrial quiescence and accelerate cervical ripening.

Taken together, these observations suggest that preterm birth is associated, in many cases, with a maternal–fetal biological stress response. The stressors that activate this cascade likely are broad, and the stress response is dependent on the stressor. For example, CRH or estriol levels are prematurely elevated in preterm birth due to infection and multifetal pregnancies but not in pregnant women with perceived stress (Gravett, 2000; Himes, 2011; Warren, 1990). Chronic, psychological stress—resulting for example from racial discrimination—appears to promote impaired cellular immune competence (Christian, 2012b). A growing body of work in the area of psychoneuroimmunology will perhaps enhance the understanding of pathways that link stress with adverse birth outcomes (Christian, 2012a).

**Infection**

There is great interest in the role of infection as a primary cause of preterm labor in pregnancies with intact membranes (Goncalves, 2002; Iams, 1987). In some cases, there is histological evidence of inflammation in the fetal membranes, decidua, or umbilical cord, whereas other cases are deemed “subclinical.” More recently, new technologies based on genomic analysis of a mixed population of microorganisms have shown that the nonpregnant vaginal tract hosts a complex microbial community that can differ widely between women who are all healthy (Gajer, 2012; White, 2011). The application of the field of *metagenomics* to understanding microbiome complexity in term and preterm birth and to identifying microbe populations that may mediate subclinical infection holds great promise. Aagaard and coworkers (2012) used metagenomics to determine how the vaginal microbiome changes during normal pregnancy. They reported that the diversity and richness of microbes is reduced through pregnancy. Compared with nonpregnant controls, there is an increased dominance of *Lactobacillus* species. These findings lay the foundation for future studies to identify microbial populations associated with “subclinical” infection-induced preterm birth.

Current data suggest that microbial invasion of the reproductive tract is sufficient to induce infection-mediated preterm birth—more specifically, there is ongoing “subclinical” infection. However, microorganisms certainly are not ubiquitous in the amnionic fluid of all women with preterm labor, and indeed, positive cultures are found in only 10 to 40 percent (Goncalves, 2002). This minority of women with amnionic fluid bacteria are more likely to develop clinical chorioamnionitis and preterm ruptured membranes compared with women with sterile cultures. Moreover, their neonates are also more likely to have complications (Hitti, 2001). Although infection is more severe when there is clinically obvious intraamnionic infection, inflammation in the absence of detectable microorganisms is also a risk factor for a fetal inflammatory response (Lee, 2007, 2008). The earlier the onset of preterm labor, the greater the likelihood of documented infection (Goldenberg, 2000; Watts, 1992). It is enigmatic that the incidence of culture-positive amnionic fluids collected by amniocentesis during spontaneous term labor is similar to that with preterm labor (Gomez, 1994; Romero, 1993). It has been suggested that at term, amnionic fluid is
infiltrated by bacteria as a consequence of labor, whereas in preterm pregnancies, bacteria represent an important cause of labor. If true, this explanation questions the contribution of fetal infection as a major cause of preterm labor and delivery.

Despite these observations, there are considerable data that associate chorioamnionitis with preterm labor (Goldenberg, 2002; Üstün, 2001). In such infections, the microbes may invade maternal tissue only and not amnionic fluid. Despite this, endotoxins can stimulate amnionic cells to secrete cytokines that enter amnionic fluid. This scenario may serve to explain the apparently contradictory observations concerning an association between amnionic fluid cytokines and preterm labor, in which microbes were not detectable in the amnionic fluid.

**Sources for Intrauterine Infection.** The patency of the female reproductive tract, although essential for achievement of pregnancy and delivery, is theoretically problematic during phase 1 of parturition. It has been suggested that bacteria can gain access to intrauterine tissues through: (1) transplacental transfer of maternal systemic infection, (2) retrograde flow of infection into the peritoneal cavity via the fallopian tubes, or (3) ascending infection with bacteria from the vagina and cervix. The lower pole of the fetal membrane–decidual junction is contiguous with the cervical canal orifice, which is patent to the vagina. This anatomical arrangement provides a passageway for microorganisms, and ascending infection is considered to be the most common. A thoughtful description of the potential degrees of intrauterine infection has been provided by Gonçalves and associates (2002). They categorize intrauterine infection into four stages of microbial invasion that include bacterial vaginosis—stage I, decidual infection—stage II, amnionic infection—stage III, and finally, fetal systemic infection—stage IV. As expected, progression of these stages is thought to increase rates of preterm birth and neonatal morbidity.

Based on these insights, it is straightforward to construct a theory for the pathogenesis of infection-induced preterm labor. Ascending microorganisms colonize the cervix, decidua, and possibly the membranes, where they then may enter the amnionic sac. Lipopolysaccharide (LPS) or other toxins elaborated by bacteria induce immune-cell recruitment into the reproductive tract and cytokine production by immune cells and by cells within the cervix, decidua, membranes, or fetus itself. Both LPS and cytokines then provoke prostaglandin release from the membranes, decidua or cervix. These influence both cervical ripening and loss of myometrial quiescence (Challis, 2002; Keelan, 2003; Olson, 2003). Current evidence based on animal and human studies suggests that many aspects of infection-mediated preterm birth differ from pathways that regulate term parturition (Hamilton, 2012; Holt, 2011; Shynlova, 2013a,b).

**Microbes Associated with Preterm Birth.** Some micro-organisms—examples include *Gardnerella vaginalis, Fusobacterium, Mycoplasma hominis,* and *Ureaplasma urealyticum*—are detected more frequently than others in amnionic fluid of women with preterm labor (Gerber, 2003; Hillier, 1988; Yoon, 1998). This finding was interpreted by some as presumptive evidence that specific microorganisms are more commonly involved as pathogens in the induction of preterm labor. Another interpretation, however, is that given direct access to the membranes after cervical dilatation, selected microorganisms, such as fusobacteria, that are more capable of burrowing through these exposed tissues will do so. Fusobacteria are found in the vaginal fluid of only 9 percent of women but in 28 percent of positive amnionic fluid cultures from pregnancies with preterm labor and intact membranes (Chaim, 1992). Knowledge from metagenomic studies will better define these interactions in the future. In addition, host responses to pathogens with respect to mucosal immunity, barrier protection of cervical and vaginal epithelia, and expression of antimicrobial peptides is likely to provide insights. Specifically, the mechanisms that render some women more susceptible to infection-mediated preterm birth may be found.
Intrauterine Inflammatory Response. The initial inflammatory response elicited by bacterial toxins is mediated, in large measure, by specific receptors on mononuclear phagocytes, decidual cells, cervical epithelia, and trophoblasts. These Toll-like receptors represent a family that has evolved to recognize pathogen-associated molecules (Janssens, 2003). Toll-like receptors are present in the placenta on trophoblast cells, in the cervical epithelia, and on fixed and invading leukocytes (Chuang, 2000; Gonzalez, 2007; Holmlund, 2002). Loss of specific Toll-like receptors results in delayed parturition in mouse models (Montalbano, 2013).

Under the influence of ligands such as bacterial LPS, these receptors increase chemokine cytokine, and prostaglandin release as part of an inflammatory response. One example is interleukin-1β (IL-1β), which is produced rapidly after LPS stimulation (Dinarello, 2002). The cytokine in turn acts to promote a series of responses that include: (1) increased synthesis of others, that is, IL-6, IL-8, and tumor-necrosis factor alpha (TNF-α); (2) proliferation, activation, and migration of leukocytes; (3) modifications in extracellular matrix proteins; and (4) mitogenic and cytotoxic effects such as fever and acute-phase response (El-Bastawissi, 2000). Also, IL-1 promotes prostaglandin formation in many tissues, including myometrium, decidua, and amnion (Casey, 1990). The importance of prostaglandins to infection-mediated preterm birth is supported by the observation that prostaglandin inhibitors can reduce the rate of LPS-induced preterm birth in both the mouse and nonhuman primate (Gravett, 2007; Gross, 2000). Inhibition of cyclooxygenase-2 prevents inflammation-mediated preterm labor in the mouse. And immunomodulators plus antibiotics delay preterm delivery after experimental intraamnionic infection in a nonhuman primate model. Thus, there appears to be a cascade of events once an inflammatory response is initiated that can result in preterm labor.

Origin of Cytokines. Cytokines within the normal term uterus are likely important for normal and preterm labor. The transfer of cytokines such as IL-1 from decidua across the membranes into amnionic fluid appears to be severely limited. It is reasonable that cytokines produced in maternal decidua and myometrium will have effects on that side, whereas cytokines produced in the membranes or in cells within the amnionic fluid will not be transferred to maternal tissues. The human myometrium expresses chemokine receptors that decline during labor (Hua, 2013). Macrophages are reported to infiltrate the human and rat decidua before labor onset and may be important for decidual activation (Hamilton, 2012). Still, the requirement of leukocytes for initiation of term labor in women remains inconclusive. In most cases of inflammation resulting from infection, resident and invading leukocytes produce the bulk of cytokines. Indeed, with infection, leukocytes—mainly neutrophils, macrophages, and T lymphocytes—infiltrate the cervix, lower uterine segment, fundus, and membranes at the time of labor. Thus, invading leukocytes may be the major source of cytokines in preterm labor. Along with proinflammatory cytokines, studies in women and animal models highlight the importance of the antiinflammatory limb of the immune response in parturition (Gotsch, 2008; Timmons, 2009).

Immunohistochemical studies in the term laboring uterus have shown that both invading leukocytes and certain parenchymal cells produce cytokines. These leukocytes appear to be the primary source of myometrial cytokines, including IL-1, IL-6, IL-8, and TNF-α (Young, 2002). In contrast, in the decidua, both stromal cells and leukocytes are likely to contribute because they have been shown to produce these same cytokines. In the cervix, glandular and surface epithelial cells appear to produce IL-6, IL-8, and TNF-α. Of these, IL-8 is considered a critical cytokine in cervical dilation, and it is produced in both cervical epithelial and stromal cells.

The presence of cytokines in amnionic fluid and their association with preterm labor has been well documented. But their exact cellular origin—with or without recoverable microorganisms—
has not been well defined. Although the rate of IL-1 secretion from forebag decidual tissue is
great, Kent (1994) found that there is negligible in vivo transfer of radiolabeled IL-1 across the
membranes. Amnionic fluid IL-1 probably does not arise from amnion, fetal urine, or fetal lung
secretions. It most likely is secreted by mononuclear phagocytes or neutrophils activated and
recruited into the amnionic fluid. Therefore, IL-1 in amnionic fluid likely is generated in situ from
newly recruited cells (Young, 2002). Thus, the amount of amnionic fluid IL-1 would be determined
by the number of leukocytes recruited, their activational status, or the effect of amnionic fluid
constituents on their IL-1 secretion rate.

Leukocyte infiltration may be regulated by fetal membrane synthesis of specific chemokines. In
term labor, there are increased amnionic fluid concentrations of the potent chemoattractant and
monocyte-macrophage activator monocyte chemotactic protein-1 (MCP-1), which is also called
chemokine (C-C motif) ligand 2 (CCL2). As is true for prostaglandins and other cytokines, the
levels of MCP-1 are much higher in the forebag compared with the upper compartment (Esplin
2003). Levels in preterm labor were significantly higher than those found in normal term amnionic
fluid (Jacobsson, 2003). MCP-1 may initiate fetal leukocyte infiltration of the placenta and
membranes, and its production may act as a marker for intraamnionic infection and inflammation.

Preterm Premature Rupture of Membranes
This term defines spontaneous rupture of the fetal membranes before 37 completed weeks and
before labor onset (American College of Obstetricians and Gynecologists, 2013d). Such rupture
likely has various causes, but intrauterine infection is believed by many to be a major predisposing
event (Gomez, 1997; Mercer, 2003). There are associated risk factors that include low
socioeconomic status, body mass index ≤ 19.8, nutritional deficiencies, and cigarette smoking.
Women with prior preterm premature rupture of membranes (PPROM) are at increased risk for
recurrence during a subsequent pregnancy (Bloom, 2001). Despite these known risk factors, none
is identified in most cases of preterm rupture.

Molecular Changes
Preterm membrane rupture pathogenesis may be related to increased apoptosis of membrane
cellular components and to increased levels of specific proteases in membranes and amnionic
fluid. Most tensile strength of the membranes is provided by the amnionic extracellular matrix and
interstitial amnionic collagens—primarily type I and III—which are produced in mesenchymal
cells (Casey, 1996). For that reason, collagen degradation has been a focus of research. The matrix
metalloproteinase (MMP) family is involved with normal tissue remodeling and particularly with
collagen degradation. The MMP-1, MMP-2, MMP-3, and MMP-9 members of this family are
found in higher concentrations in amnionic fluid from pregnancies with preterm prematurely
ruptured membranes (Maymon, 2000; Park, 2003; Romero, 2002). MMP activity is in part
regulated by tissue inhibitors of matrix metalloproteinases—TIMPs. Several of these inhibitors are
found in lower concentrations in amnionic fluid from women with ruptured membranes. Elevated
MMP levels found at a time when protease inhibitor expression decreases supports further that
their expression alters amnionic tensile strength. Studies of amniochorion explants have
demonstrated that the expression of MMPs can be increased by treatment with IL-1, TNF-α, and
IL-6 (Fortunato, 1999a,b, 2002). Recent studies by Mogami (2013) provide a mechanism by which
cellular endotoxin or TNF-α elicits release of fetal fibronectin (fFN) by amnion epithelial cells.
The fFN then binds Toll-like receptor 4 in the amnion mesenchymal cells to activate signaling
cascades. These result in increased prostaglandin E (PGE₂) synthesis and elevated activity of
MMP-1, MP-2, and MMP-9. Increased prostaglandin levels promote cervical ripening and uterine contractions. Increased MMPs allow collagen breakdown in the fetal membranes resulting in premature rupture.

In pregnancies with PPROM, the amnion exhibits a higher degree of cell death and more apoptosis markers than that in term amnion (Arechavaleta-Velasco, 2002; Fortunato, 2003). In vitro studies indicate that apoptosis is likely regulated by bacterial endotoxin, IL-1, and TNF-α. Last, there are proteins involved in the synthesis of mature cross-linked collagen or matrix proteins that bind collagen and thereby promote tensile strength. These proteins are altered in membranes with premature rupture (Wang, 2006). Taken together, these observations suggest that many PPROM cases result from collagen degradation, altered collagen assembly, and cell death, which all lead to a weakened amnion.

Infection

Several studies have been done to ascertain the incidence of infection-induced premature membrane rupture. Bacterial cultures of amnionic fluid support a role for infection in a significant proportion. A review of 18 studies comprising almost 1500 women with PPROM found that in a third, bacteria were isolated from amnionic fluid (Goncalves, 2002). Accordingly, some have given prophylactic antimicrobial treatment to prevent premature rupture (Miyazaki, 2012; Phupong, 2012).

Overall, there is compelling evidence that infection causes a significant proportion of PPROM cases. The inflammatory response that leads to membrane weakening is currently being defined. Research is focused on mediators of this process with a goal to identify early risk markers for PPROM.

Multifetal Gestation

Twins and higher-order multifetal births account for approximately 3 percent of infants born in the United States (Martin, 2009a). The majority—95 percent—of these births are twins. Compared with 1980, the rates of multiple births increased steadily and peaked in 1998. Current rates have declined since then, but remain higher than the 1980s. The increased rate of multifetal births is due to the increased number of women having babies after the age of 30, at which time the risk to conceive multiples rises. In addition, the use of fertility treatments has contributed to the elevated rates of multifetal pregnancies. Preterm delivery continues to be the major cause of the excessive perinatal morbidity and mortality with multifetal pregnancies. The effects of uterine stretch discussed on page 837 are obvious in these pregnancies, and this likely is related to the increased incidence of preterm cervical dilatation. Many of these interrelationships are discussed in Chapter 45.

Summary of Preterm Labor Pathophysiology

Preterm labor is a pathological condition with multiple etiologies. Romero (2006) termed it the *preterm parturition syndrome*. Most research in this field has been focused on the role of infection in mediating preterm birth. It is possible that intrauterine infection causes some cases currently categorized as idiopathic spontaneous preterm labor. There are various sites for intrauterine infection—maternal, fetal, or both—and increasing evidence that the inflammatory response may have distinct and compartment-specific functions that differ between uterus, fetal membranes, and cervix in normal birth. Thus, determining the proportion of pregnancies that end...
Infection does not explain all causes of preterm birth. In recent years, our understanding of other influences on the parturition process, such as maternal nutrition before or during pregnancy, genetics, the vaginal microbiome, and dynamic regulation of the extracellular matrix, has led to new avenues of research and a broader understanding of this complicated and multifactorial process. The current and future application of genomic and bioinformatics as well as molecular and biochemical studies will shed light on pathways involved in term and preterm labor and identify processes critical to all phases of cervical remodeling and uterine function.

ANTECEDENTS AND CONTRIBUTING FACTORS

Myriad genetic and environmental factors affect the frequency of preterm labor.

 Threatened Abortion
Vaginal bleeding in early pregnancy is associated with increased adverse outcomes later. Weiss (2004) reported outcomes with vaginal bleeding at 6 to 13 weeks in nearly 14,000 women. Both light and heavy bleeding were associated with subsequent preterm labor, placental abruption, and subsequent pregnancy loss before 24 weeks.

 Lifestyle Factors
Cigarette smoking, inadequate maternal weight gain, and illicit drug use have important roles in both the incidence and outcome of low-birthweight neonates (Chap. 12, p. 253). Overweight and obese mothers have an elevated risk of preterm birth (Cnattingius, 2013). Other maternal factors implicated include young or advanced maternal age, poverty, short stature, and vitamin C deficiency (Casanueva, 2005; Gielchinsky, 2002; Kramer, 1995; Meis, 1995; Satin, 1994).

As discussed on page 837, psychological factors such as depression, anxiety, and chronic stress have been reported in association with preterm birth (Copper, 1996; Li, 2008; Littleton, 2007). Neggers and coworkers (2004) found a significant link between low birthweight and preterm birth in women injured by physical abuse (Chap. 47, p. 951).

Studies of work and physical activity related to preterm birth have produced conflicting results (Goldenberg, 2008). There is some evidence, however, that working long hours and hard physical labor are probably associated with increased risk of preterm birth (Luke, 1995).

 Genetic Factors
The recurrent, familial, and racial nature of preterm birth has led to the suggestion that genetics may play a causal role. An accumulating literature on genetic variants buttresses this concept (Gibson, 2007; Hampton, 2006; Li, 2004; Macones, 2004). As discussed on page 839, several such studies have also implicated immunoregulatory genes in potentiating chorioamnionitis in cases of preterm delivery due to infection (Varner, 2005).

Birth Defects
In a secondary analysis of data from the First- and Second-Trimester Evaluation of Risl
(FASTER) Trial, it was found that birth defects were associated with preterm birth and low birthweight (Dolan, 2007).

## Periodontal Disease

Gum inflammation is a chronic anaerobic inflammation that affects as many as 50 percent of pregnant women in the United States (Goepfert, 2004). Vergnes and Sixou (2007) performed a metaanalysis of 17 studies and concluded that periodontal disease was significantly associated with preterm birth—odds ratio 2.83. The researchers concluded, however, that the data were not robust enough to recommend screening and treatment of pregnant women (Stamilio, 2007).

To better study the relationship with periodontitis, Michalowicz (2006) randomly assigned 813 pregnant women between 13 and 17 weeks’ gestation who had periodontal disease to treatment during pregnancy or postpartum. They found that treatment during pregnancy improved periodontal disease and that it is safe. However, treatment failed to significantly alter preterm birth rates.

## Interval between Pregnancies

Short intervals between pregnancies have been known for some time to be associated with adverse perinatal outcomes. In a metaanalysis, Conde-Agudelo and colleagues (2006) reported that intervals < 18 months and > 59 months were associated with increased risks for both preterm birth and small-for-gestational age newborns.

## Prior Preterm Birth

A major risk factor for preterm labor is prior preterm delivery (Spong, 2007). Shown in Table 42-6 is the incidence of recurrent preterm birth in nearly 16,000 women delivered at Parkland Hospital. The recurrent preterm delivery risk for women whose first delivery was preterm was increased threefold compared with that of women whose first neonate was born at term. More than a third of women whose first two newborns were preterm subsequently delivered a third preterm newborn. Most—70 percent—of the recurrent births in this study occurred within 2 weeks of the gestational age of the prior preterm delivery. Importantly, the causes of prior preterm delivery also recurred.

### Table 42-6. Recurrent Spontaneous Preterm Births According to Prior Outcome
Although women with prior preterm births are clearly at risk for recurrence, they contributed only 10 percent of the total preterm births in this study. Expressed another way, 90 percent of the preterm births at Parkland Hospital cannot be predicted based on a history of preterm birth. Extrapolating data from the 2003 revised birth certificates, it is estimated that approximately 2.5 percent of women delivered in 2004 had a history of prior preterm birth (Martin, 2007).

**Infection**

As discussed, a link between preterm birth and infection seems irrefutable. Goldenberg and coworkers (2008) have reviewed this association. Intrauterine infections are believed to trigger preterm labor by activation of the innate immune system. In this hypothesis, microorganisms elicit release of inflammatory cytokines such as interleukins and TNF-α, which in turn stimulate the production of prostaglandin and/or matrix-degrading enzymes. Prostaglandins stimulate uterine contractions, whereas degradation of extracellular matrix in the fetal membranes leads to preterm rupture of membranes. It is estimated that 25 to 40 percent of preterm births result from intrauterine infection. The basic science of preterm birth due to infection is discussed at length beginning on page 838.

In several studies, antimicrobial treatment has been given to prevent preterm labor due to microbial invasion. Based on available data, these strategies especially targeted mycoplasma species. Morency and colleagues (2007) performed a metaanalysis of 61 articles and suggested that antimicrobials given in the second trimester may prevent subsequent preterm birth. Andrews and associates (2006) reported results of a double-blind interconceptional trial in which they gave a course of azithromycin plus metronidazole every 4 months to 241 nonpregnant women whose last pregnancy resulted in spontaneous delivery before 34 weeks. Approximately 80 percent of the women with subsequent pregnancies had received study drug within 6 months of their subsequent conception. Such interconceptional antimicrobial treatment did not reduce the rate of recurrent preterm birth. Tita and coworkers (2007) performed a subgroup analysis of these same data and concluded that such use of antimicrobials may be harmful. In another study, Goldenberg and colleagues (2006) randomized 2661 women at four African sites to placebo or metronidazole plus erythromycin between 20 and 24 weeks’ gestation followed by ampicillin plus metronidazole during labor. This antimicrobial regimen did not reduce the rate of preterm birth or that of histological chorioamnionitis.

<sup>a</sup>Data from 15,863 women delivering their first and subsequent pregnancies at Parkland Hospital. Adapted from Bloom, 2001.
In this condition, normal, hydrogen peroxide-producing, lactobacillus-predominant vaginal flora is replaced with anaerobes that include *Gardnerella vaginalis*, *Mobiluncus* species, and *Mycoplasma hominis* (Hillier, 1995; Nugent, 1991). Its diagnosis and management are discussed in Chapter 65 (p. 1276). Using Gram staining, relative concentrations of the bacterial morphotypes characteristic of bacterial vaginosis are determined and graded as the *Nugent score*.

Bacterial vaginosis has been associated with spontaneous abortion, preterm labor, PPROM, chorioamnionitis, and amnionic fluid infection (Hillier, 1995; Kurki, 1992; Leitich, 2003a,b). Environmental factors appear to be important in bacterial vaginosis development. Exposure to chronic stress, ethnic differences, and frequent or recent douching have all been associated with increased rates of the condition (Culhane, 2002; Ness, 2002). A gene-environment interaction has been described (Macones, 2004). Women with bacterial vaginosis and a susceptible TNF-α genotype had a ninefold increased incidence of preterm birth. From all of these studies, there seems no doubt that adverse vaginal flora is associated in some way with spontaneous preterm birth. Unfortunately, to date, screening and treatment have not been shown to prevent preterm birth. Indeed, microbial resistance or antimicrobial-induced change in the vaginal flora has been reported as a result of regimens intended to eliminate bacterial vaginosis (Beigi, 2004; Carey, 2005). Okun and associates (2005) performed a systematic review of antibiotics given for bacterial vaginosis and for *Trichomonas vaginalis*. They found no evidence to support such use for the prevention of preterm birth in either low-risk or high-risk women.

**DIAGNOSIS**

Preterm labor is primarily diagnosed by symptoms and physical examination. Sonography is used to identify asymptomatic cervical dilation and effacement.

**Symptoms**

Early differentiation between true and false labor is difficult before there is demonstrable cervical effacement and dilatation. Uterine activity alone can be misleading because of *Braxton Hicks contractions*, which are discussed in detail in Chapter 21 (p. 409). These contractions, described as irregular, nonrhythmical, and either painful or painless, can cause considerable confusion in the diagnosis of true preterm labor. Not infrequently, women who deliver before term have uterine activity that is attributed to Braxton Hicks contractions, prompting an incorrect diagnosis of false labor. Accordingly, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) define preterm labor to be regular contractions before 37 weeks that are associated with cervical change.

In addition to painful or painless uterine contractions, symptoms such as pelvic pressure, menstrual-like cramps, watery vaginal discharge, and lower back pain have been empirically associated with impending preterm birth. Such complaints are thought by some to be common in normal pregnancy and are therefore often dismissed by patients, clinicians, and nurses.

The importance of these symptoms as a harbinger of labor has been emphasized by some but not all investigators (Iams, 1990; Kragt, 1990). Iams and coworkers (1994) found that the signs and symptoms signaling preterm labor, including uterine contractions, appeared only within 24 hours of preterm labor.

Chao (2011) prospectively studied 843 women with singletons who presented to Parkland
Hospital with preterm labor symptoms, between 24\textsuperscript{0/7} and 33\textsuperscript{6/7} weeks, intact membranes, and cervical dilation < 2 cm. These women underwent electronic fetal and uterine contraction monitoring for 2 hours. Those whose cervix remained < 2 cm were sent home with a diagnosis of false preterm labor. When analyzed compared with the general obstetrical population, women sent home had a similar and nonsignificant rate of birth before 34 weeks—2 versus 1 percent. However, these women had a significantly higher rate of birth between 34 and 36 weeks—5 percent compared with 2 percent. Women with cervical dilation of 1 cm at discharge were significantly more likely to deliver before 34 weeks compared with women without cervical dilatation—5 percent versus 1 percent. Importantly, almost 90 percent of the 1-cm group delivered > 21 days after the initial presentation.

### Cervical Change

#### Dilatation

Researchers have evaluated asymptomatic cervical changes that may presage and thus predict preterm labor. Asymptomatic cervical dilatation after midpregnancy is suspected to be a risk factor for preterm delivery, although some clinicians consider it to be a normal anatomical variant. Moreover, study results have suggested that parity alone is not sufficient to explain cervical dilatation discovered early in the third trimester. Cook (1996) longitudinally evaluated cervical status with transvaginal sonography between 18 and 30 weeks in both nulliparous and parous women who all subsequently gave birth at term. Cervical length and diameter were identical in both groups throughout these critical weeks. In a study from Parkland Hospital, routine digital cervical examinations were performed between 26 and 30 weeks in 185 women. Approximately 25 percent of women whose cervix was dilated 2 or 3 cm delivered before 34 weeks. Other investigators have verified cervical dilatation as a predictor of increased preterm delivery risk (Copper, 1995; Pereira, 2007).

Although women with dilatation and effacement in the third trimester are at increased risk for preterm birth, detection does not improve pregnancy outcome. Buekens and associates (1994) randomly assigned 2719 women to undergo routine cervical examinations at each prenatal visit and compared them with 2721 women in whom serial examinations were not performed. Knowledge of antenatal cervical dilatation did not affect any pregnancy outcome related to preterm birth or the frequency of interventions for preterm labor. The investigators also reported that cervical examinations were not related to preterm membrane rupture. At this time, it seems that prenatal cervical examinations are neither beneficial nor harmful.

#### Length

Vaginal-probe sonographic cervical assessment has been evaluated extensively during the past two decades. When performed by trained operators, cervical length analysis using transvaginal sonography is safe, highly reproducible, and more predictive than transabdominal sonographic screening (American College of Obstetricians and Gynecologists, 2012b). Unlike the transabdominal approach, transvaginal cervical sonography is not affected by maternal obesity, cervix position, or shadowing from the fetal presenting part. Technique is important, and Yost and colleagues (1999) have cautioned that special expertise is needed. Iams and coworkers (1996) measured cervical length at approximately 24 weeks’ gestation and again at 28 weeks in 2915 women not at risk for preterm birth. The mean cervical length at 24 weeks was approximately 35 mm, and those women with progressively shorter cervices experienced increased rates of preterm birth.
Until recently, routine cervical length evaluation in women at low risk was not advocated because, like other factors associated with potentially higher preterm birth risk, no effective treatments were available. Randomized trials done to investigate vaginal progesterone use in women with short cervix diagnosed during screening have stimulated consideration of whether or not such screening is warranted (Fonseca, 2007; Hassan, 2011). These trials are discussed subsequently on page 844.

**Ambulatory Uterine Monitoring**

An external tocodynamometer belted around the abdomen and connected to an electronic waist recorder allows a woman to ambulate while uterine activity is recorded. Results are transmitted via telephone daily. Women are educated concerning signs and symptoms of preterm labor, and clinicians are kept apprised of their progress. The 1985 approval of this monitor by the Food and Drug Administration (FDA) prompted its widespread clinical use. Subsequently, the American College of Obstetricians and Gynecologists (1995) concluded that the use of this expensive, bulky, and time-consuming system does not reduce preterm birth rates. A subsequent study by the Collaborative Home Uterine Monitoring Study Group (1995) confirmed these conclusions. A study by Iams and associates (2002) analyzed data from almost 35,000 hours of daily home monitoring and verified that no contraction pattern efficiently predicted preterm birth. The American College of Obstetricians and Gynecologists (2012a) does not recommend home uterine activity monitoring.

**Fetal Fibronectin**

This glycoprotein is produced in 20 different molecular forms by various cell types, including hepatocytes, fibroblasts, endothelial cells, and fetal amnion. Present in high concentrations in maternal blood and in amniotic fluid, it is thought to function in intercellular adhesion during implantation and in maintenance of placental adherence to uterine decidua (Leeson, 1996). Fetal fibronectin is detected in cervicovaginal secretions in women who have normal pregnancies with intact membranes at term. It appears to reflect stromal remodeling of the cervix before labor.

Lockwood (1991) reported that fibronectin detection in cervicovaginal secretions before membrane rupture was a possible marker for impending preterm labor. Fetal fibronectin is measured using an enzyme-linked immunosorbent assay, and values exceeding 50 ng/mL are considered positive. Sample contamination by amniotic fluid and maternal blood should be avoided. Interventional studies based on the use of fetal fibronectin screening in asymptomatic women have not demonstrated improved perinatal outcomes (Andrews, 2003; Grobman, 2004). The American College of Obstetricians and Gynecologists (2012b) does not recommend screening with fetal fibronectin tests.

---

**PRETERM BIRTH PREVENTION**

Prevention of preterm birth has been an elusive goal. Recent reports, however, suggest that prevention in selected populations may be achievable.

**Cervical Cerclage**
There are at least three circumstances when cerclage placement may be used to prevent preterm birth. Two are done prophylactically, and a third is done for treatment. The first prophylactic cerclage is used in women who have a history of recurrent midtrimester losses and who are diagnosed with cervical insufficiency (Chap. 18, p. 360). The second prophylactic cerclage is for women identified during sonographic examination to have a short cervix. The third indication is “rescue” cerclage, done emergently when cervical incompetence is recognized in women with threatened preterm labor.

For women with a short cervix detected by sonography, Berghella and colleagues (2005) reviewed several small trials of cerclage in this group and concluded that cerclage may reduce preterm birth rates in those women with a prior preterm birth. Owen (2009) randomly assigned 302 women with prior preterm birth from 16 centers with a short cervix—defined as length < 25 mm—to cerclage or no procedure. Women with a cervical length < 15 mm delivered before 35 weeks significantly less often following cerclage compared with women with no cerclage—30 versus 65 percent. This study suggests that recurrent preterm birth can be prevented in a subset of women who have a history of prior preterm births.

In a multinational study, To and associates (2004) screened 47,123 women and randomized the 253 women with cervices < 15 mm to cerclage or no cerclage. The frequency of preterm delivery < 33 weeks was not significantly different between the treatment groups. Thus, cerclage for sonographically detected short cervix alone has not been found to be beneficial. In contrast, women with a very short cervix, that is, < 15 mm, and a history of prior preterm birth may benefit.

### Prophylaxis with Progestin Compounds

Progesterone levels in most mammals fall rapidly before the onset of labor. This is termed progesterone withdrawal and is considered to be a parturition-triggering event. During human parturition, however, maternal, fetal, and amnionic fluid progesterone levels remain elevated with no decline. It has been proposed that human parturition involves functional progesterone withdrawal mediated by decreased progesterone activity of progesterone receptors (Ziyan, 2010). It follows conceptually that the administration of progesterone to maintain uterine quiescence may block preterm labor. This hypothesis has stimulated several studies in the past half century.

### Prior Preterm Birth and Progestin Compounds

#### Initial Studies

Studies in the past 15 years have included several investigations to evaluate progestin compounds given prophylactically. A pivotal study was done by the MFMU Network to evaluate prophylactic progestin treatment for women at high-risk for recurrent preterm birth (Meis, 2003). In this trial, 310 women with a prior preterm birth were randomized to receive 17-hydroxyprogesterone caproate (17-OHPC) (Romero, 2013). Another 153 women received placebo, and these were administered as weekly intramuscular injections of either inert oil or 17-OHPC from 16 through 36 weeks’ gestation. Delivery rates before 37, 35, and 32 weeks were all significantly reduced by 17-OHPC therapy. At the same time, however, similar studies of 17-OHPC in both twins and triplets done by the Network showed no improvement in preterm birth rates (Caritis, 2009; Rouse, 2007).

The 17-OHPC study by Meis and colleagues (2003) has been challenged because of the unexpectedly high preterm delivery rate in the placebo arm of the trial. Fifty-five percent delivered rather than the expected rate of 36 percent, which was derived from a pretrial cohort (Romero, ...
The criticism is that 17-OHPC may have been shown to be effective only because the placebo group was distorted by this high 55-percent preterm delivery rate. This compared with the 36-percent rate, which was actually observed when women were treated with 17-OHPC in the trial. To further elucidate this disparity, a confirmation trial by the Network is underway.

Also in contrast to the 17-OHPC study by Meis and coworkers (2003), O’Brien and associates (2007) randomly assigned 659 women with a prior preterm birth to treatment with daily vaginal progesterone gel (90 mg) or placebo. They found no differences in preterm birth rates.

Subsequent Studies
Perhaps no other topic in contemporary obstetrics has generated as much interest and debate since the 23rd edition of *Williams Obstetrics* as has the use of progestins to prevent preterm birth. At the center of the controversy is whether or not progestins prevent preterm birth in women with a singleton pregnancy but without prior preterm birth—especially nulliparous women. If progestins are effective in women at low risk for preterm birth, this would justify sonographic screening of all pregnant women to detect short cervices (Silver, 2011).

Three randomized trials are at the center of the controversy, and these are summarized in Table 42-7. Fonseca and colleagues (2007) randomly assigned 250 women with sonographically short cervices—15 mm or less—identified during routine prenatal care. Women were given nightly 200-mg micronized progesterone vaginal capsules or placebo from 24 to 34 weeks’ gestation. As shown in Table 42-7, spontaneous delivery before 34 weeks was significantly reduced by progesterone therapy. Importantly, this trial included not only nulliparous women but also those with twins or prior preterm birth.

aDetected sonographically.

17-OHPC = 17-hydroxyprogesterone caproate; IM = intramuscularly; NS = nonsignificant; PTB = preterm birth; UK = United Kingdom; US = United States.

Hassan and coworkers (2011) randomly assigned 465 women with a sonographically short cervix—10 to 20 mm—to vaginal progesterone gel, 90 mg daily or placebo. As shown in Table 42-7, spontaneous delivery before 34 weeks was significantly decreased by progesterone therapy.
Unlike the Fonseca (2007) trial, however, twin gestations were excluded. This trial was performed in 44 hospitals located in 10 countries including the United States. The FDA rejected progesterone gel for use in the United States because the results did not meet the level of statistical significance required to show efficacy in the subjects recruited in this country. Neither the Fonseca (2007) nor the Hassan (2011) studies report subset analyses exclusive to nulliparas (Parry, 2012). According to Likis and colleagues (2012), the heterogeneity of these two studies that included women with varied indications for progestin treatment, combined with the fact that outcomes were not reported by risk factors such as nulliparity, makes it impossible to interpret the efficacy of progesterone for specific indications. Based on these studies, the American College of Obstetricians and Gynecologists (2012a,b) concluded that it could not “mandate universal cervical length screening in women without a prior preterm birth, but that this screening strategy may be considered.”

The most recently published study that addresses use of progestins to prevent preterm birth in nulliparas included 657 randomly assigned to 17-OHPC or placebo (Grobman, 2012). This study was limited to women with singletons and sonographic cervical length < 30 mm detected between 16 and 22\(\frac{3}{7}\) weeks. Treatment with 17-OHPC given weekly did not reduce the frequency of preterm birth before 37 weeks. Subgroup analyses by cervical length and gestational age at delivery are summarized in Table 42-8. Regardless of cervical length, 17-OHPC was ineffective.

\(^a\) \(p\) value for Breslow-Day interaction term.
Data are presented as \(n/N\) (%).
CI = confidence interval; RR = relative risk; 17-OHPC = 17-hydroxyprogesterone caproate.
Data from Grobman, 2012.

Another interesting development vis-à-vis progestin therapy for preterm birth since the last edition of *Williams Obstetrics* was the marketing of 17-OHPC by KV Pharmaceuticals under th
brand name *Makena*. The original retail price was $1500 per 250-mg injectable dose. Thus, a 20-week course for one woman would cost $30,000. This caused an uproar among the leadership of organizations in obstetrics and gynecology. The United States Congress became involved, and the FDA permitted continued availability of 17-hydroxyprogesterone compounded by pharmacies as an alternative to *Makena*. In Dallas in 2013, a 250-mg injectable dose of compounded 17-OHPC cost about $18. KV Pharmaceuticals filed for Chapter 11 bankruptcy in August 2012. The company cited that it had been unable to realize the full value of its most important drug, *Makena* (St Louis Business Journal, 2012).

So, how does the clinician reconcile the conflicting evidence as to the efficacy of progestins across the spectrum of the various specific indications? Romero and Stanczyk (2013) argue that one explanation for the conflicting evidence is that progesterone is not the same as 17-hydroxyprogesterone caproate (Figure 42-9). Progesterone is a natural steroid produced by the corpus luteum and the placenta, whereas 17-hydroxyprogesterone caproate is a synthetic steroid. These authors reviewed the basic science of natural and synthetic progestins vis-à-vis effects on the uterus and cervix in pregnant women, animals, and in vitro experiments. For example, natural progesterone suppresses myometrial contractility in strips that were obtained at cesarean delivery, whereas synthetic 17-OHPC did not. This report is an excellent source of information on the issues involved with progestin use in preterm birth.

![Figure 42-9](https://example.com/figure42-9.png)

**FIGURE 42-9** Chemical structure of progesterone and 17α-hydroxyprogesterone caproate (17-OHPC).

The evidence for or against the preventive efficacy of progestins for preterm birth is clearly complex. As outlined in this section, virtually all evidence supporting use for a specific indication can be challenged in some way. Currently, at Parkland Hospital, we are prescribing weekly injections of 17-hydroxyprogesterone compounded by a local pharmacy for women with a prior preterm birth. In our view, all other indications for the use of progestin in the prevention of preterm birth are investigational.

### Geographic-Based Public Health-Care Programs

A well-organized prenatal system results in a decreased preterm birth rate in high-risk indigent populations. The decreasing preterm birth rate at Parkland Hospital between 1988 and 2006 shown in Figure 42-10 coincided with a substantial increase in prenatal care utilization. In the early 1990s, a concerted effort was made to improve access to and use of prenatal care. The intention was to develop a program of seamless care beginning with enrollment during the prenatal...
period and extending through delivery and into the puerperium. Prenatal clinics are placed strategically throughout Dallas County to provide convenient access for indigent women. When possible, these clinics were colocated with comprehensive medical and pediatric clinics that enhance patient use. Because the entire clinic system is operated by Parkland Hospital, administrative and medical oversight is seamless. For example, prenatal protocols are used by nurse practitioners at all clinic sites to guarantee homogeneous care. Women with high-risk pregnancy complications are referred to the hospital-based central clinic system. Here, high-risk pregnancy clinics operate each weekday, with specialty clinics for women with prior preterm birth, gestational diabetes, infectious diseases, multifetal pregnancy, and hypertensive disorders. Clinics are staffed by residents and midwives supervised by maternal-fetal medicine fellows and faculty. Because Parkland Hospital has a closed medical staff, all attending physicians are employed by the University of Texas Southwestern Department of Obstetrics and Gynecology. These faculty members adhere to agreed-upon practice guidelines using an evidence-based outcomes approach. Thus, prenatal care is considered one component of a comprehensive and orchestrated public health care system that is community-based. Putting this together, we hypothesize that the decrease in preterm births experienced at our inner-city hospital was attributable to a geographically based public health-care program specifically targeting minority populations of pregnant women. A similar obstetrical care system for indigent women at the University of Alabama at Birmingham has also produced salutary results (Tita, 2011).

**FIGURE 42-10** Percentage of births before 37 weeks’ gestation at Parkland Hospital from 1988 to 2006 compared with that in the United States from 1996 to 2002. Analysis in both cohorts was limited to singleton live births ≥ 500 g who received prenatal care. (Redrawn from Leveno, 2009, with permission.)

**MANAGEMENT OF PRETERM PREMATURELY RUPTURED MEMBRANES**
Methods used to diagnose ruptured membranes are detailed in Chapter 22 (p. 448). A history of vaginal leakage of fluid, either as a continuous stream or as a gush, should prompt a speculum examination to visualize gross vaginal pooling of amnionic fluid, clear fluid from the cervical canal, or both. Confirmation of ruptured membranes is usually accompanied by sonographic examination to assess amnionic fluid volume, to identify the presenting part, and if not previously determined, to estimate gestational age. Confirmation of ruptured membranes is usually accompanied by sonographic examination to assess amnionic fluid volume, to identify the presenting part, and if not previously determined, to estimate gestational age. Amnionic fluid is slightly alkaline (pH 7.1–7.3) compared with vaginal secretions (pH 4.5–6.0). This is the basis of frequently used pH testing for ruptured membranes. Blood, semen, antiseptics, or bacterial vaginosis, however, are all also alkaline and can give false-positive results.

Natural History

Cox and associates (1988) described pregnancy outcomes of 298 consecutive women who gave birth following spontaneously ruptured membranes between 24 and 34 weeks at Parkland Hospital. Although this complication was identified in only 1.7 percent of pregnancies, it contributed to 20 percent of all perinatal deaths. By the time they presented, 75 percent of the women were already in labor, 5 percent were delivered for other complications, and another 10 percent delivered within 48 hours. In only 7 percent was delivery delayed 48 hours or more after membrane rupture. This last subgroup, however, appeared to benefit from delayed delivery because there were no neonatal deaths. This contrasted with a neonatal death rate of 80 per 1000 in preterm newborns delivered within 48 hours of membrane rupture. Nelson (1994) reported similar results.

The time from PPROM to delivery is inversely proportional to the gestational age when rupture occurs (Carroll, 1995). As shown in Figure 42-11, very few days were gained when membranes ruptured during the third trimester compared with midpregnancy.
Hospitalization
Most clinicians hospitalize women with PPROM. Concerns regarding the costs of lengthy hospitalizations are usually moot, because most women enter labor within a week or less after membrane rupture. Carlan and coworkers (1993) randomly assigned 67 women with ruptured membranes to home or hospital management. No benefits were found for hospitalization, and maternal hospital stays were reduced by 50 percent in those sent home—14 versus 7 days. Importantly, the investigators emphasized that this study was too small to conclude that home management was safe vis-à-vis umbilical cord prolapse.

Intentional Delivery
Before the mid-1970s, labor was usually induced in women with preterm ruptured membranes because of fear of sepsis. Two randomized trials compared labor induction with expectant management in such pregnancies. Mercer and associates (1993) randomly assigned 93 women with pregnancies between 32 and 36 weeks to undergo delivery or expectant management. Fetal lung maturity, as evidenced by mature surfactant profiles, was present in all cases. Intentional delivery reduced the length of maternal hospitalization and also reduced infection rates in both mothers and neonates. Cox and coworkers (1995) similarly apportioned 129 women between 30 and 34 weeks. Fetal lung maturity was not assessed. One fetal death resulted from sepsis in the pregnancies.
Expectant Management

Despite extensive literature concerning expectant management of PPROM, tocolysis has been used in few studies. In randomized studies, women were assigned to receive either tocolysis or expectant management. The investigators concluded that active interventions did not improve perinatal outcomes (Garite, 1981, 1987; Nelson, 1985).

Other considerations with expectant management involve the use of digital cervical examination and cerclage. Alexander and colleagues (2000) analyzed findings in women expectantly managed between 24 and 32 weeks’ gestation. They compared those who had one or two digital cervical examinations with women who were not examined digitally. Women who were examined had a rupture-to-delivery interval of 3 days compared with 5 days in those who were not examined. This difference did not worsen maternal or neonatal outcomes.

There is uncertainty regarding ruptured membranes in the woman who has undergone cervical cerclage. McElrath and associates (2002) studied 114 women with cerclage in place who later had ruptured membranes before 34 weeks. They were compared with 288 controls who had not received a cerclage. Pregnancy outcomes were equivalent in both groups. As discussed in Chapter 18 (p. 363), such management is controversial.

Risks of Expectant Management

Maternal and fetal risks vary with the gestational age at membrane rupture. Morales (1993b) expectantly managed 94 singleton pregnancies with ruptured membranes before 25 weeks. The average time gained was 11 days. Although 41 percent of infants survived to age 1 year, only 27 percent were neurologically normal. Similar results were reported by Farooqi (1998) and Winn (2000) and their colleagues. Lieman and associates (2005) found no improved neonatal outcomes with expectant management beyond 33 weeks. In contrast, McElrath and coworkers (2003) found that prolonged latency after membrane rupture was not associated with an increased incidence of fetal neurological damage.

The volume of amniotic fluid remaining after rupture appears to have prognostic importance in pregnancies before 26 weeks. Hadi and colleagues (1994) described 178 pregnancies with ruptured membranes between 20 and 25 weeks. Forty percent of women developed oligohydramnios, defined by the absence of fluid pockets 2 cm or larger. Virtually all women with oligohydramnios delivered before 25 weeks, whereas 85 percent with adequate amniotic fluid volume were delivered in the third trimester. Carroll and coworkers (1995) observed no cases of pulmonary hypoplasia in fetuses born after membrane rupture at 24 weeks or beyond. This suggests that 23 weeks or less is the threshold for development of lung hypoplasia. Further, when contemplating early expectant management, consideration is also given to oligohydramnios and resultant limb compression deformities (Chap. 11, p. 237).

Other risk factors have also been evaluated. In neonates born to women with active herpetic lesions who were expectantly managed, the infectious morbidity risk appeared to be outweighed by risks associated with preterm delivery (Major, 2003). Lewis and associates (2007) found that expectant management of women with preterm ruptured membranes and noncephalic presentation was associated with an increased rate of umbilical cord prolapse, especially before 26 weeks.
Clinical Chorioamnionitis

Most authors report that prolonged membrane rupture is associated with increased fetal and maternal sepsis (Ho, 2003). If chorioamnionitis is diagnosed, prompt efforts to effect delivery, preferably vaginally, are initiated. Fever is the only reliable indicator for this diagnosis, and temperature of 38°C (100.4°F) or higher accompanying ruptured membranes implies infection. Maternal leukocytosis alone has not been found to be reliable. During expectant management, monitoring for sustained maternal or fetal tachycardia, for uterine tenderness, and for a malodorous vaginal discharge is warranted.

With chorioamnionitis, fetal and neonatal morbidity is substantively increased. Alexander and colleagues (1998) studied 1367 very-low-birthweight neonates delivered at Parkland Hospital. Approximately 7 percent were born to women with overt chorioamnionitis, and their outcomes were compared with similar newborns without clinical infection. Those in the infected group had a higher incidence of sepsis, respiratory distress syndrome, early-onset seizures, intraventricular hemorrhage, and periventricular leukomalacia. The investigators concluded that these very-low-birthweight neonates were vulnerable to neurological injury attributable to chorioamnionitis.

Although Locatelli and coworkers (2005) have challenged this finding, there is other evidence that very small newborns are at increased risk for sepsis. Yoon and colleagues (2000) found that intraamnionic infection in preterm neonates was related to increased rates of cerebral palsy. Petrova and associates (2001) studied more than 11 million singleton live births in the United States from 1995 to 1997. During labor, 1.6 percent of all women had fever, and this was a strong predictor of infection-related death in both term and preterm neonates. Bullard and colleagues (2002) reported similar results.

Accelerated Pulmonary Maturation

Various clinical events—some well defined—were once proposed to accelerate fetal surfactant production (Gluck, 1979). These included chronic renal or cardiovascular disease, hypertensive disorders, heroin addiction, fetal-growth restriction, placental infarction, chorioamnionitis, and preterm ruptured membranes. Although this view was widely held for many years, subsequent observations do not support this association (Hallak, 1993; Owen, 1990).

Antimicrobial Therapy

The proposed microbial pathogenesis for spontaneous preterm labor or ruptured membranes has prompted investigators to give various antimicrobials in an attempt to forestall delivery. Mercer and associates (1995) reviewed 13 randomized trials performed before 35 weeks. Metaanalysis indicated that only three of 10 outcomes were possibly benefited: (1) fewer women developed chorioamnionitis, (2) fewer newborns developed sepsis, and (3) pregnancy was more often prolonged 7 days in women given antimicrobials. Neonatal survival, however, was unaffected, as was the incidence of necrotizing enterocolitis, respiratory distress, or intracranial hemorrhage.

To further address this issue, the MFMU Network designed a trial to study expectant management combined with a 7-day treatment with ampicillin, amoxicillin plus erythromycin, or placebo. The women had membrane rupture between 24 and 32 weeks. Neither tocolytics nor corticosteroids were given. Antimicrobial-treated women had significantly fewer newborns with respiratory distress syndrome, necrotizing enterocolitis, and composite adverse outcomes (Mercer, 1997). The latency period was significantly longer. Specifically, 50 percent of women given an
antimicrobial regimen remained undelivered after 7 days of treatment compared with only 25 percent of those given placebo. There was also significant prolongation of pregnancy at 14 and 21 days. Cervicovaginal group B streptococcal colonization did not alter these results.

More recent studies have examined the efficacy of shorter treatment lengths and other antimicrobial combinations. Three-day treatment compared with 7-day regimens using either ampicillin or ampicillin-sulbactam appeared equally effective in regard to perinatal outcomes (Lewis, 2003; Segel, 2003). Similarly, erythromycin compared with placebo offered a range of significant neonatal benefits. The amoxicillin-clavulanate regimen was not recommended, however, because of its association with an increased incidence of necrotizing enterocolitis (Kenyon, 2004).

Some predicted that prolonged antimicrobial therapy in such pregnancies might have unwanted consequences. Carroll (1996) and Mercer (1999) and their coworkers cautioned that such therapy potentially increased the risk for resistant bacteria. Stoll and associates (2002) studied 4337 neonates weighing from 400 to 1500 g and born from 1998 to 2000. Their outcomes were compared with those of 7606 neonates of similar birthweight born from 1991 to 1993. The overall rate of early-onset sepsis did not change between these two epochs. But the rate of group B streptococcal sepsis decreased from 5.9 per 1000 births in the 1991 to 1993 group to 1.7 per 1000 births in the 1998 to 2000 group. Comparing these same epochs, the rate of *Escherichia coli* sepsis increased from 3.2 to 6.8 per 1000 births. Almost 85 percent of coliform isolates from the more recent cohort were ampicillin resistant. Neonates with early-onset sepsis were more likely to die, especially if they were infected with coliforms. Kenyon and coworkers (2008a) found that antimicrobials given for women with PPROM had no effect on the health of children at age 7 years.

### Corticosteroids to Accelerate Fetal Lung Maturity

The National Institutes of Health (NIH) (2000) in their Consensus Development Conference recommended a single course of antenatal corticosteroids for women with preterm membrane rupture before 32 weeks and in whom there was no evidence of chorioamnionitis. Since then, several metaanalyses have addressed this issue, and according to the American College of Obstetricians and Gynecologists (2013d), single-dose therapy is recommended from 24 to 32 weeks. There is no consensus regarding treatment between 32 and 34 weeks. Corticosteroid therapy is not recommended before 24 weeks.

### Membrane Repair

Tissue sealants have been used for various purposes in medicine and have become important in maintaining surgical hemostasis and stimulating wound healing. Devlieger and colleagues (2006) have reviewed the efficacy of sealants in the repair of fetal membrane defects such as in preterm ruptured membranes.

### Management Recommendations

The management scheme recommended by the American College of Obstetricians and Gynecologists (2013d) is summarized in Table 42-9. This management is similar to that practiced at Parkland Hospital.

*The combination of birthweight, gestational age, and sex provides the best estimate of chances of survival and should be considered in individual cases.

### MANAGEMENT OF PRETERM LABOR WITH INTACT MEMBRANES

Women with signs and symptoms of preterm labor with intact membranes are managed much the same as described above for those with preterm ruptured membranes. If possible, delivery before 34 weeks is delayed. Drugs used to abate or suppress preterm uterine contractions are subsequently discussed.

#### Amniocentesis to Detect Infection

Several tests have been used to diagnose intraamnionic infection. Romero and coworkers (1993) evaluated the diagnostic value of amnionic fluid containing an elevated leukocyte count, a low glucose level, a high IL-6 concentration, or a positive Gram stain result in 120 women with preterm labor and intact membranes. Women with positive amnionic fluid culture results were considered infected. These investigators found that a negative Gram stain result was 99-percent specific to exclude amnionic fluid bacteria. A high IL-6 level was 82-percent sensitive for detection of amnionic fluid containing bacteria. Other investigators have also found good
correlation between amnionic fluid IL-6 or leukocyte levels and chorioamnionic infection (Andrews, 1995; Yoon, 1996). Despite these correlations, amniocentesis to diagnose infection does not improve pregnancy outcomes in women with or without membrane rupture (Feinstein, 1986). The American College of Obstetricians and Gynecologists (2012a) has concluded that there is no evidence to support routine amniocentesis to identify infection.

Corticosteroids for Fetal Lung Maturation

Because glucocorticosteroids were found to accelerate lung maturation in preterm sheep fetuses, Liggins and Howie (1972) evaluated them to treat women. Corticosteroid therapy was effective in lowering the incidence of respiratory distress syndrome and neonatal mortality rates if birth was delayed for at least 24 hours after initiation of betamethasone. Infants exposed to corticosteroids in these early studies have now been followed to age 31 years with no ill effects detected. In 1995, an NIH Consensus Development Conference panel recommended corticosteroids for fetal lung maturation in threatened preterm birth.

In a subsequent meeting, the NIH Consensus Development Conference (2000) concluded that data were insufficient to assess corticosteroid effectiveness in pregnancies complicated by hypertension, diabetes, multifetal gestation, fetal-growth restriction, and fetal hydrops. It concluded, however, that it was reasonable to administer corticosteroids in women with these complications.

The issue of the fetal and neonatal safety with single versus repeat courses of intramuscular corticosteroids for lung maturation has been the topic of two major trials. Although both found repeated courses to be beneficial in reducing neonatal respiratory morbidity rates, the long-term consequences were much different. Specifically, Crowther and associates (2007) studied outcomes in 982 women who were given a single weekly dose of 11.4 mg of betamethasone. These investigators found no adverse effects in the infants followed to age 2 years. Wapner and colleagues (2007) studied infants born to 495 women who were randomly assigned to receive a single corticosteroid course or repeated courses that were given weekly. With each round, a 12-mg betamethasone dose was injected, followed by a second given 24 hours later. A nonsignificant rise in cerebral palsy rates was identified in infants exposed to repeated courses. The twice-as-large betamethasone dose in this study was worrisome because some experimental evidence supports the view that adverse corticosteroid effects are dose dependent. Bruschettini and coworkers (2006) studied the equivalent of 12-mg versus 6-mg betamethasone given to pregnant cats. They reported that the lower dose had less severe effects on somatic growth without affecting fetal brain cell proliferation. Stiles (2007) summarized these two human studies as “early gain, long-term questions.” We agree, and at Parkland Hospital, we follow the recommendation by the American College of Obstetricians and Gynecologists (2013c) for single-course therapy.

“Rescue Therapy”

This refers to administration of a repeated corticosteroid dose when delivery becomes imminent and more than 7 days have elapsed since the initial dose. The 2000 NIH Consensus Development Conference recommended that rescue therapy should not be routinely used and that it should be reserved for clinical trials. The first randomized trial, reported by Peltoniemi and coworkers (2007), allocated 326 women to placebo or 12-mg betamethasone single-dose rescue regimens. Paradoxically, these researchers found that the rescue dose of betamethasone increased the risk of respiratory distress syndrome! In a multicenter study of 437 women < 33 weeks who were randomly assigned to rescue therapy or placebo, Kurtzman and associates (2009) reported
significantly decreased rates of respiratory complications and neonatal composite morbidity with rescue corticosteroids. There were, however, no differences in perinatal mortality rates and other morbidities. In another trial, McEvoy and colleagues (2010) showed that treated infants had improved respiratory compliance.

Garite and coworkers (2009) randomly assigned 437 women with singletons or twins < 33 weeks’ gestation and with intact membranes to one “rescue” course of either betamethasone or dexamethasone or placebo. These women had all previously completed a single course of corticosteroids before 30 weeks’ gestation and at least 14 days before the “rescue” course. Respiratory distress syndrome developed in 41 percent of the infants given corticosteroids compared with 62 percent of those randomized to placebo. There were no differences in other morbidities attributable to prematurity. In a metaanalysis, Crowther and colleagues (2011) concluded that a single course of corticosteroids should be considered in women whose prior course was administered at least 7 days previously and were < 34 weeks’ gestation. The American College of Obstetricians and Gynecologists (2012a) has taken the position that a single rescue course of antenatal corticosteroids should be considered in women before 34 weeks whose prior course was administered at least 7 days previously.

Choice of Corticosteroid

As summarized by Murphy (2007), there is a 10-year question as to whether betamethasone is superior to dexamethasone for fetal lung maturation. Elimian and associates (2007) randomly assigned 299 women between 24 and 33 weeks to betamethasone or dexamethasone. These two drugs were comparable in reducing rates of major neonatal morbidities in preterm infants.

Antimicrobials

As with preterm ruptured membranes, antimicrobials have been given in an attempt to arrest preterm labor. Results have been disappointing. A Cochrane metaanalysis by King and colleagues (2000) found no difference in the rates of newborn respiratory distress syndrome or sepsis between placebo- and antimicrobial-treated groups. They did find, however, increased perinatal morbidity in the antimicrobial-treated group. Kenyon (2001) reported the ORACLE Collaborative Group study of 6295 women with spontaneous preterm labor, intact membranes, but without evidence of infection. Women were randomly assigned to receive antimicrobial or placebo therapy. The primary outcomes of neonatal death, chronic lung disease, and major cerebral abnormality were similar in both groups. In his review, Goldenberg (2002) also concluded that antimicrobial treatment of women with preterm labor for the sole purpose of preventing delivery is generally not recommended. In a follow-up of the ORACLE II trial, Kenyon and associate (2008b) reported that fetal exposure to antimicrobials in this clinical setting was associated with an increased cerebral palsy rate at age 7 years compared with that of children without fetal exposure.

Bed Rest

This is one of the most often prescribed interventions during pregnancy, yet one of the least studied. Goldenberg (1994) reviewed the available literature on bed rest in pregnancy and found no evidence supporting or refuting the benefit of either bed rest or hospitalization for women with threatened preterm labor. Moreover, Sosa and colleagues (2004) searched the Cochrane Database and concluded that evidence neither supported nor refuted bed rest to prevent preterm birth.
Goulet and coworkers (2001) randomly assigned 250 Canadian women to either home care or hospitalization after treatment of an acute episode of preterm labor and also found no benefits. Yost and associates (2005) attempted a randomized study at Parkland Hospital but terminated the study after 6 years due to low recruitment. In this study, bed rest in the hospital compared with bed rest at home had no effect on pregnancy duration in women with threatened preterm labor before 34 weeks. Kovacevich and coworkers (2000) reported that bed rest for 3 days or more increased thromboembolic complications to 16 per 1000 women compared with only 1 per 1000 with normal ambulation. Promislow and colleagues (2004) observed significant bone loss in pregnant women prescribed outpatient bed rest.

Most recently there were three articles on bed rest in the journal Obstetrics & Gynecology. Grobman and associates (2013) found that nearly 40 percent of women enrolled in a trial to study the efficacy of 17-OHPC in those with a sonographically short cervix had some form of activity restriction. Women with activity restriction were nearly 2.5 times more likely to have a preterm birth before 34 weeks. This finding, however, may reflect ascertainment bias in that women with restricted activity may have received bed rest because they were viewed to be at more imminent risk of preterm delivery. In the same journal issue, McCall and coworkers (2013) summarized the literature on bed rest. They found insufficient evidence to support the use of bed rest and found several studies showing harm with its use. They opined that it is unethical to continue to prescribe bed rest. In an accompanying editorial, Biggio (2013) called for appropriate trials to settle these issues.

### Cervical Pessaries

There is increasing interest in the use of cervical pessaries to prevent preterm birth. Silicone rings, also known as the Arabin pessary, are being used to support the cervix in women with a sonographically short cervix. For 385 Spanish women with cervical lengths ≤ 25 mm, Goya and colleagues (2012) provided a silicone pessary or expectant management. There was spontaneous delivery before 34 weeks’ gestation in 6 percent of women in the pessary group compared with 27 percent in the expectant management group. Hui and associates (2013) randomly assigned approximately 100 women with cervices < 25 mm at 20 to 24 weeks to silicone pessaries or expectant management. The prophylactic use of silicone pessary did not reduce the rate of delivery before 34 weeks. These two studies with conflicting results are the only randomized trials to date. Currently, the MFMU Network is designing a trial to study pessary use to prevent preterm labor in twin pregnancies.

### Emergency or Rescue Cerclage

There is support for the concept that cervical incompetence and preterm labor lie on a spectrum leading to preterm delivery. Consequently, investigators have evaluated cerclage performed after preterm labor begins to manifest clinically. More than 30 years ago, Harger (1983) concluded that if cervical incompetence is recognized with threatened preterm labor, then emergency cerclage can be attempted, albeit with an appreciable risk of infection and pregnancy loss. Althuisius and colleagues (2003) randomly assigned 23 women with cervical incompetence before 27 weeks to bed rest, with or without emergency McDonald cerclage. Delivery delay was significantly greater in the cerclage group compared with that assigned to bed rest alone—54 versus 24 days. Terkildsen and coworkers (2003) studied 116 women who underwent second-trimester emergency cerclage. Nulliparity, membranes extending beyond the external cervical os, and cerclage before
22 weeks were associated with a significantly decreased chance of pregnancy continuation to 28 weeks or beyond.

### Tocolysis to Treat Preterm Labor

Although several drugs and other interventions have been used to prevent or inhibit preterm labor, none has been shown to be completely effective. The American College of Obstetricians and Gynecologists (2012a) has concluded that tocolytic agents do not markedly prolong gestation but may delay delivery in some women for up to 48 hours. This may allow transport to a regional obstetrical center and permit time for corticosteroid therapy. Beta-adrenergic agonists, calcium-channel blockers, or indomethacin are the recommended tocolytic agents for such short-term use—up to 48 hours. In contrast, the College has concluded that “Maintenance therapy with tocolytics is ineffective for preventing preterm birth and improving neonatal outcome and is not recommended for this purpose.” Moreover, the College recommends that women with preterm contractions without cervical change, especially those with cervical dilation of less than 2 cm, generally should not be treated with tocolytics.

### β-Adrenergic Receptor Agonists

Several compounds react with β-adrenergic receptors to reduce intracellular ionized calcium levels and prevent activation of myometrial contractile proteins (Chap. 21, p. 421). In the United States, ritodrine and terbutaline have been used in obstetrics, but only ritodrine had been approved for preterm labor by the FDA.

**Ritodrine.** According to the Federal Register, ritodrine was voluntarily withdrawn from the United States market in 2003. A discussion is included here because knowledge concerning β-mimetic drugs accrued with its use. In an early multicenter trial, neonates whose mothers were treated with ritodrine for threatened preterm labor had lower rates of preterm birth, death, and respiratory distress (Merkatz, 1980). In a randomized trial at Parkland Hospital, Leveno and associates (1986) found that intravenous drug treatment delayed delivery for 24 hours but without other benefits. Additional studies of parenteral β-agonist therapy confirmed a delivery delay up to 48 hours (Canadian Preterm Labor Investigators Group, 1992).

Unfortunately, this delay in preterm delivery provided no fetal benefits. Macones and colleagues (1995) used metaanalysis to assess the efficacy of oral β-agonist therapy and found no benefits. Keirse (1995b) suggested that this brief delay may aid maternal transport to tertiary care or permit fetal lung maturation with corticosteroids. Although this intuitive reasoning is logical, there are no data to support this.

β-Agonist infusion has resulted in frequent and, at times, serious and even fatal maternal side effects. Pulmonary edema is a special concern, and its contribution to morbidity is discussed in Chapter 47 (p. 942). Tocolysis was the third most common cause of acute respiratory distress and death in pregnant women during a 14-year period in Mississippi (Perry, 1998). The cause of pulmonary edema is multifactorial. Risk factors include tocolytic therapy with β-agonists, multifetal gestation, concurrent corticosteroid therapy, tocolysis for more than 24 hours, and large intravenous crystalloid volume infusion. Because β-agonists cause retention of sodium and water, with time—usually 24 to 48 hours, these can cause volume overload (Hankins, 1988). The drugs have been implicated in increased capillary permeability, cardiac rhythm disturbances, and myocardial ischemia.
**Terbutaline.** This β-agonist is commonly used to forestall preterm labor. Like ritodrine, it can cause pulmonary edema (Angel, 1988). Low-dose terbutaline can be administered long-term by subcutaneous pump (Lam, 1988). Marketed between 1987 and 1993, these pumps were used in nearly 25,000 women with suspected preterm labor (Perry, 1995). Adverse reports describe a sudden maternal death and a newborn with myocardial necrosis after the mother used the pump for 12 weeks (Fletcher, 1991; Hudgens, 1993). Elliott and associates (2004) used continuous terbutaline subcutaneous infusion in 9359 patients and reported that only 12 women experienced severe adverse events—primarily pulmonary edema.

However, randomized trials have reported no benefit for terbutaline pump therapy. Wenstrom and coworkers (1997) randomly assigned 42 women with preterm labor to a terbutaline pump, to a saline pump, or to oral terbutaline. In another trial, Guinn and colleagues (1998) randomly treated 52 women with terbutaline or with saline pump therapy. Terbutaline did not significantly prolong pregnancy, prevent preterm delivery, or improve neonatal outcomes in either of these studies.

Oral terbutaline therapy to prevent preterm delivery has also not been effective (How, 1995; Parilla, 1993). In a double-blind trial, Lewis and coworkers (1996) studied 203 women with arrested preterm labor at 24 to 34 weeks. Women were randomly assigned to receive 5-mg terbutaline tablets or placebo every 4 hours. Delivery rates at 1 week were similar in both groups, as was median latency, mean gestational age at delivery, and the incidence of recurrent preterm labor. In 2011, the FDA issued a warning regarding use of terbutaline to treat preterm labor because of reports of serious maternal side effects.

**Magnesium Sulfate**

Ionic magnesium in a sufficiently high concentration can alter myometrial contractility. Its role is presumably that of a calcium antagonist, and when given in pharmacological doses, it may inhibit labor. Steer and Petrie (1977) concluded that intravenous magnesium sulfate—a 4-g loading dose followed by a continuous infusion of 2 g/hr—usually arrests labor. The pharmacology and toxicology of magnesium are considered in more detail in Chapter 40 (p. 759). Samol and associates (2005) reported 67 cases—8.5 percent—of pulmonary edema among 789 women given tocolysis with magnesium sulfate at their hospital.

There have been only two randomized placebo-controlled studies of tocolysis with magnesium sulfate. Cotton and colleagues (1984) compared magnesium sulfate, ritodrine, and placebo in 54 women in preterm labor. They identified few differences in outcomes. Cox and coworkers (1990) randomly assigned 156 women to receive magnesium sulfate or normal saline infusions. Magnesium-treated women and their fetuses had identical outcomes compared with those given placebo. Because of these findings, this method of tocolysis was abandoned at Parkland Hospital. Grimes (2006) reviewed this tocolytic agent and concluded it was ineffective and potentially harmful.

Recently, the FDA (2013) warned against prolonged use of magnesium sulfate given to arrest preterm labor due to bone thinning and fractures in fetuses exposed for more than 5 to 7 days. This was attributed to low calcium levels in the fetus.

**Prostaglandin Inhibitors**

Prostaglandins are intimately involved in contractions of normal labor (Chap. 21, p. 426). Antagonists act by inhibiting prostaglandin synthesis or by blocking their action on target organs. A group of enzymes collectively termed prostaglandin synthase is responsible for the conversion of free arachidonic acid to prostaglandins (Fig. 21-16, p. 422). Several drugs block this system,
including acetylsalicylate and indomethacin.

Indomethacin was first used as a tocolytic for 50 women by Zuckerman and associates (1974). Studies that followed reported the efficacy of indomethacin in halting contractions and delaying preterm birth (Muench, 2003; Niebyl, 1980). Morales and coworkers (1989, 1993a), however, compared indomethacin with either ritodrine or magnesium sulfate and found no difference in their efficacy to forestall preterm delivery. Berghella and associates (2006) reviewed four trials of indomethacin given to women with sonographically short cervixes and found such therapy ineffective.

Indomethacin is administered orally or rectally. A dose of 50 to 100 mg is followed at 8-hour intervals not to exceed a total 24-hour dose of 200 mg. Serum concentrations usually peak 1 to 2 hours after oral administration, whereas levels after rectal administration peak slightly earlier. Most studies have limited indomethacin use to 24 to 48 hours because of concerns for oligohydramnios, which can develop with these doses. If amnionic fluid is monitored, oligohydramnios can be detected early, and it is reversible with drug discontinuation.

Case-control studies have assessed neonatal effects of exposure to indomethacin given for preterm labor. In a study of neonates born before 30 weeks, Norton and coworkers (1993) identified necrotizing enterocolitis in 30 percent of 37 indomethacin-exposed newborns compared with 8 percent of 37 control newborns. Higher incidences of intraventricular hemorrhage and patent ductus arteriosus were also documented in the indomethacin group. The impact of treatment duration and its timing in relation to delivery were not reported. In contrast, several investigators have challenged the association between indomethacin exposure and necrotizing enterocolitis (Muench, 2001; Parilla, 2000). Finally, Gardner (1996) and Abbasi (2003) and their colleagues found no link between indomethacin use and intraventricular hemorrhage, patent ductus arteriosus, sepsis, necrotizing enterocolitis, or neonatal death.

Schmidt and associates (2001) followed 574 newborns who were randomly assigned to receive either indomethacin or placebo to prevent pulmonary hypertension from patent ductus arteriosus. The infants, who weighed 500 to 1000 g, were followed to a corrected age of 18 months. Those given indomethacin had a significantly reduced incidence of both patent ductus arteriosus and severe intraventricular hemorrhage. Survival without impairment, however, was similar in both groups. Peck and coworkers (2003) reported that indomethacin therapy for 7 or more days before 33 weeks does not increase the risk of neonatal or childhood medical problems. Two metaanalyses of the effects of antenatal indomethacin on neonatal outcomes had conflicting findings (Amin, 2007; Loe, 2005).

Calcium-Channel Blockers

Myometrial activity is directly related to cytoplasmic free calcium, and a reduction in its concentration inhibits contractions (Chap. 21, p. 417). Calcium-channel blockers act to inhibit, by various mechanisms, calcium entry through cell membrane channels. Although they were developed to treat hypertension, their ability to arrest preterm labor has been evaluated.

Using the Cochrane Database, Keirse (1995a) compared nifedipine and β-agonists. They concluded that although nifedipine treatment reduced births of neonates weighing < 2500 g, significantly more of these were admitted for intensive care. Other investigators have also concluded that calcium-channel blockers, especially nifedipine, are safer and more effective tocolytic agents than are β-agonists (King, 2003; Papatsonis, 1997). Lyell and colleagues (2007) randomized 192 women at 24 to 33 weeks to either magnesium sulfate or nifedipine and found no substantial differences in efficacy or adverse effects. Salim and associates (2012) randomly assigned 145 women in preterm labor between 24 and 33 weeks to nifedipine or atosiban. No
clear superiority of either to delay delivery was identified, and otherwise, neonatal morbidity was equivalent. Importantly, no randomized trial has compared nifedipine to placebo for acute tocolysis.

The combination of nifedipine with magnesium for tocolysis is potentially dangerous. Ben-Ami (1994) and Kurtzman (1993) and their coworkers reported that nifedipine enhances the neuromuscular blocking effects of magnesium that can interfere with pulmonary and cardiac function. How and associates (2006) randomly provided 54 women between 320/7 and 346/7 weeks with magnesium sulfate plus nifedipine or no tocolytic and found neither benefit nor harm.

**Atosiban**

This nonapeptide oxytocin analogue is a competitive antagonist of oxytocin-induced contractions. Goodwin and colleagues (1995) described its pharmacokinetics in pregnant women. In randomized clinical trials, atosiban failed to improve relevant neonatal outcomes and was linked with significant neonatal morbidity (Moutquin, 2000; Romero, 2000). The FDA has denied approval of atosiban because of concerns regarding efficacy and fetal–newborn safety. Goodwin (2004) has reviewed the history of atosiban both in the United States and in Europe, where this drug is approved and widely used as a tocolytic.

**Nitric Oxide Donors**

These potent smooth-muscle relaxants affect the vasculature, gut, and uterus. In randomized clinical trials, nitroglycerin administered orally, transdermally, or intravenously was not effective or showed no superiority to other tocolytics. In addition, maternal hypotension was a common side effect (Bisits, 2004; Clavin, 1996; El-Sayed, 1999; Lees, 1999).

**Summary of Tocolysis for Preterm Labor**

In many women, tocolytics stop contractions temporarily but rarely prevent preterm birth. In a metaanalysis of tocolytic therapy, Gyetvai and associates (1999) concluded that although delivery may be delayed long enough for administration of corticosteroids, treatment does not result in improved perinatal outcome. Berkman and colleagues (2003) reviewed 60 reports and concluded that tocolytic therapy can prolong gestation, but that β-agonists are no better than other drugs and pose potential maternal danger. They also concluded that there are no benefits of maintenance tocolytic therapy.

In general, if tocolytics are given, they should be administered concomitantly with corticosteroids. The gestational age range for their use is debatable. However, because corticosteroids are not generally used after 33 weeks and because the perinatal outcomes in preterm neonates are generally good after this time, most practitioners do not recommend use of tocolytics at or after 33 weeks (Goldenberg, 2002).

**Labor**

Whether labor is induced or spontaneous, abnormalities of fetal heart rate and uterine contractions should be sought. We prefer continuous electronic monitoring. Fetal tachycardia, especially with ruptured membranes, is suggestive of sepsis. There is some evidence that intrapartum acidemia may intensify some of the neonatal complications usually attributed to preterm delivery. For example, Low and colleagues (1995) observed that intrapartum acidosis—umbilical artery blood pH less than 7.0—had an important role in neonatal complications (Chap. 32, p. 629). Similarly,
Kimberlin and coworkers (1996) found that increasing umbilical artery blood acidemia was related to more severe respiratory disease in preterm neonates. Despite this, no effects were found in short-term neurological outcomes that included intracranial hemorrhages.

Group B streptococcal infections are common and dangerous in the preterm neonate. Accordingly, as discussed in Chapter 64 (p. 1249), prophylaxis should be provided.

**Delivery**

In the absence of a relaxed vaginal outlet, an episiotomy for delivery may be necessary once the fetal head reaches the perineum. Perinatal outcome data do not support routine forceps delivery to protect the “fragile” preterm fetal head. Staff proficient in resuscitative techniques commensurate with the gestational age and fully oriented to any specific problems should be present at delivery. Principles of resuscitation described in Chapter 32 are applicable. The importance of specialized personnel and facilities for preterm newborn care is underscored by the improved survival rates of these neonates when delivered in tertiary-care centers.

**Prevention of Neonatal Intracranial Hemorrhage**

Preterm newborns frequently have intracranial germinal matrix bleeding that can extend to more serious intraventricular hemorrhage (Chap. 34, p. 656). It was hypothesized that cesarean delivery to obviate trauma from labor and vaginal delivery might prevent these complications. This has not been validated by most subsequent studies. Malloy (1991) analyzed 1765 newborns with birthweights less than 1500 g and found that cesarean delivery did not lower the risk of mortality or intracranial hemorrhage. Anderson (1988), however, made an interesting observation regarding the role of cesarean delivery in intracranial hemorrhage prevention. These hemorrhages correlated with exposure to active-phase labor. However, they emphasized that avoidance of active-phase labor is impossible in most preterm births because decisions for delivery route are not required until active labor is firmly established.

**Magnesium Sulfate for Fetal Neuroprotection**

In intriguing reports, very-low-birthweight neonates whose mothers were treated with magnesium sulfate for preterm labor or preeclampsia were found to have a reduced incidence of cerebral palsy at 3 years (Grether, 2000; Nelson, 1995). Because epidemiological evidence suggested that maternal magnesium sulfate therapy had a fetal neuroprotective effect, randomized trials were designed to investigate this hypothesis. An Australian randomized trial by Crowther and coworkers (2003) included 1063 women at imminent risk of delivery before 30 weeks and who were given magnesium sulfate or placebo. These investigators showed that magnesium exposure improved some perinatal outcomes. Rates of both neonatal death and cerebral palsy were lower in the magnesium-treated group—but this study was not sufficiently powered. The multicenter French trial reported by Marret and associates (2008) had similar problems.

More convincing evidence for magnesium neuroprotection came from the NICHD MFMU Network study reported by Rouse and colleagues (2008). The Beneficial Effects of Antenatal Magnesium Sulfate—BEAM—Study was a placebo-controlled trial in 2241 women at imminent risk for preterm birth between 24 and 31 weeks. Almost 87 percent had preterm ruptured membranes, and almost a fifth had previously received magnesium sulfate for tocolysis. Women randomized to magnesium sulfate were given a 6-g bolus over 20 to 30 minutes followed by a maintenance infusion of 2 g per hour. Magnesium sulfate was actually infusing at the time of delivery.

[Continued...]
delivery in approximately half of the treated women. A 2-year follow-up was available for 96 percent of the children. Selected results are shown in Table 42-10. This trial can be interpreted differently depending on statistical philosophy. Some opt to interpret these findings to mean that magnesium sulfate infusion prevents cerebral palsy regardless of the gestational age at which the therapy is given. Those with a differing view conclude that this trial only supports use of magnesium sulfate for prevention of cerebral palsy before 28 weeks. What is certain, however, is that maternally administered magnesium sulfate infusions cannot be implicated in increased perinatal deaths as reported by Mittendorf (1997).

Subsequent to these studies, Doyle and associates (2009) performed a Cochrane review of the five available randomized trials to assess neuroprotective effects of magnesium sulfate. A total of 6145 infants were studied, and as expected, most came from the three larger Australian, French, and MFMU Network multicenter studies. These reviewers reported that magnesium exposure compared with no exposure significantly decreased risks for cerebral palsy, with a relative risk of 0.68. There were no significant effects on rates of pediatric mortality or other neurological impairments or disabilities. It was calculated that treatment given to 63 women would prevent one case of cerebral palsy. 

There was debate regarding magnesium efficacy for neuroprotection at the 2011 annual meeting of the Society for Maternal-Fetal Medicine. Rouse (2011) spoke for the benefits of magnesium sulfate, whereas Sibai (2011) challenged that the reported benefits vis-à-vis neuroprotection were false positive due to random statistical error in the Doyle (2009) metaanalysis. The American College of Obstetricians and Gynecologists (2013a) recognized that “none of the individual studies found a benefit with regard to their primary outcome.” It was concluded that “Physicians electing to use magnesium sulfate for fetal neuroprotection should develop specific guidelines regarding inclusion criteria, treatment regimen. …” Subsequently, the American College of Obstetricians and Gynecologists (2012a) issued a Patient Safety Checklist that could be used if magnesium sulfate is given for neuroprotection.
Because of these findings, at Parkland Hospital our policy is to provide magnesium sulfate for threatened preterm delivery from 24\(0/7\) to 27\(6/7\) weeks. A 6-g loading dose is followed by an infusion of 2 g per hour for at least 12 hours.

The adjectives postterm, prolonged, postdates, and postmature are often loosely used interchangeably to describe pregnancies that have exceeded a duration considered to be the upper limit of normal. We do not recommend use of the term postdates because the real issue in many postterm pregnancies is “post-what dates?” Postmature is reserved for the relatively uncommon specific clinical fetal syndrome in which the infant has recognizable clinical features indicating a pathologically prolonged pregnancy. Therefore, postterm or prolonged pregnancy is our preferred expression for an extended pregnancy.

The international definition of prolonged pregnancy, endorsed by the American College of Obstetricians and Gynecologists (2013a), is 42 completed weeks—294 days—or more from the first day of the last menstrual period. It is important to emphasize the phrase “42 completed weeks.” Prolonged pregnancy could begin either on day 294 or on day 295 following the onset of the last menses. Which is it? Day 294 or 295? We cannot resolve this question, and emphasize this dilemma only to ensure that litigators and others understand that some imprecision is inevitable when there is biological variation such as with prolonged pregnancy. Amersi and Grimes (1998) have cautioned against use of ordinal numbers such as “42nd week” because of imprecision. For example, “42nd week” refers to 41 weeks and 1 through 6 days, whereas the cardinal number “42 weeks” refers to precisely 42 completed weeks.
The definition of postterm pregnancy as one that persists for 42 weeks or more from the onset of a menstrual period assumes that the last menses was followed by ovulation 2 weeks later. That said, some pregnancies may not actually be postterm, but rather are the result of an error in gestational age estimation because of faulty menstrual date recall or delayed ovulation. Thus, there are two categories of pregnancies that reach 42 completed weeks: (1) those truly 40 weeks past conception, and (2) those of less-advanced gestation but with inaccurately estimated gestational age. Even with precisely recalled menstrual dates, there is still not precision. Specifically, Munster and associates (1992) reported that large variations in menstrual cycle lengths are common in normal women. Boyce and coworkers (1976) studied 317 French women with periconceptional basal body temperature profiles. Almost 70 percent who completed 42 postmenstrual weeks had a less-advanced gestation based on ovulation dates. These variations in the menstrual cycle may partially explain why a relatively small proportion of fetuses delivered postterm have evidence of *postmaturity syndrome*. Even so, because there is no accurate method to identify the truly prolonged pregnancy, all those judged to have reached 42 completed weeks should be managed as if abnormally prolonged. Sonographic evaluation of gestational age during pregnancy has been used to add precision. Blondel and colleagues (2002) studied 44,623 women delivered at the Royal Victoria Hospital in Montreal. Postterm pregnancy rates were analyzed according to six algorithms for gestational age based on the last menstrual period, sonographic evaluation at 16 to 18 weeks, or both. The proportion of births at 42 weeks or longer was 6.4 percent when based on the last menstrual period alone, but was 1.9 percent when based on sonographic measurements alone. Similarly, sonographic pregnancy dating at ≤ 12 weeks resulted in a 2.7-percent incidence of postterm gestation compared with 3.7 percent in a group assessed at 13 to 24 weeks (Caughey, 2008). These findings suggest that menstrual dates are frequently inaccurate in predicting postterm pregnancy. Other clinical studies confirmed these observations (Bennett, 2004; Joseph, 2007; Wingate, 2007).

**INCIDENCE**

From a review, the incidence of postterm pregnancy ranged from 4 to 19 percent (Divon, 2008). Using criteria that likely overestimate the incidence, approximately 6 percent of 4 million infants born in the United States during 2009 were estimated to have been delivered at 42 weeks or more (Martin, 2011). The trend toward fewer births at 42 weeks suggests earlier intervention. Specifically, in 2000, 7.2 percent of births in this country were 42 weeks or beyond compared with 5.5 percent in 2009. Zhang and colleagues (2010) studied live births in this country from 1992 through 2003 and reported dramatic increases in labor induction rates at 41 and 42 weeks’ gestation (Fig. 43-1). This significantly increased use of labor induction was posited to contribute to a downward shift of the overall mean birthweight for these infants born in the United States.
There are contradictory findings concerning maternal demographic factors such as parity, prior postterm birth, socioeconomic class, and age as risks for postterm pregnancy. Olesen and associates (2006) analyzed various risk factors in 3392 participants in the 1998 to 2001 Danish Birth Cohort. Only prepregnancy body mass index (BMI) ≥ 25 and nulliparity were significantly associated with prolonged pregnancy. Caughey (2009) and Arrowsmith (2011) and their coworkers also reported similar associations.

The tendency for some mothers to have repeated postterm births suggests that some prolonged pregnancies are biologically determined. And Mogren and colleagues (1999) reported that prolonged pregnancy recurred across generations in Swedish women. When mother and daughter had a prolonged pregnancy, the risk for the daughter to have a subsequent postterm pregnancy was increased two- to threefold. In another Swedish study, Laursen and associates (2004) found that maternal, but not paternal, genes influenced prolonged pregnancy. As noted in Chapter 21 (p. 426), rare fetal–placental factors that have been reported as predisposing to postterm pregnancy include anencephaly, adrenal hypoplasia, and X-linked placental sulfatase deficiency (MacDonald, 1965).

**PERINATAL MORTALITY**

Perinatal mortality rates increase after the expected due date has passed. This is best seen when perinatal mortality rates are analyzed from times before widespread intervention for postterm pregnancies. In two large Swedish studies shown in Figure 43-2, after reaching a nadir at 39 to 40 weeks, the perinatal mortality rate increased as pregnancy exceeded 41 weeks. This trend has also been reported for the United States (MacDorman, 2009). Another study in this country of more than 2.5 million births has similar findings (Cheng, 2008). The major causes of death in these pregnancies included gestational hypertension, prolonged labor with cephalopelvic disproportion, “unexplained anoxia,” and malformations. Similar outcomes were reported by Olesen and
colleagues (2003) in 78,022 women with postterm pregnancies delivered before routine labor induction was adopted in Denmark. Moster and associates (2010) found increased rates of cerebral palsy in postterm births, and Yang and coworkers (2010) reported lower intelligence quotient (IQ) scores at age 6.5 years in children born ≥ 42 weeks’ gestation. Conversely, autism was not associated with postterm birth (Gardener, 2011).

Alexander and colleagues (2000a) reviewed 56,317 consecutive singleton pregnancies delivered at ≥ 40 weeks between 1988 and 1998 at Parkland Hospital. As shown in Table 43-1, labor was induced in 35 percent of pregnancies completing 42 weeks. The rate of cesarean delivery for dystocia and fetal distress was significantly increased at 42 weeks compared with earlier deliveries. More infants of postterm pregnancies were admitted to intensive care units. Importantly, the incidence of neonatal seizures and deaths doubled at 42 weeks. Smith (2001) has challenged analyses such as these because the population at risk for perinatal mortality in a given week consists of all ongoing pregnancies rather than just the births in a given week. Figure 43-3 shows perinatal mortality rates calculated using only births in a given week of gestation from 37 to 43 completed weeks compared with the cumulative probability—the perinatal index—of death when all ongoing pregnancies are included in the denominator. As shown, delivery at 38 weeks had the lowest risk index for perinatal death.

**FIGURE 43-2** Perinatal mortality rates in late pregnancy according to gestational age in Sweden of all births during 1943–1952 compared with those during 1977–1978. The partially compressed scale is used for convenience in depiction. (Adapted from Bakketeig, 1991, and Lindell, 1956.)

**TABLE 43-1. Pregnancy Outcomes in 56,317 Consecutive Singleton Pregnancies Delivered at or Beyond 40 Weeks at Parkland Hospital from 1988 through 1998**
FIGURE 43-3 Perinatal mortality rate and perinatal risk index for births between 37 and 43 weeks in Scotland from 1985 through 1996. The perinatal mortality rate is the number of perinatal deaths with delivery in a given gestational week divided by the total number of births in that week multiplied by 1000. The perinatal risk index is the cumulative probability of perinatal death multiplied by 1000. (Redrawn from Smith, 2001, with permission.)

Postmaturity Syndrome

The postmature infant presents a unique appearance such as shown in Figure 43-4. Features include wrinkled, patchy, peeling skin; a long, thin body suggesting wasting; and advanced maturity in that the infant is open-eyed, unusually alert, and appears old and worried. Skin wrinkling can be particularly prominent on the palms and soles. The nails are typically long. Most postmature infants are not technically growth restricted because their birthweight seldom falls below the 10th percentile for gestational age. On the other hand, severe growth restriction—which logically must have preceded completion of 42 weeks—may be present.

FIGURE 43-4 Postmaturity syndrome. Infant delivered at 43 weeks’ gestation with thick, viscous meconium coating the desquamating skin. Note the long, thin appearance and wrinkling of the hands.
The incidence of postmaturity syndrome in infants at 41, 42, or 43 weeks, respectively, has not been conclusively determined. In one of the rare contemporary reports that chronicle postmaturity, Shime and colleagues (1984) found this syndrome in approximately 10 percent of pregnancies between 41 and 43 weeks. The incidence increased to 33 percent at 44 weeks. Associated oligohydramnios substantially increases the likelihood of postmaturity. Trimmer and associates (1990) reported that 88 percent of infants were postmature if there was oligohydramnios defined by a sonographic maximal vertical amnionic fluid pocket that measured ≤ 1 cm at 42 weeks.

**Placental Dysfunction**

Clifford (1954) proposed that the skin changes of postmaturity were due to loss of the protective effects of vernix caseosa. He also attributed the postmaturity syndrome to placental senescence, although he did not find placental degeneration histologically. Still, the concept that postmaturity is due to placental insufficiency has persisted despite an absence of morphological or significant quantitative findings (Larsen, 1995; Rushton, 1991). There are findings that placental apoptosis—programmed cell death—was significantly increased at 41 to 42 completed weeks compared with that at 36 to 39 weeks (Smith, 1999). Several proapoptotic genes such as kisspeptin were shown to be upregulated in postterm placental explants compared with the same genes in term placental explants (Torricelli, 2012). The clinical significance of such apoptosis is currently unclear.

Jazayeri and coworkers (1998) investigated cord blood erythropoietin levels in 124 appropriately grown newborns delivered from 37 to 43 weeks. The only known stimulator of erythropoietin is decreased partial oxygen pressure. Thus, they sought to assess whether fetal oxygenation was compromised due to placental aging in postterm pregnancies. All women had an uncomplicated labor and delivery. These investigators reported that cord blood erythropoietin levels were significantly increased in pregnancies reaching 41 weeks or more. Although Apgar scores and acid-base studies were normal, these researchers concluded that there was decreased fetal oxygenation in some postterm gestations.

Another scenario is that the postterm fetus may continue to gain weight and thus be unusually large at birth. This at least suggests that placental function is not severely compromised. Indeed, continued fetal growth is the norm—albeit at a slower rate beginning at 37 completed weeks (Fig. 43-5). Nahum and colleagues (1995) confirmed that fetal growth continues until at least 42 weeks, however, Link and associates (2007) showed that umbilical blood flow did not increase concomitantly.
Fetal Distress and Oligohydramnios

The principal reasons for increased risks to postterm fetuses were described by Leveno and associates (1984). Both antepartum fetal jeopardy and intrapartum fetal distress were found to be the consequence of cord compression associated with oligohydramnios. In their analysis of 727 postterm pregnancies, intrapartum fetal distress detected with electronic monitoring was not associated with late decelerations characteristic of uteroplacental insufficiency. Instead, one or more prolonged decelerations such as shown in Figure 43-6 preceded three fourths of emergency cesarean deliveries for nonreassuring fetal heart rate tracings. In all but two cases, there were also variable decelerations (Fig. 43-7). Another common fetal heart rate pattern, although not ominous by itself, was the saltatory baseline shown in Figure 43-8. As described in Chapter 24 (p. 484), these findings are consistent with cord occlusion as the proximate cause of the nonreassuring tracings. Other correlates included oligohydramnios and viscous meconium. Schaffer and colleagues (2005) implicated a nuchal cord in abnormal intrapartum fetal heart rate patterns, meconium, and compromised newborn condition in prolonged pregnancies.
FIGURE 43-6 Prolonged fetal heart rate deceleration before emergency cesarean delivery in a postterm pregnancy with oligohydramnios. (Redrawn from Leveno, 1984, with permission.)

FIGURE 43-7 Severe—less than 70 bpm for 60 seconds or longer—variable decelerations in a postterm pregnancy with oligohydramnios. (Redrawn from Leveno, 1984, with permission.)
The volume of amniotic fluid normally continues to decrease after 38 weeks and may become problematic (Fig. 11-1, p. 233). Moreover, meconium release into an already reduced amniotic fluid volume results in thick, viscous meconium that may cause meconium aspiration syndrome (Chap. 33, p. 637).

Trimmer and coworkers (1990) sonographically measured hourly fetal urine production using sequential bladder volume measurements in 38 pregnancies of ≥ 42 weeks. Diminished urine production was found to be associated with oligohydramnios. They hypothesized that decreased fetal urine flow was likely the result of preexisting oligohydramnios that limited fetal swallowing. Oz and associates (2002), using Doppler waveforms, concluded that fetal renal blood flow is reduced in those postterm pregnancies complicated by oligohydramnios. The study mentioned above, by Link and associates (2007), showed that umbilical blood flow did not increase past term.

Fetal-Growth Restriction

It was not until the late 1990s that the clinical significance of fetal-growth restriction in the otherwise uncomplicated pregnancy became more fully appreciated. Divon (1998) and Clausson (1999) and their coworkers analyzed births between 1991 and 1995 in the National Swedish Medical Birth Registry. As shown in Table 43-2, stillbirths were more common among growth-restricted infants who were delivered after 42 weeks. Indeed, a third of postterm stillborn infants were growth restricted. During this time in Sweden, labor induction and antenatal fetal testing usually commenced at 42 weeks. In a study from Parkland Hospital, Alexander and colleagues (2000d) analyzed outcomes for 355 infants who were ≥ 42 weeks and whose birthweights were <
3rd percentile. They compared these with outcomes of 14,520 similarly aged infants above the 3rd percentile and found that morbidity and mortality rates were significantly increased in the growth-restricted infants. Notably, a fourth of all stillbirths associated with prolonged pregnancy were in this comparatively small number of growth-restricted infants.

### COMPLICATIONS

## OLIGOHYDRAMNIOS

Most clinical studies support the view that diminished amnionic fluid determined by various sonographic methods identifies a postterm fetus with increased risks. Indeed, decreased amnionic fluid in any pregnancy signifies increased fetal risk (Chap. 11, p. 238). Unfortunately, lack of an exact method to define “decreased amnionic fluid” has limited investigators, and many different criteria for sonographic diagnosis have been proposed. Fischer and colleagues (1993) attempted to determine which criteria were most predictive of normal versus abnormal outcomes in postterm pregnancies. As shown in Figure 43-9, the smaller the amnionic fluid pocket, the greater the likelihood that there was clinically significant oligohydramnios. Importantly, normal amnionic fluid volume did not preclude abnormal outcomes. Alfirevic and coworkers (1997) randomly assigned 500 women with postterm pregnancies to assessment using either the amnionic fluid index (AFI) or the deepest vertical pocket (Chap. 11, p. 232). They concluded that the AFI overestimated the number of abnormal outcomes in postterm pregnancies.
Regardless of the criteria used to diagnose oligohydramnios in postterm pregnancies, most investigators have found an increased incidence of some sort of “fetal distress” during labor. Thus, oligohydramnios by most definitions is a clinically meaningful finding. Conversely, reassurance of continued fetal well-being in the presence of “normal” amnionic fluid volume is tenuous. This may be related to how quickly pathological oligohydramnios develops. Although such cases are unusual, Clement and coworkers (1987) described six postterm pregnancies in which amnionic fluid volume diminished abruptly over 24 hours, and in one of these, the fetus died.

### Macrosomia

The velocity of fetal weight gain peaks at approximately 37 weeks as shown in Figure 43-5. Although growth velocity slows at that time, most fetuses continue to gain weight. For example, the percentage of fetuses born in 2009 whose birthweight exceeded 4000 g was 8.2 percent at 37 to 41 weeks and increased to 11.0 percent at 42 weeks or more (Martin, 2011). However, in some studies, brachial plexus injury was not related to postterm gestation (Walsh, 2011). Intuitively at least, it seems that both maternal and fetal morbidity associated with macrosomia would be mitigated with timely induction to preempt further growth. This does not appear to be the case, however, and the American College of Obstetricians and Gynecologists (2013b) has concluded...
that current evidence does not support such a practice in women at term with suspected fetal macrosomia. Moreover, the College concluded that in the absence of diabetes, vaginal delivery is not contraindicated for women with an estimated fetal weight up to 5000 g. Cesarean delivery was recommended for estimated fetal weights greater than 4500 g if there is prolonged second-stage labor or arrest of descent. Obvious problems with all such recommendations are substantive variations in fetal weight estimation (Chap. 44, p. 885).

Medical or Obstetrical Complications

In the event of a medical or other obstetrical complication, it is generally not recommended that a pregnancy be allowed to continue past 42 weeks. Indeed, in many such instances, earlier delivery is indicated. Common examples include gestational hypertensive disorders, prior cesarean delivery, and diabetes.

MANAGEMENT

Although some form of intervention is considered to be indicated for prolonged pregnancies, the types and timing of interventions are not unanimous (Divon, 2008). The decision centers on whether labor induction is warranted or if expectant management with fetal surveillance is best. In a survey done 10 years ago, Cleary-Goldman and associates (2006) reported that 73 percent of members of the American College of Obstetricians and Gynecologists routinely induced women at 41 weeks. Most of the remainder performed twice weekly fetal testing until 42 weeks.

Prognostic Factors for Successful Induction

Unfavorable Cervix

Although all obstetricians know what an “unfavorable cervix” is, the term unfortunately defies precise objective definition. Thus, various investigators have used different criteria for studies of prolonged pregnancies. For example, Harris and coworkers (1983) defined an unfavorable cervix by a Bishop score < 7 and reported this in 92 percent of women at 42 weeks. Hannah and colleagues (1992) found that only 40 percent of 3407 women with a 41-week pregnancy had an “undilated cervix.” In a study of 800 women undergoing induction for postterm pregnancy at Parkland Hospital, Alexander and associates (2000b) reported that women in whom there was no cervical dilatation had a twofold increased cesarean delivery rate for “dystocia.” Yang and coworkers (2004) found that cervical length ≤ 3 cm measured with transvaginal sonography was predictive of successful induction. In a similar study, Vankayalapati and associates (2008) found that cervical length ≤ 25 mm was predictive of spontaneous labor or successful induction.

Cervical Ripening. A number of investigators have evaluated prostaglandin E\(_2\) (PGE\(_2\)) for induction in women with an unfavorable cervix and prolonged pregnancies. The study by the National Institute of Child Health and Human Development Network of Maternal–Fetal Medicine Units (1994) found that PGE\(_2\) gel was not more effective than placebo. Alexander and associates (2000c) treated 393 women with a postterm pregnancy with PGE\(_2\), regardless of cervical “favorability,” and reported that almost half of the 84 women with cervical dilatation of 2 to 4 cm
entered labor with prostaglandin E\(_2\) use alone. The American College of Obstetricians and Gynecologists (2011) previously concluded that PGE\(_2\) gel could be used safely in postterm pregnancies. In another study, mifepristone was reported to increase uterine activity without uterotonic agents in women beyond 41 weeks (Fasset, 2008). Prostaglandins and other agents used for cervical ripening are discussed in Chapter 26 (p. 525).

**Sweeping or stripping of the membranes** to induce labor and thereby prevent postterm pregnancy was studied in 15 randomized trials during the 1990s. Boulvain and coworkers (1999) performed a metaanalysis of these and found that membrane stripping at 38 to 40 weeks decreased the frequency of postterm pregnancy. Moreover, maternal and neonatal infection rates were not increased by cervical manipulation. However, this practice did not modify the cesarean delivery risk. Since then, randomized trials by Wong (2002), Kashanian (2006), Hill (2008), and their coworkers found that sweeping membranes did not reduce the need to induce labor. Drawbacks of membrane stripping included pain, vaginal bleeding, and irregular contractions without labor.

**Station of Vertex**
The station of the fetal head within the pelvis is another important predictor of successful postterm pregnancy induction. Shin and colleagues (2004) studied 484 nulliparas who underwent induction after 41 weeks. The cesarean delivery rate was directly related to station. It was 6 percent if the vertex before induction was at −1 station; 20 percent at −2; 43 percent at −3; and 77 percent at −4.

**Induction versus Fetal Testing**
Because of marginal benefits for induction with an unfavorable cervix as discussed above, some clinicians prefer to use the alternative strategy of fetal testing beginning at 41 completed weeks. There now are several quality studies designed to resolve these important questions.

In a Canadian study, 3407 women were randomly assigned at 41 or more weeks to induction or to fetal testing (Hannah, 1992). In the surveillance group, evaluation included: (1) counting fetal movements during a 2-hour period each day, (2) nonstress testing three times weekly, and (3) amnionic fluid volume assessment two to three times weekly with pockets < 3 cm considered abnormal. Labor induction resulted in a small but significant reduction in cesarean delivery rate compared with fetal testing—21 versus 24 percent, respectively. This difference was due to fewer procedures for fetal distress. Importantly, the only two stillbirths were in the fetal testing group.

The Maternal–Fetal Medicine Network performed a randomized trial of induction versus fetal testing beginning at 41 weeks (Gardner, 1996). Fetal surveillance included nonstress testing and sonographic estimation of amnionic fluid volume performed twice weekly in 175 women. Perinatal outcomes were compared with those of 265 women also at 41 weeks randomly assigned to induction with or without cervical ripening. There were no perinatal deaths, and the cesarean delivery rate was not different between management groups. The results of this study could be used to support the validity of either of these management schemes. Similar results were subsequently reported from a Norwegian randomized trial of 508 women (Heimstad, 2007).

In an analysis of 19 trials in the Cochrane Pregnancy and Childbirth Trials Registry Gulmezoglu and colleagues (2006) found that induction after 41 weeks was associated with fewer perinatal deaths without significantly increasing the cesarean delivery rate. In a review of two metaanalyses and a recent randomized controlled study, similar conclusions were reached (Mozurkewich, 2009).
In an attempt to “lower” the number of postterm pregnancies, Harrington and associates (2006) randomly assigned 463 women to pregnancy dating with sonography between 8 and 12 weeks versus no first-trimester sonographic evaluation. Their primary end point was the labor induction rate for prolonged pregnancy, and they found no advantages to early sonographic pregnancy dating.

At 42 weeks, labor induction has a higher cesarean delivery rate compared with spontaneous labor. From Parkland Hospital, Alexander and coworkers (2001) evaluated pregnancy outcomes in 638 such women in whom labor was induced and compared them with outcomes of 687 women with postterm pregnancies who had spontaneous labor. Cesarean delivery rates were significantly increased—19 versus 14 percent—in the induced group because of failure to progress. When these investigators corrected for risk factors, however, they concluded that intrinsic maternal factors, rather than the induction itself, led to the higher rate. These factors included nulliparity, an unfavorable cervix, and epidural analgesia.

Evidence to substantiate intervention—whether induction or fetal testing—commencing at 41 versus 42 weeks is limited. Most evidence used to justify intervention at 41 weeks is from the randomized Canadian and American investigations cited earlier. No randomized studies have specifically assessed intervention at 41 weeks versus an identical intervention used at 42 weeks. But there have been observational studies. In one, Usher and colleagues (1988) analyzed outcomes in 7663 pregnancies in women at 40, 41, or 42 weeks confirmed by early sonographic evaluation. After correction for malformations, perinatal death rates were 1.5, 0.7, and 3.0 per 1000 at 40, 41, and 42 weeks, respectively. These results could be used to challenge the concept of routine intervention at 41 instead of 42 weeks.

**Management Recommendations**

Because of the studies discussed above, the American College of Obstetricians and Gynecologists (2013a) defines postterm pregnancies as having completed 42 weeks. There is insufficient evidence to recommend a management strategy between 40 and 42 completed weeks. Thus, although not considered mandatory, initiation of fetal surveillance at 41 weeks is a reasonable option. After completing 42 weeks, recommendations are for either antenatal testing or labor induction. These are summarized in Figure 43-10.
At Parkland Hospital, based on results discussed above, we consider 41-week pregnancies without other complications to be normal. Thus, no interventions are practiced solely based on fetal age until 42 completed weeks. If there are complications such as hypertension, decreased fetal movement, or oligohydramnios, then labor induction is carried out. It is our view that large, randomized trials should be performed before otherwise uncomplicated 41-week gestations are routinely considered pathologically prolonged. In women in whom a certain gestational age is known, labor is induced at the completion of 42 weeks. Almost 90 percent of such women are induced successfully or enter labor within 2 days of induction. For those who do not deliver with the first induction, a second induction is performed within 3 days. Almost all women are delivered using this management plan, but in the unusual few who are not delivered, management decisions involve a third—or even more—induction versus cesarean delivery. Women classified as having uncertain postterm pregnancies are managed with weekly nonstress fetal testing and assessment of amniotic fluid volume. Women with an AFI ≤ 5 cm or with reports of diminished fetal movement undergo labor induction.

**INTRAPARTUM MANAGEMENT**

Labor is a particularly dangerous time for the postterm fetus. Therefore, women whose
pregnancies are known or suspected to be postterm should come to the hospital as soon as they suspect labor. While being evaluated for active labor, we recommend that fetal heart rate and uterine contractions be monitored electronically for variations consistent with fetal compromise.

The decision to perform amniotomy is problematic. Further reduction in fluid volume following amniotomy can certainly enhance the possibility of cord compression. Conversely, amniotomy aids identification of thick meconium, which may be dangerous to the fetus if aspirated. Also, after membrane rupture, a scalp electrode and intrauterine pressure catheter can be placed. These usually provide more precise data concerning fetal heart rate and uterine contractions.

Identification of thick meconium in the amniotic fluid is particularly worrisome. The viscosity probably signifies the lack of liquid and thus oligohydramnios. Aspiration of thick meconium may cause severe pulmonary dysfunction and neonatal death (Chap. 33, p. 637). Because of this, amnioinfusion during labor has been proposed as a way of diluting meconium to decrease the incidence of aspiration syndrome (Wenstrom, 1989). As discussed in Chapter 24 (p. 494), the benefits of amnioinfusion remain controversial. In a large randomized trial by Fraser and colleagues (2005), amnioinfusion did not reduce the risk of meconium aspiration syndrome or perinatal death. According to the American College of Obstetricians and Gynecologists (2012), amnioinfusion does not prevent meconium aspiration, however, it remains a reasonable treatment approach for repetitive variable decelerations.

The likelihood of a successful vaginal delivery is reduced appreciably for the nulliparous woman who is in early labor with thick, meconium-stained amniotic fluid. Therefore, if the woman is remote from delivery, strong consideration should be given to prompt cesarean delivery, especially when cephalopelvic disproportion is suspected or either hypotonic or hypertonic dysfunctional labor is evident. Some practitioners choose to avoid oxytocin use in these cases.

Until recently, it was taught—including at Parkland Hospital—that aspiration of meconium could be minimized but not eliminated by suctioning the pharynx as soon as the head was delivered. According to the American Academy of Pediatrics guidelines, this is no longer recommended (Perlman, 2010). The American College of Obstetricians and Gynecologists (2013c) does not recommend routine intrapartum suctioning. Alternatively, if the depressed newborn has meconium-stained fluid, then intubation is carried out. The American Academy of Pediatrics states that tracheal suctioning is neither supported nor refuted (Perlman, 2010).

Nearly 20 percent of the almost 4 million infants born in the United States are at the low and high extremes of fetal growth. In 2010, 8.2 percent of infants weighed < 2500 g at birth, whereas 7.6 percent weighed > 4000 g. And although most low-birthweight infants are born preterm, approximately 3 percent are term. The proportion of infants with birthweight < 2500 g has increased by more than 20 percent since 1984, and at the same time, the incidence of birthweight > 4000 g continues to decline (Martin, 2012). This shift away from the upper extreme is difficult to explain because it coincides with the epidemic prevalence of obesity (Morisaki, 2013).

Human fetal growth is characterized by sequential patterns of tissue and organ growth, differentiation, and maturation. However, the “obstetrical dilemma” postulates a conflict between the need to walk upright—requiring a narrow pelvis—and the need to think—requiring a large brain, and thus a large head. Some have speculated that there may be evolutionary pressure to restrict growth late in pregnancy (Dunsworth, 2012; Espinoza, 2012). Thus, the ability to growth restrict may be adaptive rather than pathological.

Fetal growth has been divided into three phases. The initial phase of hyperplasia occurs in the first 16 weeks and is characterized by a rapid increase in cell number. The second phase, which extends up to 32 weeks’ gestation, includes both cellular hyperplasia and hypertrophy. After 32 weeks, fetal growth is by cellular hypertrophy, and it is during this phase that most fetal fat and glycogen are accumulated. The corresponding fetal-growth rates during these three phases are 5 g/day at 15 weeks’ gestation, 15 to 20 g/day at 24 weeks, and 30 to 35 g/day at 34 weeks (Williams, 1982). As shown in Figure 44-1, there is considerable biological variation in the velocity of fetal growth.
Fetal development is determined by maternal provision of substrate, placental transfer of these substrates, and fetal growth potential governed by the genome. However, the precise cellular and molecular mechanisms by which normal fetal growth ensues are incompletely understood. That said, there is considerable evidence that insulin and insulin-like growth factors, particularly insulin-like growth factor-I (IGF-I), have an important role in regulation of fetal growth and weight gain (Luo, 2012; Murray, 2013). These growth factors are produced by virtually all fetal organs and are potent stimulators of cell division and differentiation.

Other hormones implicated in fetal growth have been identified in recent years, particularly hormones derived from adipose tissue. These hormones are known broadly as adipokines and include leptin, the protein product of the obesity gene. Fetal leptin concentrations increase during gestation, and they correlate with birthweight (Forhead, 2009; Karakosta, 2011). This relationship, however, is controversial in growth-restricted fetuses (Kyriakakou, 2008; Mise, 2007). Other adipokines under investigation include adiponectin, ghrelin, follistatin, resistin, visfatin, vaspin, omentin-1, apelin, and chemerin. Data for these adipokines are often conflicting, and their roles in normal and disordered fetal growth are still being elucidated (Chap. 48, p. 961).

Fetal growth is also dependent on an adequate supply of nutrients. As discussed in Chapter 4 (p. 53), glucose transfer has been extensively studied during pregnancy. Both excessive and diminished maternal glucose availability affect fetal growth. Reducing maternal glucose levels may result in a lower birthweight. Still, growth-restricted neonates do not typically show pathologically low glucose concentrations in their cord blood (Pardi, 2006). Fetal-growth restriction in response to glucose deprivation generally results only after long-term severe maternal caloric deprivation (Lechtig, 1975).

Excessive glycemia produces macrosomia. Varying levels of glucose affect fetal growth via insulin and its associated insulin-like growth factors discussed earlier. The Hyperglycemia and
Adverse Pregnancy Outcomes (HAPO) Study Cooperative Research Group (2008) found that elevated cord C-peptide levels, which reflect fetal hyperinsulinemia, have been associated with increased birthweight. This relationship was noted even in women with maternal glucose levels below the threshold for diabetes. Overgrowth does occur in the fetuses of euglycemic women. Its etiology is thus likely more complicated than a paradigm of dysregulated glucose metabolism resulting in fetal hyperinsulinemia (Catalano, 2011).

Excessive transfer of lipids to the fetus has also been postulated to result in fetal overgrowth (Higa, 2013). Free or nonesterified fatty acids in maternal plasma may be transferred to the fetus via facilitated diffusion or after liberation of fatty acids from triglycerides by trophoblastic lipases (Gil-Sánchez, 2012). Generally speaking, lipolytic activity is increased in pregnancy, and fatty acids have been reported to be increased in nonobese women during the third trimester (Diderholm, 2005). In obese women without diabetes who were fed a controlled diet, neonatal adiposity was strongly linked both with fasting triglyceride levels in early pregnancy and with free fatty acid levels at 26 to 28 weeks’ gestation (Harmon, 2011). Other studies have correlated maternal triglyceride levels with birthweight in both early and late pregnancy (Di Cianni, 2005; Vrijkotte, 2011). Overgrown infants have higher placental levels of certain fatty acids, particularly omega-3, and this has been associated with increased trophoblastic lipase expression (Varastehpour, 2006). Conversely, growth restriction in the third trimester has been associated with decreased maternal lipolysis (Diderholm, 2006). This may be related to dysregulation of the triglyceride lipase gene family, which has been reported in placentas from pregnancies complicated by fetal-growth restriction (Gauster, 2007).

Amino acids undergo active transport from maternal blood to the fetus, which explains the normally higher fetal concentrations. This concentration differential is decreased in growth restriction because of lower fetal amino acid levels and higher maternal amino acid concentrations (Cetin, 1996). The etiology of this altered ratio is uncertain, but there are multiple points at which dysregulation can occur. Amino acids that reach the fetus must first cross the microvillus membrane at the maternal interface, traverse the trophoblastic cell, and finally cross the basal membrane into fetal blood (Chap. 5, p. 92). This process is incompletely understood, particularly with respect to trophoblast metabolism of amino acids and export mechanisms from the trophoblast to the fetus. Jansson and colleagues (2013) have linked expression and activity of particular amino-acid transporters at the microvillous membrane with increasing birthweight and maternal body mass index (BMI). Expression of particular amino acid efflux transporters has been positively correlated with multiple measures of fetal and neonatal growth (Cleal, 2011).

Normal Birthweight

Normative data for fetal growth based on birthweight vary with ethnicity and geographic region. For example, infants born to women who reside at high altitudes are smaller than those born at sea level. Term infants average 3400 g at sea level, 3200 g at 5000 feet, and 2900 g at 10,000 feet. Accordingly, researchers have developed fetal-growth curves using various populations and geographic locations throughout the United States (Brenner, 1976; Ott, 1993; Overpeck, 1999 Williams, 1975). Because these curves are based on specific ethnic or regional groups, they are not representative of the entire population.

To address this, data such as those shown in Table 44-1 were derived on a nationwide basis in both the United States and Canada (Alexander, 1996; Kramer, 2001). Data from more than 3.1 million mothers with singleton liveborn infants in the United States during 1991 were used to
derive the growth curve by Alexander and colleagues, colored red in Figure 44-2. Also shown, the previously published regional fetal-growth curve data in general underestimated birthweights compared with national data. Importantly, there are significant ethnic and racial variations in neonatal mortality rates within the national neonatal mortality rate and within national birthweight and gestational age categories (Alexander, 1999, 2003).

From Alexander, 1996, with permission.
The work of Alexander and associates (1996) is most accurately termed a population reference, rather than a standard. Iams (2010) emphasizes the problems that result from blending a population reference for fetal growth with a fetal-growth standard. A population reference incorporates pregnancies of varying risks, along with the resulting outcomes, both normal and abnormal. In contrast, a standard incorporates normal pregnancies with normal outcomes. Because population references include preterm births, which are more likely to be growth restricted, it has been argued that the associated birthweight data underestimate deficient fetal growth (Mayer, 2013; Zhang, 2010). That said, there is not a widely accepted standard for the United States.

**Fetal Growth versus Birthweight**

Most of what is known regarding normal and abnormal human fetal growth is actually based on birthweights that are assembled as references for fetal growth at particular gestational ages. This is problematic, however, because birthweight does not define the rate of fetal growth. Indeed, such birthweight curves reveal compromised growth only at the extreme of impaired growth. Thus, they cannot be used to identify the fetus who fails to achieve an expected size but whose birthweight is above the 10th percentile. For example, a fetus with a birthweight in the 40th percentile may not have achieved its genomic growth potential for a birthweight in the 80th percentile. The rate or velocity of fetal growth can be estimated by serial sonographic anthropometry. For example, Milovanovic (2012) demonstrated that the growth rate of intrinsically small-for-gestational age newborns approximates that of appropriate-for-gestational age neonates. Diminished growth velocity has been linked to perinatal morbidity and adverse postnatal
metabolic changes that are independent of birthweight (Beltrand, 2008; Owen, 1997, 1998). Conversely, an excessive fetal-growth velocity, particularly of the abdominal circumference—which may be correlated with increased hepatic blood flow—is associated with an overgrown neonate. This is especially true when detected earlier in pregnancy (Ebbing, 2011; Kessler, 2011; Mulder, 2010).

FETAL–GROWTH RESTRICTION

Definition

Low-birthweight newborns who are small for gestational age are often designated as having \textit{fetal-growth restriction}. In 1963, Lubchenco and coworkers published detailed comparisons of gestational ages with birthweights to derive norms for expected fetal size at a given gestational week. Battaglia and Lubchenco (1967) then classified \textit{small-for-gestational-age (SGA)} neonates as those whose weights were below the 10th percentile for their gestational age. Such infants were shown to be at increased risk for neonatal death. For example, the neonatal mortality rate of SGA infants born at 38 weeks was 1 percent compared with 0.2 percent in those with appropriate birthweights.

Many infants with birthweights < 10th percentile, however, are not pathologically growth restricted, but are small simply because of normal biological factors. As many as 25 to 60 percent of SGA infants are thought to be appropriately grown when maternal ethnic group, parity, weight, and height are considered (Gardosi, 1992; Manning, 1991). These small but normal infants also do not show evidence of the postnatal metabolic derangements commonly associated with deficient fetal growth. Moreover, intrinsically SGA infants remain significantly smaller during surveillance to 2 years compared with appropriate-for-gestational age neonates, but they do not show differences in measures of metabolic risk (Milovanovic, 2012).

Because of these disparities, other classifications have been developed. Seeds (1984) suggested a definition based on birthweight < 5th percentile. Usher and McLean (1969) suggested that fetal-growth standards should be based on mean weights-for-age, with normal limits defined by ±2 standard deviations. This definition would limit SGA infants to 3 percent of births instead of 10 percent. In a population-based analysis of 122,754 births at Parkland Hospital, McIntire and colleagues (1999) showed this definition to be clinically meaningful. Also, as shown in Figure 44-3, most adverse outcomes are in infants < 3rd percentile.
FIGURE 44-3 Relationship between birthweight percentile and perinatal mortality and morbidity rates in 1560 small-for-gestational age fetuses. A progressive increase in both mortality and morbidity rates is observed as birthweight percentile falls. (Data from Manning, 1995.)

More recently, individual or customized fetal-growth potential has been proposed in place of a population-based cutoff. In this model, a fetus that deviates from its individual optimal size at a given gestational age is considered either overgrown or growth restricted (Bukowski, 2008). Such optimal projections are based on maternal race or ethnicity. However, the superiority of customized growth curves has not been established (Hutcheon, 2011a,b; Larkin, 2012; Zhang, 2011).  

Symmetrical versus Asymmetrical Growth Restriction

Campbell and Thoms (1977) described the use of the sonographically determined head-to-abdomen circumference ratio ($HC/AC$) to differentiate growth-restricted fetuses. Those who were symmetrical were proportionately small, and those who were asymmetrical had disproportionately lagging abdominal growth. Furthermore, the onset or etiology of a particular fetal insult has been hypothetically linked to either type of growth restriction. In the instance of symmetrical growth restriction, an early insult could result in a relative decrease in cell number and size. For example, global insults such as from chemical exposure, viral infection, or cellular maldevelopment with aneuploidy may cause a proportionate reduction of both head and body size. Asymmetrical growth restriction might follow a late pregnancy insult such as placental
insufficiency from hypertension. Resultant diminished glucose transfer and hepatic storage would primarily affect cell size and not number, and fetal abdominal circumference—which reflects liver size—would be reduced. Such somatic-growth restriction is proposed to result from preferential shunting of oxygen and nutrients to the brain. This allows normal brain and head growth, that is—brain sparing. Accordingly, the ratio of brain weight to liver weight during the last 12 weeks—usually about 3 to 1—may be increased to 5 to 1 or more in severely growth-restricted infants.

Because of brain-sparing effects, asymmetrical fetuses were thought to be preferentially protected from the full effects of growth restriction. Considerable evidence has since accrued that fetal-growth patterns are much more complex. For example, Nicolaides and coworkers (1991) observed that fetuses with aneuploidy typically had disproportionately large head sizes and thus were asymmetrically growth restricted, which was contrary to contemporaneous thinking. Moreover, most preterm infants with growth restriction due to preeclampsia and associated uteroplacental insufficiency were found to have more symmetrical growth impairment—again, a departure from accepted principles (Salafia, 1995).

More evidence of the complexity of growth patterns was presented by Dashe and associates (2000). These investigators analyzed 8722 consecutive liveborn singletons who had undergone sonographic examination within 4 weeks of delivery. Although only 20 percent of growth-restricted fetuses demonstrated sonographic head-to-abdomen asymmetry, these fetuses were at increased risk for intrapartum and neonatal complications. Symmetrically growth-restricted fetuses were not at increased risk for adverse outcomes compared with those appropriately grown. These investigators concluded that asymmetrical fetal-growth restriction represented significantly disordered growth, whereas symmetrical growth restriction more likely represented normal, genetically determined small stature.

Finally, data from Holland further challenge the concept of “brain sparing.” Roza and associates (2008) provided surveillance of 935 Rotterdam toddlers enrolled between 2003 and 2007 in the Generation R Study. Using the Child Behavior Checklist at age 18 months, they found that infants with circulatory redistribution—brain sparing—had a higher incidence of behavioral problems. In another study, evidence of brain sparing was found in half of 62 growth-restricted fetuses with birthweight < 10th percentile and who showed abnormal umbilical artery Doppler flow studies (Figueras, 2011a). Compared with controls, these neonates had significantly lower neurobehavioral scores in multiple areas, suggesting profound brain injury.

**Placental Abnormalities**

Fetal-growth restriction was included by Brosens and colleagues (2011) as one of the “great obstetrical syndromes” associated with defects in early placentation. Rogers and coworkers (1999) had observed that implantation site disorders such as incomplete trophoblastic invasion are associated with both fetal-growth restriction and hypertensive disorders. They concluded that implantation site disorders may be both a cause and consequence of hypoperfusion at the placental site. These disorders ultimately lead to pregnancy complications such as fetal-growth restriction with or without maternal hypertension. This comports with the association of certain placental angiogenic factors with pregnancy hypertensive disorders (Chap. 40, p. 735). Thus, it may be that placentas from pregnancies complicated by hypertension elaborate these angiogenic factors in response to placental site hypoperfusion, whereas pregnancies complicated by fetal-growth restriction without hypertension do not (Jeyabalan, 2008).

Mechanisms leading to abnormal trophoblastic invasion are likely multifactorial, and both vascular and immunological etiologies have been proposed. Recently, *atrial natriuretic peptide*
converting enzyme, also known as corrin, has been shown to play a critical role in trophoblastic invasion and remodeling of the uterine spiral arteries. These processes are impaired in corrin-deficient mice, which also develop evidence of preeclampsia. Moreover, mutations in the gene for corrin have also been reported in women with preeclampsia (Cui, 2012).

Notably, several immunological abnormalities have been associated with fetal-growth restriction. This raises the prospect of maternal rejection of the “paternal semiallograft.” Rudzinski and colleagues (2013) studied C4d, a component of complement that is associated with humoral rejection of transplanted tissues. They found this to be highly associated with chronic villitis—88 percent of cases versus only 5 percent of controls—and with reduced placental weight. Greer and associates (2012) studied 10,204 placentas and reported that chronic villitis was associated with placental hypoperfusion, fetal acidemia, and fetal-growth restriction and its sequelae. Kovo and coworkers (2010) found that chronic villitis is more strongly associated with fetal-growth restriction than with preeclampsia. Redline (2007) described the findings of activated maternal lymphocytes among fetal trophoblast. However, this author notes uncertainty as to whether these pathological changes represent maternal immunological rejection.

Morbidity and Mortality

Perinatal Risk

As shown in Figure 44-3, fetal-growth restriction is associated with substantive perinatal morbidity and mortality rates. Rates of stillbirth, birth asphyxia, meconium aspiration, and neonatal hypoglycemia and hypothermia are all increased, as is the prevalence of abnormal neurological development (Jacobsson, 2008; Paz, 1995). This is true for both term and preterm growth-restricted infants (McIntire, 1999; Wu, 2006). Smulian and colleagues (2002) reported that SGA infants had a higher 1-year infant mortality rate compared with that of normally grown infants. Boulet and associates (2006) demonstrated that for a fetus at the 10th percentile, the risk of neonatal death is increased but varies with gestational age. Risk is increased threefold at 26 weeks’ gestation compared with only a 1.13-fold increased risk at 40 weeks. More recently, in an analysis of 123,383 nonanomalous singleton live births, Chen and coworkers (2011) reported that SGA infants had a twofold risk for early and late neonatal death but not for postneonatal demise.

Long-Term Sequelae

Fetal Undergrowth. In his book Fetal and Infant Origins of Adult Disease, Barker (1992) hypothesized that adult mortality and morbidity are related to fetal and infant health. This includes both under- and overgrowth. In the context of fetal-growth restriction, there are numerous reports of a relationship between suboptimal fetal nutrition and an increased risk of subsequent adult hypertension, atherosclerosis, type 2 diabetes, and metabolic derangement (Gluckman, 2008). The degree to which low birthweight mediates adult disease is controversial. For example, it is unclear whether poor health in adulthood is mainly modulated by low birthweight, postnatal compensatory growth, or an interaction of the two (Crowther, 2008; Kerkhof, 2012; Leunissen, 2008; Nobili, 2008; Ong, 2007).

There is increasing evidence that fetal-growth restriction may affect organ development, particularly that of the heart. Individuals with low birthweight demonstrate cardiac structural changes and dysfunction persisting through childhood, adolescence, and adulthood. Crispi and coworkers (2012) studied 50 children aged between 3 and 6 years who were born small-for-gestational age at > 34 weeks and compared them with 100 normally grown children. The heart shape was altered in children born SGA. They had a more globular ventricle that resulted in
systolic and diastolic dysfunction. Hietalampi and associates (2012) performed echocardiography in 418 adolescents at a mean age of 15 years and found that low birthweight was associated with increased left ventricular posterior wall thickness. Importantly, current weight and physical activity affected measurements. In another study, 102 adults previously born preterm at a mean gestational age of 30.3 weeks underwent cardiac magnetic resonance (MR) imaging. Their ventricular mass was increased compared with that of 132 adults who were delivered at term (Lewandowski, 2013). Adults previously born preterm also had persistent structural remodeling and had reduced systolic and diastolic function.

Deficient fetal growth is also associated with postnatal structural and functional renal changes. Ritz and colleagues (2011) reviewed the numerous studies associating low birth-weight with disordered nephrogenesis, renal dysfunction, chronic kidney disease, and hypertension. They found that although a low nephron number is associated with hypertension in white individuals, this association does not hold true for blacks.

**Fetal Overgrowth.** On the other end of the spectrum, fetal overgrowth, particularly in women with diabetes and elevated cord blood levels of IGF-I, is associated with increased neonatal fat mass and morphological heart changes. Aman and coworkers (2011) reported interventricular septal hypertrophy in overgrown neonates of mothers with well-controlled diabetes in pregnancy. Garcia-Flores (2011) also reported increased fetal cardiac intraventricular septal thickness using sonography in women with well-controlled diabetes. Large-for-gestational age infants delivered of women without impaired glucose tolerance show higher insulin levels in childhood (Evagelidou, 2006). Not surprisingly, fetal overgrowth has been associated with development of the metabolic syndrome even in childhood (Boney, 2005).

**Accelerated Lung Maturation**

Numerous reports describe accelerated fetal pulmonary maturation in complicated pregnancies associated with growth restriction (Perelman, 1985). One possible explanation is that the fetus responds to a stressed environment by increasing adrenal glucocorticoid secretion, which leads to accelerated fetal lung maturation (Laatikainen, 1988). Although this concept pervades modern perinatal thinking, there is negligible evidence to support it.

To examine this hypothesis, Owen and associates (1990) analyzed perinatal outcomes in 178 women delivered because of hypertension. They compared these with outcomes in infants of 159 women delivered because of spontaneous preterm labor or ruptured membranes. They concluded that a “stressed” pregnancy did not confer an appreciable survival advantage. Similar findings were reported by Friedman and colleagues (1995) in women with severe preeclampsia. Two studies from Parkland Hospital also substantiate that the preterm infant accrues no apparent advantages from fetal-growth restriction (McIntire, 1999; Tyson, 1995).

**Risk Factors and Etiologies**

Risk factors for impaired fetal growth include potential abnormalities in the mother, fetus, and placenta. These three “compartments” are depicted in Figure 44-4. Some of these factors are known causes of fetal-growth restriction and may affect more than one compartment. For instance, infectious causes such as cytomegalovirus may affect the fetus directly. In contrast, bacterial infections such as tuberculosis may have significant maternal effects that lead to poor fetal growth. Malaria, a protozoal infection, possibly creates placental dysfunction (Umbers, 2011).
Importantly, many causes of diminished fetal growth are prospectively considered risk factors, because impaired fetal growth is not consistent in all affected women.

**FIGURE 44-4** Risk factors and causes of impaired fetal growth centering on the mother, her fetus, and the placenta.

**Constitutionally Small Mothers**

It is axiomatic that small women typically have smaller newborns. If a woman begins pregnancy weighing less than 100 pounds, the risk of delivering an SGA infant is increased at least twofold (Simpson, 1975). As discussed subsequently, both prepregnancy weight and gestational weight gain modulate this risk. Durie and colleagues (2011) showed that the risk of delivering an SGA neonate was highest among underweight women who gained less weight than recommended by the Institute of Medicine (Chap. 9, p. 177). Also, both maternal and paternal size influences birthweight. In a Swedish study of 137,538 term singleton mother-father-child units, researchers estimated that the maternal and paternal birthweights explained 6 and 3 percent of variance in birthweight, respectively (Mattsson, 2013).

**Gestational Weight Gain and Nutrition**

In the woman of average or low BMI, poor weight gain throughout pregnancy may be associated with fetal-growth restriction (Rode, 2007). In the study by Durie cited above, gestational weight gain during the second and third trimesters that was less than that recommended by the Institute of Medicine was associated with SGA neonates in women of all weight categories except class II or III obesity. Conversely, excessive gestational weight gain was associated with an overgrown newborn in all weight categories.

As perhaps expected, eating disorders are associated with significantly increased risks of low birthweight and preterm birth (Pasternak, 2012). This is discussed further in Chapter 61 (p. 1211).
Marked weight gain restriction after midpregnancy should not be encouraged even in obese women (Chap. 9, p. 177). Even so, it appears that food restriction to < 1500 kcal/day adversely affects fetal growth minimally (Lechtig, 1975). The best documented effect of famine on fetal growth was in the Hunger Winter of 1944 in Holland. For 6 months, the German Occupation army restricted dietary intake to 500 kcal/day for civilians, including pregnant women. This resulted in an average birthweight decline of only 250 g (Stein, 1975).

It is unclear whether undernourished women may benefit from micronutrient supplementation. In the study by the Supplementation with Multiple Micronutrients Intervention Trial (SUMMIT) Study Group (2008), almost 32,000 Indonesian women were randomized to receive micronutrient supplementation or only iron and folate tablets. Infants of those receiving the supplement had lower risks of early infant mortality and low birthweight and had improved childhood motor and cognitive abilities (Prado, 2012). Conversely, Liu and coworkers (2013) randomized 18,775 nulliparous pregnant women to folic acid alone; folic acid and iron; or folic acid, iron, and 13 other micronutrients. Folic acid and iron with or without the additional micronutrients resulted in a 30-percent reduction in risk of third-trimester anemia. However, it did not affect other maternal or neonatal outcomes. The importance of antenatal vitamins and trace metals is further discussed in Chapter 9 (p. 179).

Social Deprivation

The effect of social deprivation on birthweight is interconnected to the influence of associated lifestyle factors such as smoking, alcohol or other substance abuse, and poor nutrition. Importantly, Coker and associates (2012) found that women screened during pregnancy for psychosocial risk factors had more appropriate interventions. These women were significantly less likely to deliver a low-birthweight infant and also had fewer preterm births and other pregnancy complications.

Women who are immigrants may be at particular risk in pregnancy. Poeran and colleagues (2013) studied 56,443 singleton pregnancies in Rotterdam between 2000 and 2007 and found that social deprivation was associated with adverse perinatal outcomes that included SGA infants among socially deprived women. However, a similar linkage was not noted in socially deprived women of non-Western origin. The effect of immigration, however, is complex and dependent on the population studied. A paradoxical relationship between pregnancy outcomes in foreign-born Latina women delivering in the United States compared with Latina women born in the United States has been described (Flores, 2012). In particular, foreign-born Latina women appear to have lower risks of preterm birth and SGA neonates.

Vascular Disease

Especially when complicated by superimposed preeclampsia, chronic vascular disease commonly causes growth restriction (Chap. 50, p. 1004). Preeclampsia may cause fetal-growth failure, which can be an indicator of its severity (Backes, 2011). In a study of more than 2000 women, vascular disease as evidenced by abnormal uterine artery Doppler velocimetry early in pregnancy was associated with increased rates of preeclampsia, SGA neonates, and delivery before 34 weeks (Groom, 2009). Roos-Hesselin and coworkers (2013) described pregnancy outcomes in women with heart disease, and only 25 of the 1321 women had ischemic heart disease, emphasizing its rareness. But these women had the worst outcomes, with significantly lower neonatal birthweights and the highest rates of preterm birth and perinatal mortality.

Renal Disease
Chronic renal insufficiency is frequently associated with underlying hypertension and vascular
disease. Nephropathies are commonly accompanied by restricted fetal growth (Bramham, 2011;
Cunningham, 1990; Vidaeff, 2008). These relationships are considered further in Chapter 53 (p.
1059).

**Pregestational Diabetes**

Fetal-growth restriction in women with diabetes may be related to congenital malformations or
may follow substrate deprivation from advanced maternal vascular disease (Chap. 57, p. 1128).
Also, the likelihood of restricted growth increases with development of nephropathy and
proliferative retinopathy—especially in combination (Haeri, 2008). That said, the prevalence of
serious vascular disease associated with diabetes in pregnancy is low, and the primary effect of
overt diabetes, especially type 1, is fetal overgrowth. For example, Murphy and coworkers (2011)
performed a prospective study of 682 consecutive pregnancies complicated by diabetes. Women
with type 1 diabetes had significantly fewer of the traditional risk factors for fetal overgrowth,
such as increased age, multiparity, and obesity. Yet, they were significantly more likely than
women with type 2 diabetes to have a neonate weighing > 90th and 97.7th percentiles. Additionally,
women with type 1 diabetes were significantly less likely to deliver an SGA newborn. Similarly, in a smaller study by Cyganek and colleagues (2011), the rate of macrosomia
was higher among pregnancies complicated by type 1 diabetes. However, the rates of low
birthweight were similar for those with type 1 and type 2 diabetes.

**Chronic Hypoxia**

Conditions associated with chronic uteroplacental hypoxia include preeclampsia, chronic
hypertension, asthma, smoking, and high altitude. When exposed to a chronically hypoxic
environment, some fetuses have significantly reduced birthweight. Gonzales and Tapia (2009)
constructed growth charts based on 63,620 Peruvian live births between 26 and 42 weeks’
gestation. They reported that mean birthweight was significantly decreased at higher altitudes
compared with lower altitudes—3065 ± 475 g versus 3280 ± 525 grams. At low altitude, the rate
of birthweight < 2500 g was 6.2 percent, and it was 9.2 percent at high altitude. In contrast, the
rate of birthweight > 4000 g was 6.3 percent at low altitude and 1.6 percent at high altitude. As
discussed in Chapter 49 (p. 985), severe hypoxia from maternal cyanotic heart disease frequently
is associated with severely growth-restricted fetuses (Patton, 1990).

**Anemia**

In most cases, maternal anemia does not cause restricted fetal growth. Exceptions include sickle-
cell disease and some other inherited anemias (Chakravarty, 2008; Tongsong, 2009). Conversely,
curtailed maternal blood-volume expansion has been linked to fetal-growth restriction (Duvekot,
1995; Scholten, 2011). This is further discussed in Chapter 40 (p. 737).

**Antiphospholipid Antibody Syndrome**

Adverse obstetrical outcomes including fetal-growth restriction have been associated with three
species of antiphospholipid antibodies: anticardiolipin antibodies, lupus anticoagulant, and
antibodies against beta-2-glycoprotein-I. Mechanistically, a “two-hit” hypothesis suggests that
initial endothelial damage is then followed by intervillous placental thrombosis. More
specifically, oxidative damage to certain membrane proteins such as beta-2-glycoprotein I is
followed by antiphospholipid antibody binding, which leads to immune complex formation and
ultimately to thrombosis (Giannakopoulos, 2013). This syndrome is considered in detail in Chapters 52 (p. 1033) and 59 (p. 1173). Pregnancy outcomes in women with these antibodies may be poor and include early-onset preeclampsia and fetal demise (Levine, 2002). The primary autoantibody that predicts obstetrical antiphospholipid syndrome appears to be lupus anticoagulant (Lockshin, 2012).

**Inherited Thrombophilias**

Numerous investigators have evaluated the role of genetic polymorphisms in the mother or fetus and their relationship to growth restriction (Lockwood, 2002; Stonek, 2007). Most suggest that inherited thrombophilias are not a significant factor in fetal-growth restriction (Infante-Rivard, 2002; Rodger, 2008). Facco and colleagues (2009) attribute positive associations primarily to publication bias.

**Infertility**

Pregnancies in women with prior infertility with or without infertility treatment have an increased risk of SGA newborns (Zhu, 2007). Kondapalli and Perales-Puchalt (2013) have recently reviewed possible links between low birthweight and infertility with its various interventions. They concluded that the association remains unexplained.

**Placental and Cord Abnormalities**

Several placental abnormalities may cause poor fetal growth. These are discussed further throughout Chapter 6 and include chronic placental abruption, extensive infarction, chorioangioma, marginal or velamentous cord insertion, placenta previa, and umbilical artery thrombosis. Growth failure in these cases is presumed secondary to uteroplacental insufficiency.

Abnormal placental implantation leading to endothelial dysfunction may also result in limited fetal growth (Brosens, 2011). This pathology has been implicated in pregnancies complicated by preeclampsia as discussed in Chapter 40 (p. 732).

If the placenta is implanted outside the uterus, the fetus is usually growth restricted (Chap. 19, p. 388). Also, some uterine malformations have been linked to impaired fetal growth (Chap. 3, p. 40).

**Multiple Fetuses**

As shown in Figure 44-5, pregnancy with two or more fetuses is more likely to be complicated by diminished growth of one or more fetuses compared with that with normal singletons (Chap. 45, p. 899).
Drugs with Teratogenic and Fetal Effects
Several drugs and chemicals are capable of limiting fetal growth. Some are teratogenic and affect the fetus before organogenesis is complete. Some exert—or continue to exert—fetal effects after embryogenesis ends at 8 weeks. Many of these are considered in detail in Chapter 12, and some examples include anticonvulsants and antineoplastic agents. Some immunosuppressive drugs used for organ transplantation maintenance are also implicated in poor fetal growth (Mastrobattista, 2008). In addition, cigarette smoking, opiates and related drugs, alcohol, and cocaine may cause growth restriction, either primarily or by decreasing maternal food intake. There is a possible link with caffeine use throughout pregnancy and fetal-growth restriction (CARE Study Group, 2008). According to the American College of Obstetricians and Gynecologists (2013c), however, this relationship remains speculative (Chap. 9, p. 187).

Maternal and Fetal Infections
Viral, bacterial, protozoan, and spirochetal infections have been implicated in up to 5 percent of fetal-growth restriction cases and are discussed throughout Chapters 64 and 65. The best known of these are rubella and cytomegalovirus infection. Both promote calcifications in the fetus that are associated with cell death, and infection earlier in pregnancy correlates with worse outcomes. Picone and associates (2013) described 238 primary cytomegalovirus infections and reported that no severe cases were observed when infection occurred after 14 weeks’ gestation.

Tuberculosis and syphilis have both been associated with poor fetal growth. As discussed in Chapter 51 (p. 1020), both extrapulmonary and pulmonary tuberculosis have been linked with low birthweight (Jana, 1994, 1999). The etiology is uncertain. However, the adverse effect of tuberculosis on maternal health, compounded by effects of poor nutrition and poverty, is important (Jana, 2012). Congenital or transplacental tuberculosis is rare, whereas congenital syphilis is more common. Paradoxically, with syphilis, the placenta is almost always larger and heavier due to edema and perivascular inflammation. Congenital syphilis is also strongly linked with preterm birth and thus low-birthweight infants (Sheffield, 2002).
Toxoplasma gondii can also cause congenital infection, and Paquet and Yudin (2013) describe its classic association with fetal-growth restriction. Despite this, an analysis of 386 women who seroconverted during pregnancy from toxoplasma infection found no connection with low birthweight (Freeman, 2005). Congenital malaria has also been implicated, and malaria prophylaxis is associated with a decreased risk of low birth-weight in Sub-Saharan Africa (Kayentao, 2013).

**Congenital Malformations**

In a study of more than 13,000 fetuses with major structural anomalies, 22 percent had accompanying growth restriction (Khoury, 1988). In their study of 115 pregnancies complicated by fetal gastroschisis, Tam Tam and coworkers (2011) identified low birthweights in 63 percent and fetal-growth restriction in 45 percent of affected newborns. As a general rule, the more severe the malformation, the more likely the fetus is to be SGA. This is especially evident in fetuses with chromosomal abnormalities or those with serious cardiovascular malformations.

**Chromosomal Aneuploidies**

Depending on which chromosome is redundant, there may be associated poor growth in fetuses with autosomal trisomies. For example, in trisomy 21, fetal-growth restriction is generally mild. By contrast, fetal growth in trisomy 18 is virtually always significantly limited. Growth failure has been documented as early as the first trimester using crown-rump length (Baken, 2013). Bahado-Singh (1997) and Schemmer (1997) and their associates found that crown-rump length in fetuses with trisomy 18 and 13, unlike that with trisomy 21, was shorter than expected. By the second trimester, long-bone measurements typically are < 3rd percentile.

As discussed in Chapter 13 (p. 269), aneuploidic patches in the placenta—confined placental mosaicism—can cause placental insufficiency that may account for many previously unexplained growth-restricted fetuses (Wilkins-Haug, 2006). Although addition of an X chromosome in confined placental mosaicism can be associated with diminished fetal growth, this is not so with Klinefelter syndrome (47,XXY). Conversely, monosomy X or Turner syndrome has been associated with a low embryo volume during first-trimester sonography (Baken, 2013). This early finding manifests as growth restriction at delivery. Hagman and colleagues (2010) compared 494 children with monosomy X with normal girls and found a 6.6-fold increased risk for SGA in newborns with Turner syndrome.

First-trimester prenatal screening programs to identify women at risk for aneuploidy may incidentally identify pregnancies at risk for fetal-growth restriction unrelated to karyotype. In their analysis of 8012 women, Krantz and associates (2004) identified an increased risk for growth restriction in eukaryotic fetuses with extremely low free β-human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein-A (PAPP-A) levels. From her review, Dugoff (2010) concluded that although most studies have found that a low PAPP-A level is strongly associated with poor fetal growth, studies of free β-hCG are conflicting. Second-trimester analytes, including elevated alpha-fetoprotein and inhibin A levels and low unconjugated serum estriol concentrations, are significantly associated with birthweight < 5th percentile. An even greater risk of poor growth has been associated with certain combinations of these analytes. Still, these markers are poor screening tools for complications such as fetal-growth restriction due to low sensitivity and positive predictive values (Dugoff, 2010). Nuchal translucency has also not been shown to be predictive of fetal-growth restriction. These markers are discussed further in Chapter 14 (p. 289).
Recognition of Fetal-Growth Restriction

Early establishment of gestational age, ascertainment of maternal weight gain, and careful measurement of uterine fundal growth throughout pregnancy will identify many cases of abnormal fetal growth in low-risk women. Risk factors, including a previous growth-restricted fetus, have an increased risk for recurrence of nearly 20 percent (Berghella, 2007). In women with risks, serial sonographic evaluation is considered. Although examination frequency varies depending on indications, an initial early dating examination followed by an examination at 32 to 34 weeks, or when otherwise clinically indicated, will identify many growth-restricted fetuses. Even so, definitive diagnosis frequently cannot be made until delivery.

Identification of the inappropriately growing fetus remains a challenge. There are, however, both simple clinical techniques and more complex technologies that may prove useful.

Uterine Fundal Height
According to a recent systematic review, insufficient evidence supports the utility of fundal height measurement to detect fetal-growth restriction (Robert Peter, 2012). Nonetheless, carefully performed serial fundal height measurements are recommended as a simple, safe, inexpensive, and reasonably accurate screening method to detect growth-restricted fetuses (Figueras, 2011b). As a screening tool, its principal drawback is imprecision (Jelks, 2007). For example, Sparks and coworkers (2011) reported sensitivities < 35 percent for detecting excessive or deficient fetal growth. Specificity, however, was reported to be > 90 percent.

The method used by most for fundal height measurement is described in Chapter 9 (p. 176). Between 18 and 30 weeks’ gestation, the uterine fundal height in centimeters coincides within 2 weeks of gestational age. Thus, if the measurement is more than 2 to 3 cm from the expected height, inappropriate fetal growth is suspected.

Sonographic Measurements of Fetal Size
One argument in the debate regarding routine sonographic evaluation of all pregnancies is the potential for diagnosis of growth restriction. Typically, such routine screening incorporates an early initial sonographic examination—usually at 16 to 20 weeks’ gestation, but increasingly in the first trimester—to establish gestational age and identify anomalies. Proponents of this view then repeat sonographic evaluation at 32 to 34 weeks to evaluate fetal growth (Chap. 10, p. 198). Although fetal-growth restriction can be detected during the first trimester, its detection using an initial sonogram from the second trimester is more likely to correspond to a birthweight that is small-for-gestational age (Baken, 2013; Mook-Kanamori, 2010; Tuuli, 2011). At Parkland Hospital, we provide midpregnancy sonographic screening examination of all pregnancies. Additional sonographic evaluations of fetal growth are performed as clinically indicated.

With sonography, the most common method for identifying poor fetal growth is estimation of weight using multiple fetal biometric measurements. Combining head, abdomen, and femur dimensions has been shown to optimize accuracy, whereas little incremental improvement is gained by adding other biometric measurements (Platz, 2008). Of the dimensions, femur length measurement is technically the easiest and the most reproducible. Biparietal diameter and head circumference measurements are dependent on the plane of section and may also be affected by deformatory pressures on the skull. Last, abdominal circumference measurements are more variable. However, these are most frequently abnormal with fetal-growth restriction because soft tissue predominates in this dimension (Fig. 44-6). Shown in Figure 44-7 is an example of a severely growth-restricted newborn.
FIGURE 44-6 Correlation of sonographic fetal weight estimation using abdominal circumference (AC) and actual birthweight. Data from pregnancies managed at Parkland Hospital. (Image courtesy of Dr. Don McIntire.)
Some studies have reported a significant predictive value for small abdominal circumference with respect to lagging fetal growth. However, newer data indicate that abnormal Doppler velocimetry of the umbilical arteries and a combined estimated fetal weight < 3rd percentile are most strongly associated with poor obstetrical outcome (Unterscheider, 2013).

Importantly, sonographic estimates of fetal weight and actual weight may be discordant by 20 percent or more, leading to both false-positive and false-negative findings. Dashe and associates (2000) studied 8400 live births at Parkland Hospital in which fetal sonographic evaluation had been performed within 4 weeks of delivery. They reported that 30 percent of growth-restricted fetuses were not detected. In a study of 1000 high-risk fetuses, Larsen and coworkers (1992) performed serial sonographic examinations beginning at 28 weeks and then every 3 weeks subsequently. Reporting results compared with withholding results from clinicians significantly increased the diagnosis of SGA fetuses. Elective delivery rates were increased in the group whose providers received sonographic reports, but there was no overall improvement in neonatal
Amnionic Fluid Volume Measurement

An association between pathological fetal-growth restriction and oligohydramnios has long been recognized (Chap. 11, p. 236). Chauhan and colleagues (2007) found oligohydramnios in nearly 10 percent of pregnancies suspected of growth restriction. This group of women was two times more likely to undergo cesarean delivery for nonreassuring fetal heart rate patterns. Petrozella and associates (2011) reported that decreased amnionic fluid volume between 24 and 34 weeks’ gestation was significantly associated with malformations. In the absence of malformations, a birthweight < 3rd percentile was seen in 37 percent of pregnancies with oligohydramnios, in 21 percent with borderline amnionic fluid volume, but in only 4 percent with normal volumes. Hypoxia and diminished renal blood flow has been hypothesized as an explanation for oligohydramnios. However, Magann and coworkers (2011) reviewed the literature and determined that the etiology of oligohydramnios is likely more complex and possibly involves altered intramembranous absorption as well.

Doppler Velocimetry

With this technique, early changes in placenta-based growth restriction are detected in peripheral vessels such as the umbilical and middle cerebral arteries. Late changes are characterized by abnormal flow in the ductus venosus and fetal aortic and pulmonary outflow tracts and by reversal of umbilical artery flow.

Of these, abnormal umbilical artery Doppler velocimetry findings—characterized by absent or reversed end-diastolic flow—have been uniquely linked with fetal-growth restriction (Chap. 10, p. 220). These abnormalities highlight early versus severe fetal-growth restriction and represent the transition from fetal adaptation to failure. Thus, persistently absent or reversed end-diastolic flow has long been correlated with hypoxia, acidosis, and fetal death (Pardi, 1993; Woo, 1987). Umbilical artery Doppler velocimetry is considered standard in the evaluation and management of the growth-restricted fetus (Fig. 44-8). The American College of Obstetricians and Gynecologists (2013a) notes that umbilical-artery Doppler velocimetry has been shown to improve clinical outcomes. It is recommended in the management of fetal-growth restriction as an adjunct to standard surveillance techniques such as nonstress testing and biophysical profile.
FIGURE 44-8 Umbilical arterial Doppler velocimetry studies, ranging from normal to markedly abnormal. A. Normal velocimetry pattern with a systolic to diastolic (S/D) ratio of < 3. B. The diastolic velocity approaching zero reflects increased placental vascular resistance. C. During diastole, arterial flow is reversed (negative S/D ratio), which is an ominous sign that may precede fetal demise.

As noted earlier, other Doppler assessments have been proposed but are still investigational. The ductus venosus was evaluated in a series of 604 neonates < 33 weeks who had an abdominal circumference < 5th percentile (Baschat, 2007). Investigators found that the ductus venosus Doppler parameters were the primary cardiovascular factor in predicting neonatal outcome. These late changes are felt to reflect myocardial deterioration and acidemia, which are major contributors to adverse perinatal and neurological outcome. In their longitudinal evaluation of 46 growth-restricted fetuses, Figueras and coworkers (2009) determined that Doppler flow abnormalities at the aortic valve isthmus preceded those in the ductus venosus by 1 week. Turan and associates (2008), in their evaluation of several fetal vessels, described the sequence of changes characteristic of mild placental dysfunction, progressive placental dysfunction, and severe
early-onset placental dysfunction.

Prevention

Prevention of fetal-growth restriction ideally begins before conception, with optimization of maternal medical conditions, medications, and nutrition as discussed throughout Chapter 8. Smoking cessation is critical. Other risk factors should be tailored to the maternal condition, such as antimalarial prophylaxis for women living in endemic areas and correction of nutritional deficiencies. Studies have shown that treatment of mild to moderate hypertension does not reduce the incidence of growth-restricted infants (Chap. 50, p. 1005).

Accurate dating is essential during early pregnancy. Serial sonographic evaluations are typically used, but the best interval between assessments has not been clearly established. Given that a history of SGA is associated with other adverse outcomes in a subsequent pregnancy, particularly stillbirth and preterm birth, surveillance during a subsequent pregnancy may be beneficial (Gordon, 2012; Spong, 2012). According to the American College of Obstetricians and Gynecologists (2013a), if growth is normal during a pregnancy following a prior pregnancy complicated by fetal-growth restriction, Doppler velocimetry and fetal surveillance are not indicated. Prophylaxis with low-dose aspirin beginning early in gestation is not recommended because of its poor efficacy to reduce growth restriction (American College of Obstetricians and Gynecologists, 2013a; Berghella, 2007).

Management

If fetal-growth restriction is suspected, then efforts are made to confirm the diagnosis, assess fetal condition, and search for possible causes. Early-onset growth restriction is easier to recognize but presents challenging issues of management (Miller, 2008). In pregnancies in which there is a strong suspicion of fetal anomalies, patient counseling and prenatal diagnostic testing are indicated (American College of Obstetricians and Gynecologists, 2013a).

One algorithm for management is shown in Figure 44-9. In pregnancies with suspected fetal-growth restriction, antepartum fetal surveillance should include periodic Doppler velocimetry of the umbilical arteries in addition to more frequent fetal testing. At Parkland Hospital, if fetal viability has been reached, we hospitalize these women. Daily fetal heart rate tracings, weekly Doppler velocimetry, and sonographic assessment of fetal growth every 3 to 4 weeks are initiated. Other modalities of Doppler velocimetry, such as middle cerebral arteries or ductus venosus assessment, are considered experimental. The American College of Obstetricians and Gynecologists (2013a) recommends that pregnancies complicated by fetal-growth restriction and at risk for birth before 34 weeks receive antenatal corticosteroids for pulmonary maturation. According to Vidaeff and Blackwell (2011), growth-restricted fetuses may not tolerate the metabolic effects of corticosteroids in the same way as an unstressed fetus. They suggest increased surveillance during administration.
The timing of delivery is crucial, and the risks of fetal death versus the hazards of preterm delivery must be considered. Unfortunately, there are no studies that have elucidated the optimal timing of delivery. For the preterm fetus, the only randomized trial of delivery timing is the Growth Restriction Intervention Trial (GRIT) reported by Thornton and colleagues (2004). This trial was carried out in 13 European countries and involved 548 women between 24 and 36 weeks’ gestation with clinical uncertainty regarding delivery timing. Women were randomly assigned to immediate delivery or to delayed delivery until the situation worsened. The primary outcome was perinatal death or disability after reaching age 2 years. There were no differences in mortality rates through 2 years of age. Moreover, children aged 6 to 13 years did not show clinically
significant differences between the two groups (Walker, 2011).

The DIGITAT—Disproportionate Intrauterine Growth Intervention Trial at Term—was designed to study delivery timing of growth-restricted fetuses who were 36 weeks’ gestation or older. There were no differences in composite neonatal morbidity in 321 women with fetal-growth restriction and a gestational age of at least 360/7 weeks who were randomly assigned to induction or to expectant management (Boers, 2010). Secondary analyses included assessment of neurodevelopmental and behavioral outcomes that did not differ at age 2 years (Van Wyk, 2012).

Management of the Near-Term Fetus

As shown in Figure 44-9, delivery of a suspected growth-restricted fetus with normal umbilical artery Doppler velocimetry, normal amnionic fluid volume, and reassuring fetal heart rate testing can likely be deferred until 38 weeks’ gestation. Said another way, uncertainty regarding the diagnosis should preclude intervention until fetal lung maturity is assured. Expectant management can be guided using antepartum fetal surveillance techniques described in Chapter 17. Most clinicians, however, recommend delivery at 34 weeks or beyond if there is clinically significant oligohydramnios. Consensus statements by the Society of Maternal-Fetal Medicine (Spong, 2011) and the American College of Obstetricians and Gynecologists (2013d) are similar. These recommend delivery between 34 and 37 weeks when there are concurrent conditions such as oligohydramnios. With a reassuring fetal heart rate pattern, vaginal delivery is planned. However, some of these fetuses do not tolerate labor, necessitating cesarean delivery.

Management of the Fetus Remote from Term

If growth restriction is identified in an anatomically normal fetus before 34 weeks, and amnionic fluid volume and fetal surveillance findings are normal, then observation is recommended. Screening for toxoplasmosis, cytomegalovirus infection, rubella, herpes, and other infections is recommended by some. However, we and others have not found this to be productive (Yamamoto, 2013).

As long as there is interval fetal growth and fetal surveillance test results are normal, pregnancy is allowed to continue until fetal lung maturity is reached (see Fig. 44-9). Reassessment of fetal growth is typically made no sooner than 3 to 4 weeks. Weekly assessment of umbilical artery Doppler velocimetry and amnionic fluid volume is combined with periodic nonstress testing, although the optimal frequency has not been determined. As mentioned, we hospitalize these women in our High-Risk Pregnancy Unit and monitor their fetuses daily. If interval growth amnionic fluid volume, and umbilical artery Doppler velocimetry are normal, then the mother is discharged with intermittent outpatient surveillance.

With growth restriction remote from term, no specific treatment ameliorates the condition. For example, there is no evidence that diminished activity and bed rest result in accelerated growth or improved outcomes. Despite this, many clinicians intuitively advise a program of modified rest. Nutrient supplementation, attempts at plasma volume expansion, oxygen therapy, antihypertensive drugs, heparin, and aspirin have all been shown to be ineffective (American College of Obstetricians and Gynecologists, 2013a).

In most cases diagnosed before term, neither a precise etiology nor a specific therapy is apparent. Management decisions hinge on assessment of the relative risks of fetal death during expectant management versus the risks from preterm delivery. Although reassuring fetal testing may allow observation with continued maturation, long-term neurological outcome is a concern (Baschat, 2011; Thornton, 2004). Baschat and associates (2009) showed that neurodevelopmental
outcome at 2 years in growth-restricted fetuses was best predicted by birthweight and gestational age. Doppler abnormalities are generally not associated with poor cognitive development scores among low-birthweight children delivered in the third trimester (Llurba, 2013). These findings emphasize that adverse neurodevelopmental outcomes cannot always be predicted.

Labor and Delivery

Fetal-growth restriction is commonly the result of placental insufficiency due to faulty maternal perfusion, reduction of functional placenta, or both. If present, these conditions are likely aggravated by labor. Equally important, diminished amnionic fluid volume increases the likelihood of cord compression during labor. For these reasons, a woman with a suspected growth-restricted fetus should undergo “high-risk” intrapartum monitoring (Chap. 22, p. 450). For these and other reasons, the frequency of cesarean delivery is increased.

The risk of neonatal hypoxia or meconium aspiration is also increased. Thus, care for the newborn should be provided immediately by an attendant who can skillfully clear the airway and ventilate an infant as needed (Chap. 32, p. 625). The severely growth-restricted newborn is particularly susceptible to hypothermia and may also develop other metabolic derangements such as hypoglycemia, polycythemia, and hyperviscosity. In addition, low-birthweight infants are at increased risk for motor and other neurological disabilities. Risk is greatest at the lowest extremes of birthweight (Baschat, 2007, 2009, 2011; Llurba, 2013).

FETAL OVERGROWTH

The term macrosomia is used rather imprecisely to describe a very large fetus or neonate. Although there is general agreement among obstetricians that newborns weighing < 4000 g are not excessively large, a similar consensus has not been reached for the definition of macrosomia.

Newborn weight rarely exceeds 11 pounds (5000 g), and excessively large infants are a curiosity. The largest newborn cited in the Guinness Book of World Records was a 23-lb 12-oz (10,800 g) infant boy born to a Canadian woman, Anna Bates, in 1879 (Barnes, 1957). In the United States in 2010, of more than 4 million births, 6.6 percent weighed 4000 to 4499 g; 1 percent weighed 4500 to 4999 g; and 0.1 percent were born weighing 5000 g or more (Martin, 2012). To be sure, the incidence of excessively large infants increased during the 20th century. According to Williams (1903), at the beginning of the 20th century, the incidence of birthweight > 5000 g was 1 to 2 per 10,000 births. This compares with 16 per 10,000 at Parkland Hospital from 1988 through 2008 and 11 per 10,000 in the United States in 2010.

The influence of increasing maternal obesity is overwhelming, and its association with diabetes is well known. Of Parkland mothers with infants born weighing > 5000 g, more than 15 percent were diabetic. Henriksen (2008) searched the Cochrane Database and reported that the rapid increase in the prevalence of large infants was due to maternal obesity and type 2 diabetes. Importantly however, review of data from the National Center for Health Statistics indicates that the rate of birthweight ≥ 4000 g has steadily declined more than 30 percent since 1990—from 10.9 percent to 7.6 percent in 2010 (Martin, 2012). This is discussed further in Chapters 48 (p. 967) and 57 (p. 1140).

Definition
Because there are no widely accepted and precise definitions of pathological fetal overgrowth, several terms are currently used clinically. The most common of these—macrosomia—is defined by birthweights that exceed certain percentiles for a given population. Another commonly used scheme is to define macrosomia by an empirical birthweight threshold.

**Birthweight Distribution**

Frequently, macrosomia is defined based on mathematical distributions of birthweight. Those infants exceeding the 90th percentile for a given gestational week are usually used as the threshold for macrosomia or large-for-gestational age (LGA) birthweight. For example, the 90th percentile at 39 weeks is 4000 g. If, however, birthweights that are 2 standard deviations above the mean are used, then thresholds lie at the 97th percentile. Thus, substantially larger infants are considered macrosomic compared with those at the 90th percentile. Specifically, the birthweight threshold at 39 weeks to be macrosomic would be approximately 4500 g for the 97th percentile rather than 4000 g for the 90th percentile.

**Empirical Birthweight**

Newborn weight exceeding 4000 g—8 lb 13 oz—is also a frequently used threshold to define macrosomia. Others use 4250 g or even 4500 g—10 lb. As shown in Table 44-2, birthweights of 4500 g or more are uncommon. During a 30-year period at Parkland Hospital, during which there were more than 350,000 singleton births, only 1.4 percent of newborns weighed 4500 g or more. We are of the view that the upper limit of fetal growth, above which growth can be deemed abnormal, is likely two standard deviations above the mean, representing perhaps 3 percent of births. At 40 weeks, such a threshold would correspond to approximately 4500 g. The American College of Obstetricians and Gynecologists (2013b) concluded that the term macrosomia was an appropriate appellation for newborns who weigh 4500 g or more at birth.

Risk Factors

Some factors associated with fetal overgrowth are listed in Table 44-3. Many are interrelated and thus likely are additive. For example, advancing age is usually related to multiparity and diabetes, and obesity is obviously related to diabetes. Koyanagi and coworkers (2013) reported that the incidence of macrosomia exceeds 15 to 20 percent in Africa, Asia, and Latin America when women have diabetes, are obese, or have a postterm pregnancy. Of these, maternal diabetes is an important risk factor for fetal overgrowth (Chap. 57, p. 1129). As shown in Table 44-2, the incidence of maternal diabetes increases as birthweight > 4000 g increases. It should be emphasized, however, that maternal diabetes is associated with only a small percentage of the total number of such large infants.

Maternal and Perinatal Morbidity

The adverse consequences of excessive fetal growth are considerable. Neonates with a birthweight of at least 4500 g have been reported to have cesarean delivery rates exceeding 50 percent (Das, 2009; Gyurkovits, 2011; Weissmann-Brenner, 2012). The rate of shoulder dystocia has been reported to be as high as 17 percent for neonates with birthweights of at least 4500 g, and 23 percent for neonates with birthweights of at least 5000 g (Stotland, 2004). Rates of postpartum hemorrhage, perineal laceration, and maternal infection, which are related complications, are also increased in mothers delivering overgrown neonates. Maternal and neonatal outcomes by birthweight for large babies > 4000 g and delivered at Parkland Hospital are shown in Table 44-4.

**TABLE 44-4. Maternal and Fetal Outcomes for 176,844 Pregnancies Delivered at Parkland Hospital from 1998 Through 2012**
Diagnosis

Because there are no current methods to estimate excessive fetal size accurately, macrosomia cannot be definitively diagnosed until delivery. Inaccuracy in clinical estimates of fetal weight by physical examination is often attributable, at least in part, to maternal obesity. Numerous attempts have been made to improve the accuracy of sonographic fetal-weight estimation. Several formulas have been proposed to calculate fetal weight using measurements of the head, femur, and abdomen. Estimates provided by these computations, although reasonably accurate for predicting the weight of small, preterm fetuses, are less valid in predicting the weight of large fetuses. Rouse and coworkers (1996) reviewed 13 studies completed between 1985 and 1995 to assess the accuracy of sonographic prediction for suspected fetal macrosomia. They found only fair sensitivity—60 percent—in the accurate diagnosis of macrosomia, but higher specificity—90 percent—in excluding excessive fetal size. Thus, sonographic estimation of fetal weight is unreliable, and its routine use to identify macrosomia is not recommended. Indeed, the findings of several studies
indicate that clinical fetal-weight estimates are as reliable as, or even superior to, those made from sonographic measurements (Mattsson, 2007; Noumi, 2005; O’Reilly-Green, 2000).

Management

Several interventions have been proposed to interdict fetal overgrowth. Some include prophylactic labor induction for poorly defined indications such as “impending macrosomia,” or elective cesarean delivery to avoid difficult delivery and shoulder dystocia. For women with diabetes in pregnancy, insulin therapy and close attention to good glycemic control reduces birthweight, but this has not consistently translated into reduced cesarean delivery rates (Crowther, 2005; Naylor, 1996). Irrespective of diabetes mellitus, fetal overgrowth among women is strongly associated with maternal obesity and excessive gestational weight gain (Durie, 2011; Johnson, 2013; Vesco, 2011). Dietary intervention to limit fetal overgrowth by curbing gestational weight gain is an active area of research. However, data to safely guide efforts to limit fetal overgrowth among at-risk women are lacking.

“Prophylactic” Labor Induction

Some clinicians have proposed labor induction when fetal macrosomia is suspected in nondiabetic women. This approach is suggested to obviate further fetal growth and thereby reduce potential delivery complications. Such prophylactic induction should theoretically reduce the risk of shoulder dystocia and cesarean delivery. Gonen and colleagues (1997) randomly assigned 273 nondiabetic women with sonographic fetal weight estimates of 4000 to 4500 g to either induction or expectant management. Labor induction did not decrease the rate of cesarean delivery or shoulder dystocia. Similar results were reported by Leaphart and associates (1997), who found that induction unnecessarily increased the cesarean delivery rate. In their systematic review of 11 studies of expectant management versus labor induction for suspected macrosomia, Sanchez-Ramos and coworkers (2002) found that labor induction results in increased cesarean delivery rates without improved perinatal outcomes.

A review of early term births indicates that elective delivery before 39 weeks’ gestation does not improve maternal outcomes and is associated with worse neonatal outcomes (Wetta, 2012). We agree with the American College of Obstetricians and Gynecologists (2013b,d) that current evidence does not support a policy for early labor induction before 39 weeks’ gestation or delivery for suspected macrosomia. Moreover, delivery or induction for suspected macrosomia at term is likewise not indicated.

Elective Cesarean Delivery

Rouse and colleagues (1996, 1999) analyzed the potential effects of a policy of elective cesarean delivery for sonographically diagnosed fetal macrosomia compared with standard obstetrical management. They concluded that for women who are not diabetic, a policy of elective cesarean delivery was medically and economically unsound. The American College of Obstetricians and Gynecologists (2013b) does not recommend routine cesarean delivery in women without diabetes when the estimated fetal weight is < 5000 g. Conversely, in diabetic women with overgrown fetuses, such a policy of elective cesarean delivery seems tenable. Conway and Langer (1998) described a protocol of routine cesarean delivery for sonographic estimates of 4250 g or greater in diabetic women. This management significantly reduced the shoulder dystocia rate from 2.4 to 1.1 percent.
Prevention of Shoulder Dystocia

With the delivery of macrosomic infants, shoulder dystocia and its attendant risks described in Chapter 27 (p. 541) are major concerns. That said, the American College of Obstetricians and Gynecologists (2012) notes that fewer than 10 percent of all shoulder dystocia cases result in a persistent brachial plexus injury, and 4 percent of these follow cesarean delivery.

It appears that planned cesarean delivery on the basis of suspected macrosomia to prevent brachial plexopathy is an unreasonable strategy in the general population (Chauhan, 2005). Ecker and coworkers (1997) analyzed 80 cases of brachial plexus injury in 77,616 consecutive infants born at Brigham and Women’s Hospital. They concluded that an excessive number of otherwise unnecessary cesarean deliveries would be needed to prevent a single brachial plexus injury in neonates born to women without diabetes. Conversely, planned cesarean delivery may be a reasonable strategy for diabetic women with an estimated fetal weight > 4250 or > 4500 g.

In summary, when fetal overgrowth is suspected, the obstetrician naturally seeks to balance the risks to the fetus with maternal risks. Although interventions to prevent shoulder dystocia may someday prove beneficial, eliminating shoulder dystocia will likely remain an impossible goal. We agree with the American College of Obstetricians and Gynecologists that elective delivery for the fetus that is suspected to be overgrown is inadvisable, particularly before 39 weeks’ gestation. Finally, we agree that elective cesarean delivery is not indicated when estimated fetal weight is < 5000 g among women without diabetes and < 4500 g among women with diabetes (American College of Obstetricians and Gynecologists, 2013b).

Multifetal pregnancies may result from two or more fertilization events, from a single fertilization followed by an “erroneous” splitting of the zygote, or from a combination of both. Such pregnancies are associated with increased risk for both mother and child, and this risk increases with the number of offspring. For example, 60 percent of twins, 90 percent of triplets, and virtually all of quadruplets are born preterm (Martin, 2012). From these observations, it is apparent that women were not intended to concurrently bear more than one offspring. And although they are often viewed as a novelty or miracle, multifetal pregnancies represent a potentially perilous journey for the mother and her unborn children.

Fueled largely by infertility therapy, both the rate and the number of twin and higher-order multifetal births have increased dramatically since 1980. Specifically, the twinning rate rose 76 percent from 18.9 to 32.1 per 1000 live births in 2009 (Martin, 2012). During the same time, the number of higher-order multifetal births increased more than 400 percent to a peak in 1998. Since then, however, evolving infertility management has resulted in decreased rates of higher-order
multifetal births to its lowest level in 15 years. Specifically, the rate of triplets or more decreased by 10 percent from 153 per 100,000 births in 2009 to 138 per 100,000 births in 2010 (Martin, 2012).

The overall increase in prevalence of multifetal births is of concern because the corresponding increase in the rate of preterm birth compromises neonatal survival and increases the risk of lifelong disability. For example, in this country, about a fourth of very-low-birthweight neonates—those born weighing < 2500 g—are from multifetal gestations, and 15 percent of infants who die in the first year after birth are from multifetal pregnancies (Martin, 2012). In 2009, the infant mortality rate for multiple births was five times the rate for singletons (Mathews, 2013). A comparison of singleton and twin outcomes from infants delivered at Parkland Hospital is shown in Table 45-1. These risks are magnified further with triplets or quadruplets. In addition to these adverse outcomes, the risks for congenital malformations are increased with multifetal gestation. Importantly, this increased risk is for each fetus and is not simply because there are more fetuses per pregnancy.

The mother may also experience higher obstetrical morbidity and mortality rates. These also increase with the number of fetuses (Mhyre, 2012; Wen, 2004). In a study of more than 44,000 multifetal pregnancies, Walker and colleagues (2004) reported that, compared with singletons, the risks for preeclampsia, postpartum hemorrhage, and maternal death were increased twofold or more. The risk for peripartum hysterectomy is also increased, and Francois and associates (2005) reported this to be threefold for twins and 24-fold for triplets or quadruplets. Finally, these mothers are at increased risk for depression compared with women with a singleton pregnancy (Choi, 2009).

**MECHANISMS OF MULTIFETAL GESTATIONS**

Twin fetuses usually result from fertilization of two separate ova—dizygotic or fraternal twins. Less often, twins arise from a single fertilized ovum that divides—monozygotic or identical twins.
Either or both processes may be involved in the formation of higher numbers. Quadruplets, for example, may arise from as few as one to as many as four ova.

Dizygotic versus Monozygotic Twinning

Dizygotic twins are not in a strict sense true twins because they result from the maturation and fertilization of two ova during a single ovulatory cycle. Moreover, from a genetic perspective, dizygotic twins are like any other pair of siblings. On the other hand, monozygotic or identical twins, although they have virtually the same genetic heritage, are usually not identical.

As discussed subsequently, the division of one fertilized zygote into two does not necessarily result in equal sharing of protoplasmic material. Monozygotic twins may actually be discordant for genetic mutations because of a postzygotic mutation, or may have the same genetic disease but with marked variability in expression. In female fetuses, skewed lyonization can produce differential expression of X-linked traits or diseases. Furthermore, the process of monozygotic twinning is in a sense a teratogenic event, and monozygotic twins have an increased incidence of often discordant malformations (Glinianaia, 2008). For example, in a study of 926 monozygotic twins, Pettit (2013) reported a 12-fold increase in the prevalence of congenital heart defects, but 68 percent of affected infants had a normal sibling. Accordingly, dizygotic or fraternal twins of the same sex may appear more nearly identical at birth than monozygotic twins.

Genesis of Monozygotic Twins

The developmental mechanisms underlying monozygotic twinning are poorly understood. Minor trauma to the blastocyst during assisted reproductive technology (ART) may lead to the increased incidence of monozygotic twinning observed in pregnancies conceived in this manner (Wenstrom, 1993).

The outcome of the monozygotic twinning process depends on when division occurs. If zygotes divide within the first 72 hours after fertilization, two embryos, two amnions, and two chorions develop, and a diamniotic, dichorionic twin pregnancy evolves (Fig. 45-1). Two distinct placentas or a single, fused placenta may develop. If division occurs between the fourth and eighth day, a diamniotic, monochorionic twin pregnancy results. By approximately 8 days after fertilization, the chorion and the amnion have already differentiated, and division results in two embryos within a common amniotic sac, that is, a monoamniotic, monochorionic twin pregnancy. Conjoined twins result if twinning is initiated later.
FIGURE 45-1 Mechanism of monozygotic twinning. Black boxing and blue arrows in columns A, B, and C indicate timing of division. **A.** At 0 to 4 days postfertilization, an early conceptus may divide into two. Division at this early stage creates two chorions and two amnions (dichorionic, diamnionic). Placentas may be separate or fused. **B.** Division between 4 and 8 days leads to formation of a blastocyst with two separate embryoblasts (inner cell masses). Each embryoblast will form its own amnion within a shared chorion (monochorionic, diamnionic). **C.** Between 8 and 12 days, the amnion and amnionic cavity form above the germinal disc. Embryonic division leads to two embryos with a shared amnion and shared chorion (monochorionic, monoamnionic). **D.** Differing theories explain conjoined twin development. One describes an incomplete splitting of one embryo into two. The other describes fusion of a portion of one embryo from a monozygotic pair onto the other.
It has long been accepted that monochorionicity incontrovertibly indicated monozygosity. Rarely, however, monochorionic twins may in fact be dizygotic (Hack, 2009). Mechanisms for this are speculative, but Ekelund and coworkers (2008) found in their review of 14 such cases that nearly all have been conceived after ART procedures.

**Superfetation and Superfecundation**

In *superfetation*, an interval as long as or longer than a menstrual cycle intervenes between fertilizations. Superfetation requires ovulation and fertilization during the course of an established pregnancy, which is theoretically possible until the uterine cavity is obliterated by fusion of the decidua capsularis to the decidua parietalis. Although known to occur in mares, superfetation is not known to occur spontaneously in humans. Lantieri and colleagues (2010) reported a case after ovarian hyperstimulation and intrauterine insemination in the presence of an undiagnosed tubal pregnancy. Most authorities believe that alleged cases of human superfetation result from markedly unequal growth and development of twin fetuses with the same gestational age.

*Superfecundation* refers to fertilization of two ova within the same menstrual cycle but not at the same coitus, nor necessarily by sperm from the same male. An instance of superfecundation or heteropaternity, documented by Harris (1982), is demonstrated in Figure 45-2. The mother was sexually assaulted on the 10th day of her menstrual cycle and had intercourse 1 week later with her husband. She was delivered of a black neonate whose blood type was A and a white neonate whose blood type was O. The blood type of the mother and her husband was O.

![Figure 45-2](image)

**FIGURE 45-2** An example of dizygotic twin boys as the consequence of superfecundation.

**Frequency of Twinning**

Dizygotic twinning is much more common than monozygous splitting of a single oocyte, and its
incidence is influenced by race, heredity, maternal age, parity, and, especially, fertility treatment. By contrast, the frequency of monozygotic twin births is relatively constant worldwide—approximately one set per 250 births, and this incidence is generally independent of race, heredity, age, and parity. One exception is that zygotic splitting is increased following ART (Aston, 2008).

The “Vanishing Twin”

The incidence of twins in the first trimester is much greater than the incidence of twins at birth. Studies in which fetuses were evaluated with sonography in the first trimester have shown that one twin is lost or “vanishes” before the second trimester in up to 10 to 40 percent of all twin pregnancies (Brady, 2013). The incidence is higher in the setting of ART. Monochorionic twins have a significantly greater risk of abortion than dichorionic twins (Sperling, 2006). In some cases, the entire pregnancy aborts. In many cases, however, only one fetus dies, and the remaining fetus delivers as a singleton. Undoubtedly, some threatened abortions have resulted in death and resorption of one embryo from an unrecognized twin gestation. It has been estimated that 1 in 80 births are multifetal, whereas 1 in 8 pregnancies begin multifetal followed by spontaneous reduction of one or more embryos or fetuses (Corsello, 2010).

Dickey and associates (2002) described spontaneous reduction in 709 women with a multifetal pregnancy. Before 12 weeks, one or more embryos died in 36 percent of twin pregnancies, 53 percent of triplet pregnancies, and 65 percent of quadruplet pregnancies. Interestingly, pregnancy duration and birthweight were inversely related to the initial gestational sac number regardless of the final number of fetuses at delivery. This effect was most pronounced in twins who started as quadruplets. Chasen and coworkers (2006) reported that spontaneous reduction of an in vitro fertilization (IVF) twin pregnancy to a singleton pregnancy was associated with perinatal outcomes intermediate between IVF singleton pregnancies and IVF twin pregnancies that did not undergo spontaneous reduction.

In one analysis of 41 cases of spontaneous reduction, higher values of pregnancy-associated plasma protein A (PAPP-A) and free β-human chorionic gonadotropin (β-hCG) were identified (Chasen, 2006). Gjerris and colleagues (2009) compared 56 cases of “vanishing twin” to 897 singletons after ART and did not identify any differences in first-trimester serum markers as long as the reduction was identified before 9 weeks. If diagnosed after 9 weeks, the serum markers were higher and less precise than in singleton ART gestations. Therefore, the diagnosis of vanishing twin should be excluded to avoid confusion during maternal serum screening for Down syndrome or neural-tube defects (Chap. 14, p. 283).

Factors That Influence Twinning

Race. The frequency of multifetal births varies significantly among different races and ethnic groups (Table 45-2). Abel and Kruger (2012) analyzed more than 8 million births in the United States between 2004 and 2008. These investigators found the highest rate of twinning in African American women (3.5 percent) and lower rates in white (3.0 percent) women. Hispanic, Asian, and Native American women had comparatively lower rates then white women. In one rural community in Nigeria, Knox and Morley (1960) found that twinning occurred once in every 20 births! These marked differences in twinning frequency may be the consequence of racial variations in levels of follicle-stimulating hormone—FSH (Nylander, 1973).

References:
Maternal Age. As depicted in Figure 45-3, maternal age is another important risk factor for multiple births. Dizygotic twinning frequency increases almost fourfold between the ages of 15 and 37 years (Painter, 2010). It is in this age range that maximal FSH stimulation increases the rate of multiple follicles developing (Beemsterboer, 2006). The rate of twinning also increases dramatically with advancing maternal age because the use of ART is more likely in older women (Ananth, 2012). Although paternal age has been linked to frequency of twinning, its affect is felt to be small (Abel, 2012).
Parity. Increasing parity has been shown to independently increase the incidence of twinning in all populations studied. Antsaklis and coworkers (2013) noted a progressive increase in multiparity in twinning during a 30-year period, but cautioned that some of this increase is presumably due to ART. In a two-year study from Nigeria, where such technology is not commonly available, Olusanya (2012) calculated an eightfold increase in multiple gestations when parity was 4 or less and a 20-fold increase when parity was 5 or more compared with primiparas.
**Heredity.** As a determinant of twinning, the family history of the mother is more important than that of the father. In a study of 4000 genealogical records, White and Wyshak (1964) found that women who themselves were a dizygotic twin gave birth to twins at a rate of 1 set per 58 births. Women who were not a twin, but whose husbands were a dizygotic twin, gave birth to twins at a rate of 1 set per 116 pregnancies. Painter and associates (2010) performed genome-wide linkage analyses on more than 500 families of mothers of dizygotic twins and identified four potential linkage peaks. The highest peak was on the long arm of chromosome 6, with other suggestive peaks on chromosomes 7, 9, and 16. That said, the contribution of these variants to the overall incidence of twinning is likely small (Hoekstra, 2008).

**Nutritional Factors.** In animals, litter size increases in proportion to nutritional sufficiency. Evidence from various sources indicates that this occurs in humans as well. Nylander (1971) showed a definite increasing gradient in the twinning rate related to greater nutritional status as reflected by maternal size. Taller, heavier women had a twinning rate 25 to 30 percent greater than short, nutritionally deprived women. Evidence acquired during and after World War II showed that twinning correlated more with nutrition than body size. Widespread undernourishment in Europe during those years was associated with a marked fall in the dizygotic twinning rate (Bulmer, 1959). Several investigators have reported a 40-percent increase in the prevalence of twinning among women who have taken supplementary folic acid (Ericson, 2001; Haggarty, 2006; Hasbargen, 2000). Conversely, in a systematic review, Muggli and Halliday (2007) were unable to demonstrate a significant association. Analysis of twinning rate in Texas after folic acid fortification of cereal-grain products also did not demonstrate an independent increase in twinning between 1996 and 1998 (Waller, 2003).

**Pituitary Gonadotropin.** The common factor linking race, age, weight, and fertility to multifetal gestation may be FSH levels (Benirschke, 1973). This theory is supported by the fact that increased fecundity and a higher rate of dizygotic twinning have been reported in women who conceive within 1 month after stopping oral contraceptives, but not during subsequent months (Rothman, 1977). This may be due to the sudden release of pituitary gonadotropin in amounts greater than usual during the first spontaneous cycle after stopping hormonal contraception. Indeed, the paradox of declining fertility but increasing twinning with advancing maternal age can be explained by an exaggerated pituitary release of FSH in response to decreased negative feedback from impending ovarian failure (Beemsterboer, 2006).

**Infertility Therapy.** Ovulation induction with FSH plus chorionic gonadotropin or clomiphene citrate remarkably enhances the likelihood of multiple ovulations. A mainstay of current infertility therapy and common antecedent to IVF is ovarian stimulation followed by timed intrauterine insemination. In their review of this practice, McClamrock and coworkers (2012) reported rates of twin and higher-order multifetal pregnancies as high as 28.6 percent and 9.3 percent, respectively. Rates this high remain a major concern. There are currently two ongoing multicenter trials—Assessment of Multiple Gestations from Ovarian Stimulation (AMIGOS) and Pregnancy in Polycystic Ovary Syndrome II (PPCOSII)—that are designed to provide guidance on achieving maximum pregnancy rates while minimizing multifetal gestation rates (Diamond, 2011; Legro, 2012).

In general with IVF, the greater the number of embryos that are transferred, the greater the risk of twins and multiple fetuses. In 2005, 1 percent of infants born in the United States were conceived through ART, and these infants accounted for 17 percent of multifetal births (Wright, 2008). The American Society for Reproductive Medicine (2013) recently revised their age-related
guidelines on numbers of cleavage-stage embryos or blastocysts to transfer in an effort to reduce the incidence of higher-order multifetal pregnancies. For example, women younger than 35 years with a favorable prognosis should have no more than two embryos transferred. These practices have effectively lowered rates (Kulkarni, 2013).

**Sex Ratios with Multiple Fetuses**

In humans, as the number of fetuses per pregnancy increases, the percentage of male conceptuses decreases. Strandskov and coworkers (1946) found the percentage of males in 31 million singleton births in the United States was 51.6 percent. For twins, it was 50.9 percent; for triplets, 49.5 percent; and for quadruplets, 46.5 percent. Swedish birth data spanning 135 years reveals the number of males per 100 female infants born was 106 among singletons, 103 among twins, and 99 among triplets (Fellman, 2010). Females predominate even more in twins from late twinning events. For example, 68 percent of thoracopagus conjoined twins are female (Mutchinick, 2011). Two explanations have been offered. First, beginning in utero and extending throughout the life cycle, mortality rates are lower in females. Second, female zygotes have a greater tendency to divide.

**Determination of Zygosity**

Twins of opposite sex are almost always dizygotic. In rare instances, due to somatic mutations or chromosome aberrations, the karyotype or phenotype of a monozygous twin gestation can be different. Most reported cases are related to postzygotic loss of the Y chromosome in one 46,XY twin. This results in a phenotypically female twin due to Turner syndrome (45,X). Zech and colleagues (2008) reported a rare case of a 47,XXY zygote that underwent postzygotic loss of the X chromosome in some cells and loss of the Y chromosome in other cells. The phenotype of the resultant twins was one male and one female. Karyotype analyses revealed both to be 46,XX/46,XY genetic mosaics.

The risk for twin-specific complications varies in relation to zygosity as well as *chorionicity*—the number of chorions. As shown in Table 45-3, the latter is the more important determinant. Specifically, there are increased rates of perinatal mortality and neurological injury in monochorionic diamnionic twins compared with dichorionic pairs (Hack, 2008; Lee, 2008). In their retrospective analysis of more than 2000 twins, McPherson and associates (2012) reported that the risk of fetal demise in one or both monochorionic twins was twice that in dichorionic multifetal gestations.

**TABLE 45-3. Overview of the Incidence of Twin Pregnancy Zygosity and Corresponding Twin-Specific Complications**
Sonographic Determination of Chorionicity

Chorionicity can sometimes be identified in the first trimester with sonography. Two separate placentas suggest dizygosity. In pregnancies with a single placental mass, it may be difficult to identify chorionicity. Identification of a thick dividing membrane—generally 2 mm or greater—supports a presumed diagnosis of dichorionicity. Also, the twin peak sign is seen by examining the point of origin of the dividing membrane on the placental surface. The peak appears as a triangular projection of placental tissue extending a short distance between the layers of the dividing membrane (Fig. 45-4).

¹Delivery before 37 weeks.
Modified from Manning, 1995, with permission.
FIGURE 45-4  A. Sonographic image of the “twin-peak” sign, also termed the “lambda sign,” in a 24-week gestation. At the top of this sonogram, tissue from the anterior placenta is seen extending downward between the amnion layers. This sign confirms dichorionic twinning. B. Schematic diagram of the “twin-peak” sign. A triangular portion of placenta is seen insinuating between the amniochorion layers.

In contrast, monochorionic pregnancies have a dividing membrane that is so thin it may not be seen until the second trimester. The membrane is generally less than 2-mm thick, and magnification reveals only two layers. The right-angle relationship between the membranes and placenta and no
apparent extension of placenta between the dividing membranes is called the *T* sign (Fig. 45-5). Evaluation of the dividing membrane can establish chorionicity in more than 99 percent of pregnancies in the first trimester (Miller, 2012).

**FIGURE 45-5** A. Sonographic image of the “T” sign in a monochorionic diamniotic gestation at 30 weeks. B. Schematic diagram of the “T” sign. Twins are separated only by a membrane created by the juxtaposed amnion of each twin. A “T” is formed at the point at which amnions meet the placenta.
Placental Examination

A carefully performed visual examination of the placenta and membranes after delivery serves to establish zygosity and chorionicity promptly in approximately two thirds of cases. The following systematic examination is recommended. As the first neonate is delivered, one clamp is placed on a portion of its cord. Cord blood is generally not collected until after delivery of the other twin. As the second neonate is delivered, two clamps are placed on that cord. Three clamps are used to mark the cord of a third neonate, and so on as necessary. Until the delivery of the last fetus, each cord segment must remain clamped to prevent fetal hypovolemia and anemia caused by blood leaving the placenta via anastomoses and then through an unclamped cord.

The placenta should be carefully delivered to preserve the attachment of the amnion and chorion. With one common amnionic sac, or with juxtaposed amnions not separated by chorion arising between the fetuses, the fetuses are monozygotic. If adjacent amnions are separated by chorion, then the fetuses could be either dizygotic or monozygotic, but dizygosity is more common (see Figs. 45-1 and 45-6). If the neonates are of the same sex, blood typing of cord blood samples may be helpful. Different blood types confirm dizygosity, although demonstrating the same blood type in each fetus does not confirm monozygosity. For definitive diagnosis, more complicated techniques such as DNA fingerprinting can be used, but these tests are generally not performed at birth unless there is a pressing medical indication.

FIGURE 45-6 Dichorionic diamnionic twin placenta. The membrane partition that separated twin fetuses is elevated and consists of chorion (c) between two amnions (a).

DIAGNOSIS OF MULTIPLE FETUSES

Clinical Evaluation
During examination, accurate fundal height measurement, described in Chapter 9 (p. 176), is essential. With multiple fetuses, uterine size is typically larger during the second trimester than expected. Rouse and associates (1993) reported fundal heights in 336 well-dated twin pregnancies. Between 20 and 30 weeks, fundal heights averaged approximately 5 cm greater than expected for singletons of the same fetal age.

In general, it is difficult to diagnose twins by palpation of fetal parts before the third trimester. Even late in pregnancy, it may be difficult to identify twins by abdominal palpation, especially if one twin overlies the other, if the woman is obese, or if there is hydramnios. Palpating two fetal heads, often in different uterine quadrants, strongly supports a twin diagnosis.

Late in the first trimester, fetal heart action may be detected with Doppler ultrasonic equipment. Thereafter, it becomes possible to identify two fetal heartbeats if their rates are clearly distinct from each other and from that of the mother. Careful examination with an aural fetal stethoscope can identify fetal heart sounds in twins as early as 18 to 20 weeks.

**Sonography**

By careful sonographic examination, separate gestational sacs can be identified early in twin pregnancy (Fig. 45-7). Subsequently, each fetal head should be seen in two perpendicular planes so as not to mistake a cross section of the fetal trunk for a second fetal head. Ideally, two fetal heads or two abdomens should be seen in the same image plane, to avoid scanning the same fetus twice and interpreting it as twins. Sonographic examination should detect practically all sets of twins. Given the increased frequency of sonographic examinations during the first trimester, early detection of a twin pregnancy is common. Indeed, one argument in favor of routine first-trimester sonographic screening is earlier detection of multiple fetuses.

**FIGURE 45-7** Sonograms of first-trimester twins. **A.** Dichorionic diamnionic twin pregnancy at 6 weeks’ gestation. Note the thick dividing chorion (yellow arrow). One of the yolk sacs is indicated
Higher-order multifetal gestations are more difficult to evaluate. Even in the first trimester, it can be difficult to identify the actual number of fetuses and their position. This determination is especially important if pregnancy reduction or selective termination is considered (p. 919).

Other Diagnostic Aids

Radiography and Magnetic Resonance Imaging

Abdominal radiography can be used if fetal number in a higher-order multifetal gestation is uncertain. However, radiographs generally have limited utility and may lead to an incorrect diagnosis if there is hydramnios, obesity, fetal movement during the exposure, or inappropriate exposure time. Additionally, fetal skeletons before 18 weeks’ gestation are insufficiently radiopaque and may be poorly seen.

Although not typically used to diagnose multifetal pregnancy, magnetic resonance (MR) imaging may help delineate complications in monochorionic twins (Hu, 2006). Bekiesinska-Figatowska and colleagues (2013) reviewed their experience with 17 complicated twin gestations evaluated by both sonographic and MR imaging. They concluded that MR imaging provides a more detailed assessment of pathology in twins and is particularly helpful in cases of conjoined twins.

Biochemical Tests

There is no biochemical test that reliably identifies multiple fetuses. Serum and urine levels of β-hCG and maternal serum alpha-fetoprotein (MSAFP) are generally higher with twins compared with singletons. However, levels may vary considerably and overlap with those of singletons.

MATERNAL ADAPTATION TO MULTIFETAL PREGNANCY

The various physiological burdens of pregnancy and the likelihood of serious maternal complications are typically greater with multiple fetuses than with a singleton. This should be considered, especially when counseling a woman whose health is compromised and in whom multifetal gestation is recognized early. Similar consideration is given to a woman who is not pregnant but is considering infertility treatment.

Beginning in the first trimester, and temporarily associated with higher serum β-hCG levels, women with multifetal gestation often have nausea and vomiting in excess of women with a singleton pregnancy. In women with multiple fetuses, blood volume expansion is greater and averages 50 to 60 percent compared with 40 to 50 percent in those with a singleton (Pritchard, 1965). Although the red cell mass also increases, it does so proportionately less in twin pregnancies. Combined with increased iron and folate requirements, this predisposes to anemia. This augmented hypervolemia teleologically offsets blood loss with vaginal delivery of twins, which is twice that with a single fetus.

Women carrying twins also have a typical pattern of arterial blood pressure change. MacDonald-Wallis and coworkers (2012) analyzed serial blood pressures in more than 13,000 singleton and twin pregnancies. As early as 8 weeks’ gestation, the diastolic blood pressure in
women with twins was lower than that with singleton pregnancies but generally increased to a greater degree at term. In an earlier study, Campbell (1986) demonstrated that this increase was at least 15 mm Hg in 95 percent of women with twins compared with only 54 percent of women with a singleton.

Hypervolemia along with decreased vascular resistance has an impressive affect on cardiac function. Kametas and associates (2003) assessed function in 119 women with a twin pregnancy. In these women, cardiac output was increased another 20 percent above that in women with a singleton pregnancy. Kuleva and colleagues (2011) compared serial echocardiography results in 20 women with uncomplicated twin pregnancies with those of 10 women with singletons. Similarly, they also demonstrated a greater increase in cardiac output in those with twins. Both studies found the cardiac output rise was predominantly due to greater stroke volume and to a much lesser degree due to increased heart rate. Vascular resistance was significantly lower in twin gestations throughout pregnancy compared with singleton gestations (Kuleva, 2011).

Uterine growth in a multifetal gestation is substantively greater than in a singleton pregnancy. The uterus and its nonfetal contents may achieve a volume of 10 L or more and weigh in excess of 20 pounds. Especially with monozygotic twins, excessive amounts of amnionic fluid may rapidly accumulate. In these circumstances, maternal abdominal viscera and lungs can be appreciably compressed and displaced by the expanding uterus. As a result, the size and weight of the large uterus may preclude more than a sedentary existence for these women.

If hydramnios develops, maternal renal function can become seriously impaired, most likely as the consequence of obstructive uropathy (Quigley, 1977). With severe hydramnios, therapeutic amniocentesis may provide relief for the mother, may improve obstructive uropathy, and possibly may lower the preterm delivery risk that follows preterm labor or prematurely ruptured membranes (Chap. 11, p. 236). Unfortunately, hydramnios is often characterized by acute onset remote from term and by rapid reaccumulation following amniocentesis.

PREGNANCY COMPLICATIONS

Spontaneous Abortion

Miscarriage is more likely with multiple fetuses. During a 16-year study, Joo and colleagues (2012) demonstrated that the spontaneous abortion rate per live birth in singleton pregnancies was 0.9 percent compared with 7.3 percent in multiple pregnancies. Furthermore, they found that monochorial placentation was more common in multiple gestations ending in miscarriage than in those resulting in a livebirth. Twin pregnancies achieved through ART are at increased risk for abortion compared with those conceived spontaneously (Szymusik, 2012).

Congenital Malformations

The incidence of congenital malformations is appreciably increased in multifetal gestations compared with singletons. Glinianaia and associates (2008) reported that the rate of congenital malformations was 406 per 10,000 twins versus 238 per 10,000 singletons. In this survey-based study, the malformation rate in monochorionic twins was almost twice that of dichorionic twin gestations. This increase has been attributed to the high incidence of structural defects in monozygotic twins. But from a 30-year European registry of multifetal births, Boyle an
coworkers (2013) found a steady increase in structural anomalies from 1987 (2.16 percent) to 2007 (3.26 percent). During this time, the proportion of dizygotic twins increased by 30 percent, while the proportion of monozygotic twins remained stable. This higher risk of congenital malformations in dizygotic twins over time correlates with increased availability of ART. An increase in birth defects related to ART has been reported repeatedly (Talauliker, 2012).

**Low Birthweight**

Multifetal gestations are more likely to be low birthweight than singleton pregnancies due to restricted fetal growth and preterm delivery. From 1988 to 2012 at Parkland Hospital, data were collected from 357,205 singleton neonates without malformations and from 3714 normal twins who were both liveborn. Birthweights in twin infants closely paralleled those of singletons until 28 to 30 weeks’ gestation. Thereafter, twin birthweights progressively lagged (Fig. 45-8). Beginning at 35 to 36 weeks, twin birthweights clearly diverge from those of singletons.

**FIGURE 45-8** Birthweight percentiles (25th to 75th) for 357,205 singleton neonates compared with the 50th birthweight percentile for 3714 twins, Parkland Hospital 1988—2012. Infants with major malformations, pregnancies complicated by stillbirth, and twin gestations with > 25 percent discordance were excluded. (Data courtesy of Dr. Don McIntire.)

In general, the degree of growth restriction increases with fetal number. The caveat is that this assessment is based on growth curves established for singletons. Several authorities argue that fetal growth in twins is different from that of singleton pregnancies, and thus abnormal growth should be diagnosed only when fetal size is less than expected for multifetal gestation. Accordingly, twin and triplet growth curves have been developed (Kim, 2010; Odibo, 2013; Vora, 2006).

The degree of growth restriction in monozygotic twins is likely to be greater than that in dizygotic pairs (Fig. 45-9). With monochorionic embryos, allocation of blastomeres may not be equal, vascular anastomoses within the placenta may cause unequal distribution of nutrients and oxygen, and discordant structural anomalies resulting from the twinning event itself may affect
growth. For example, the quintuplets shown in Figure 45-10 represent three dizygotic and two monozygotic fetuses. When delivered at 31 weeks, the three neonates from separate ova weighed 1420, 1530, and 1440 g, whereas the two derived from the same ovum weighed 990 and 860 g.

**FIGURE 45-9** Marked growth discordance in monochorionic twins. (Photograph contributed by Dr. Laura Greer.)
Hypertension

Hypertensive disorders due to pregnancy are more likely to develop with multiple fetuses. The exact incidence attributable to twin gestation is difficult to determine because twin pregnancies are more likely to deliver preterm before preeclampsia can develop and because women with twin pregnancies are often older and multiparous. The incidence of pregnancy-related hypertension in women with twins is 20 percent at Parkland Hospital. In their analysis of 513 twin pregnancies > 20 weeks’ gestation, Fox and coworkers (2014) also identified 20 percent of parturients with either gestational hypertension or preeclampsia. Case-control analyses suggest that prepregnancy body mass index (BMI) ≥ 30 kg/m² and egg donation are additional independent risk factors for preeclampsia. Gonzalez and colleagues (2012) compared 257 women with twins and gestational diabetes with 277 nondiabetic women carrying twins. These researchers found a twofold increased risk of preeclampsia in women diagnosed with gestational diabetes. Finally, in the Matched Multiple Birth Dataset for the National Center for Health Statistics, Luke and associate
(2008) analyzed 316,696 twin, 12,193 triplet, and 778 quadruple pregnancies. These investigators found that the risk for pregnancy-associated hypertension was significantly increased for triplets and quadruplets (11 and 12 percent, respectively) compared with that for twins (8 percent).

These data suggest that fetal number and placental mass are involved in preeclampsia pathogenesis. Women with twin pregnancies have levels of antiangiogenic soluble fms-like tyrosine kinase-1 (sFlt-1) that are twice that of singletons. Levels are seemingly related to increased placental mass rather than primary placental pathology (Bdolah, 2008; Maynard, 2008). Rana and coworkers (2012) measured antiangiogenic sFlt-1 and proangiogenic placental growth factor (PIGF) in 79 women with twins referred for evaluation of preeclampsia. In the 58 women identified with either gestational hypertension or preeclampsia, there was a stepwise increase in sFlt-1 concentrations, decrease in PIGF levels, and increase in sFlt-1/PIGF ratios compared with normotensive twin pregnancies. With multifetal gestation, hypertension not only develops more often but also tends to develop earlier and be more severe. In the analysis of angiogenic factors mentioned above, more than one half presented before 34 weeks, and in those who did, the sFlt-1/PIGF ratio rise was more striking (Rana, 2012). This relationship is discussed in Chapter 40 (p. 735).

**Preterm Birth**

The duration of gestation decreases with increasing fetal number (Fig. 45-11). According to Martin and colleagues (2012), more than five of every 10 twins and nine of 10 triplets born in the United States in 2010 were delivered preterm. Delivery before term is a major reason for increased neonatal morbidity and mortality rates in multifetal pregnancy. Prematurity is increased sixfold and tenfold in twins and triplets, respectively (Giuffre, 2012). In their review, Chauhan and associates (2010) reported that, similar to singleton pregnancies, approximately 60 percent of preterm births in twins are indicated, about a third result from spontaneous labor, and 10 percent follow prematurely ruptured membranes. In their analysis of almost 300,000 live births in Ohio, Pakrashi and DeFranco (2013) found that the proportion of preterm birth associated with premature membrane rupture increased with gestational plurality from 13 percent with singletons to 20 percent with triplets or more.
The preterm birth rate among multifetal gestations has increased during the past two decades. In an analysis of nearly 350,000 twin births, Kogan and coworkers (2000) showed that during the 16-year period ending in 1997, the term birth rate among twins declined by 22 percent. Joseph and colleagues (2001) attributed this decline to an increased rate of indicated preterm deliveries. This trend is not necessarily negative, as it was associated with decreased perinatal morbidity and mortality rates among twins that reached 34 weeks. Although the causes of preterm delivery in twins and singletons may be different, neonatal outcome is generally the same at similar gestational ages (Gardner, 1995; Kilpatrick, 1996; Ray, 2009). Importantly, outcomes for preterm twins who are markedly discordant may not be comparable with those for singletons because whatever caused the discordance may have long-lasting effects.

Prolonged Pregnancy

More than 40 years ago, Bennett and Dunn (1969) suggested that a twin pregnancy of 40 weeks or more should be considered postterm. Twin stillborn neonates delivered at 40 weeks or beyond commonly had features similar to those of postmature singletons (Chap. 43, p. 864). From an analysis of almost 300,000 twin births, Kahn and coworkers (2003) calculated that at and beyond 39 weeks, the risk of subsequent stillbirth was greater than the risk of neonatal mortality. At Parkland Hospital, twin gestations have empirically been considered to be prolonged at 40 weeks.

Long-Term Infant Development

Historically, twins have been considered cognitively delayed compared with singletons (Record, 1970; Ronalds, 2005). However, in cohort studies evaluating normal-birthweight term infants, cognitive outcomes between twins and singletons are similar (Lorenz, 2012). Christensen and associates (2006) found similar national standardized test scores in ninth grade in 3411 twins and 7796 singletons born between 1986 and 1988. In contrast, among normal-birthweight infants, the cerebral palsy risk is higher among twins and higher-order multiples. For example, the cerebral palsy rate has been reported to be 2.3 per 1000 in singletons, 12.6 per 1000 in twins, and 44.8 per 1000 in triplets (Giuffre, 2012). Much of this excess risk is thought to be related to an increased risk of fetal-growth restriction, congenital anomalies, twin-twin transfusion syndrome, and fetal demise of a cotwin (Lorenz, 2012).

UNIQUE FETAL COMPLICATIONS

Several unique and fascinating complications arise in multifetal pregnancies. These have been best described in twins but can be found in higher-order multifetal gestations. Most fetal complications due to the twinning process itself are seen with monozygotic twins. Their pathogenesis is best understood after reviewing the possibilities shown in Figure 45-1.
Monoamnionic Twins

Only about 1 percent of all monozygotic twins will share an amnionic sac (Hall, 2003). Said another way, approximately 1 in 20 monochorionic twins are monoamnionic (Lewi, 2013). This configuration is associated with a high fetal death rate from cord entanglement, congenital anomalies, preterm birth, or twin-twin-transfusion syndrome, which is described subsequently. In a comprehensive review, Allen and associates (2001) reported that monoamnionic twins diagnosed antenatally and alive at 20 weeks have approximately a 10-percent risk of subsequent fetal demise. In a Dutch report of 98 monoamnionic twin pregnancies, the perinatal mortality rate was 17 percent (Hack, 2009). Umbilical cord entanglement, a frequent cause of death, is estimated to complicate at least half of cases (Fig. 45-12). Diamnionic twins can become monoamnionic if the dividing membrane ruptures and therefore have similar associated morbidity and mortality rates.

FIGURE 45-12 Monozygotic twins in a single amnionic sac. The smaller fetus apparently died first, and the second subsequently succumbed when umbilical cords entwined.

Unfortunately, there are no management methods that guarantee good outcomes for either or both twins. This is because of the unpredictability of fetal death from cord entanglement and the lack of an effective means of monitoring for it. Quinn and colleagues (2011) retrospectively evaluated the feasibility of inpatient continuous fetal heart monitoring in 17 sets of monoamnionic twins. After review of more than 10,000 hours of fetal tracing, these investigators concluded that this was possible in only 50 percent of cases. Importantly, an abnormal fetal heart rate tracing prompted
delivery in only six cases. Morbid cord entanglement appears to occur early, and monoamnionic pregnancies that have successfully reached 30 to 32 weeks are at reduced risk. In the Dutch series described above, the incidence of intrauterine demise dropped from 15 percent after 20 weeks to 4 percent when gestational age exceeded 32 weeks (Hack, 2009).

Although umbilical cords frequently entangle, factors that lead to pathological umbilical vessel constriction are unknown. Color-flow Doppler sonography can be used to diagnose entanglement (Fig. 45-13). However, once identified, evidence to guide management is observational, retrospective, and subject to biased reporting. One proposed management scheme is based on a study by Heyborne and coworkers (2005), who reported no stillbirths in 43 twin pregnancies of women admitted at 26 to 27 weeks’ gestation for daily fetal surveillance. Conversely, there were 13 stillbirths in 44 women who were managed as outpatients and admitted only for an obstetrical indication. Because of this report, women with monoamnionic twins are recommended to undergo 1 hour of daily fetal heart rate monitoring, either as outpatients or as inpatients, beginning at 26 to 28 weeks. With initial testing, a course of betamethasone is given to promote pulmonary maturation (Chap. 42, p. 850). If fetal testing remains reassuring, cesarean delivery is performed at 34 weeks and after a second course of betamethasone. This management scheme is used at Parkland Hospital and resulted in the successful 34-week delivery of the twins depicted in Figure 45-13.
Aberrant Twinning Mechanisms

Several aberrations in the twinning process result in a spectrum of fetal malformations. These are traditionally ascribed to incomplete splitting of an embryo into two separate twins. However, it is possible that they may result from early secondary fusion of two separate embryos. These separated embryos are either symmetrical or asymmetrical, and the spectrum of anomalies is shown in Figure 45-14.

Conjoined Twins

In the United States, united or conjoined twins have been referred to as Siamese twins—after Chang and Eng Bunker of Siam (Thailand), who were displayed worldwide by P. T. Barnum. Joining o
the twins may begin at either pole and may produce characteristic forms depending on which body parts are joined or shared (Fig. 45-15). Of these, thoracopagus is the most common (Mutchinick, 2011). The frequency of conjoined twins is not well established. At Kandang Kerbau Hospital in Singapore, Tan and coworkers (1971) identified seven cases of conjoined twins among more than 400,000 deliveries—an incidence of 1 in 60,000.

As reviewed by McHugh and associates (2006), conjoined twins can frequently be identified using sonography at midpregnancy. This provides an opportunity for parents to decide whether to continue the pregnancy. As shown in Figure 45-16, identification of cases during the first trimester is also possible. A targeted examination, including a careful evaluation of the connection and the organs involved, is necessary before counseling can be provided. As shown in Figure 45-17, MR imaging can play an important adjunctive role in clarifying shared organs. Compared with sonography, MR imaging may provide superior views, especially in later pregnancy when amniotic fluid is diminished and fetal crowding is increased (Hibbeln, 2012).
**FIGURE 45-16** Sonogram of a conjoined twin pregnancy at 13 weeks’ gestation. These thoracoomphalopagus twins have two heads but a shared chest and abdomen.

**FIGURE 45-17** Magnetic resonance imaging of conjoined twins. This T2-weighted HASTE sagittal image demonstrates fusion from the level of the xiphoid process to just below the level of the umbilicus, that is, omphalopagus twins. Below the fused liver (L), there is a midline cystic mass (arrow) within the tissue connecting the twins. An omphalomesenteric cyst was favored given the location within the shared tissue. (Image contributed by Dr. April Bailey.)
Surgical separation of an almost completely joined twin pair may be successful if essential organs are not shared (Spitz, 2003; Tannuri, 2013). Consultation with a pediatric surgeon often assists parental decision making. Conjoined twins may have discordant structural anomalies that further complicate decisions about whether to continue the pregnancy.

Viable conjoined twins should be delivered by cesarean. For the purpose of pregnancy termination, however, vaginal delivery is possible because the union is most often pliable (Fig. 45-18). Still, dystocia is common, and if the fetuses are mature, vaginal delivery may be traumatic to the uterus or cervix.

**FIGURE 45-18** Conjoined twins aborted at 17 weeks’ gestation. (Photograph contributed by Dr. Jonathan Willms.)

**External Parasitic Twins**

This is a grossly defective fetus or merely fetal parts, attached externally to a relatively normal twin. A parasitic twin usually consists of externally attached supernumerary limbs, often with some viscera. Classically, however, a functional heart or brain is absent. Attachment mirrors those sites described earlier for conjoined twins (see Fig. 45-14). Parasites are believed to result from demise of the defective twin, with its surviving tissues attached to and vascularized by its normal twin (Spencer, 2001). In a worldwide collaborative epidemiological study, parasitic twins were found to account for 3.9 percent of all conjoined twins and to occur more frequently in male fetuses (Mutchinick, 2011).

**Fetus-in-Fetu**

Early in development, one embryo may be enfolded within its twin. Normal development of this rare parasitic twin usually arrests in the first trimester. As a result, normal spatial arrangement of and presence of many organs is lost. Classically, vertebral or axial bones are found in these
fetiform masses, whereas heart and brain are lacking. These masses are typically supported by their host by a few large parasitic vessels (Spencer, 2000). Malignant degeneration is rare (Kaufman, 2007).

**Monochorionic Twins and Vascular Anastomoses**

Another group of fascinating fetal syndromes can arise when monozygotic twinning results in two amnionic sacs and a common surrounding chorion. This leads to anatomical sharing of the two fetal circulations through anastomoses of placental arteries and veins. All monochorionic placentas likely share some anastomotic connections. However, there are marked variations in the number, size, and direction of these seemingly haphazard connections (Fig. 45-19). In their analyses of more than 200 monochorionic placentas, Zhao and colleagues (2013) found the median number of anastomoses to be 8 with an interquartile range of 4 to 14. With rare exceptions, anastomoses between twins are unique to monochorionic twin placentas.

![FIGURE 45-19 Shared placenta from pregnancy complicated by twin-twin transfusion syndrome. The following color code was applied for injection. Left twin: yellow = artery, blue = vein; right twin: red = artery, green = vein. A. Part of the arterial network of the right twin is filled with yellow dye, due to the presence of a small artery-to-artery anastomosis (arrow). B. Close-up of the lower portion of the placenta displays the yellow dye-filled anastomosis. (From De Paepe, 2005, with permission.)](image)

Artery-to-artery anastomoses are most common and are identified on the chorionic surface of the placenta in up to 75 percent of monochorionic twin placentas. Vein-to-vein and artery-to-vein communications are each found in approximately half. One vessel may have several connections, sometimes to both arteries and veins. In contrast to these superficial vascular connections on the surface of the chorion, deep artery-to-vein communications can extend through the capillary bed of a given villus (Fig. 45-20). These deep arteriovenous anastomoses create a common villous compartment or third circulation that has been identified in approximately half of monochorionic
twin placentas.

Anastomoses between twins may be artery-to-vein (AV), artery-to-artery (AA), or vein-to-vein (VV). Schematic representation of an AV anastomosis in twin-twin transfusion syndrome that forms a “common villous district” or “third circulation” deep within the villous tissue. Blood from a donor twin may be transferred to a recipient twin through this shared circulation. This transfer leads to a growth-restricted discordant donor twin with markedly reduced amnionic fluid, causing it to be “stuck.”

Whether these anastomoses are dangerous to either twin depends on the degree to which they are hemodynamically balanced. In those with significant pressure or flow gradients, a shunt will develop between fetuses. This chronic fetofetal transfusion may result in several clinical syndromes that include twin-twin transfusion syndrome (TTTS), twin anemia polycythemia sequence (TAPS), and acardiac twinning.
Twin-Twin Transfusion Syndrome (TTTS)
The prevalence of this condition is approximately 1 to 3 per 10,000 births (Simpson, 2013). In this syndrome, blood is transfused from a donor twin to its recipient sibling such that the donor may eventually become anemic and its growth may be restricted. In contrast, the recipient becomes polycythemic and may develop circulatory overload manifest as hydrops. The donor twin is pale, and its recipient sibling is plethoric (Fig. 45-21). Similarly, one portion of the placenta often appears pale compared with the remainder.

![Fig. 45-21](image)

**FIGURE 45-21** Twin-twin transfusion syndrome at 23 weeks. **A.** Pale donor twin (690 g) also had oligohydramnios. **B.** The plethoric recipient twin (730 g) had hydramnios. (From Mahone, 1993, with permission.)

The recipient neonate may have circulatory overload from heart failure and severe hypervolemia and hyperviscosity. Occlusive thrombosis is another concern. Finally, polycythemia
in the recipient twin may lead to severe hyperbilirubinemia and kernicterus (Chap. 33, p. 644).

**Pathophysiology.** Any of the different types of vascular anastomoses discussed before may be found with monochorionic placentas. Classically, chronic TTTS results from unidirectional flow through arteriovenous anastomoses. Deoxygenated blood from a donor placental artery is pumped into a cotyledon shared by the recipient (see Fig. 45-20). Once oxygen exchange is completed in the chorionic villus, the oxygenated blood leaves the cotyledon via a placental vein of the recipient twin. Unless compensated—typically through arterioarterial anastomoses—this unidirectional flow leads to an imbalance in blood volumes (Lewi, 2013).

Clinically important twin-twin transfusion syndrome frequently is chronic and results from significant vascular volume differences between the twins. Even so, the pathogenesis is more complex than a net transfer of red blood cells from one twin to another. Indeed, in most monochorionic twin pregnancies complicated by the syndrome, there is no difference in hemoglobin concentrations between the donor and recipient twin (Lewi, 2013).

The syndrome typically presents in midpregnancy when the donor fetus becomes oliguric from decreased renal perfusion (Simpson, 2013). This fetus develops oligohydramnios, and the recipient fetus develops severe hydramnios, presumably due to increased urine production. Virtual absence of amniotic fluid in the donor sac prevents fetal motion, giving rise to the descriptive term stuck twin or polyhydramnios-oligohydramnios–syndrome—“poly-oli.” This amniotic fluid imbalance is associated with growth restriction, contractures, and pulmonary hypoplasia in the donor twin, and premature rupture of the membranes and heart failure in the recipient.

**Fetal Brain Damage.** Cerebral palsy, microcephaly, porencephaly, and multicystic encephalomalacia are serious complications associated with placental vascular anastomoses in multifetal gestation. The exact pathogenesis of neurological damage is not fully understood but is likely caused by ischemic necrosis leading to cavitary brain lesions (Fig. 45-22). In the donor twin, ischemia results from hypotension, anemia, or both. In the recipient, ischemia develops from blood pressure instability and episodes of severe hypotension (Lopriore, 2011). Cerebral lesions may also be due to postnatal injury associated with preterm delivery. Quarello and associates (2007) reviewed data from 315 liveborn fetuses from pregnancies with twin-twin-transfusion syndrome and reported cerebral abnormalities in 8 percent.
If one twin of an affected pregnancy dies, cerebral pathology in the survivor probably results from acute hypotension. A less likely cause is emboli of thromboplastic material originating from the dead fetus. Fusi and coworkers (1990, 1991) observed that with the death of one twin, acute twin-twin anastomotic transfusion from the high-pressure vessels of the living twin to the low-resistance vessels of the dead twin leads rapidly to hypovolemia and ischemic antenatal brain damage in the survivor. In their systematic review of 343 twin pregnancies complicated by single fetal demise, Hillman and colleagues (2011) calculated a 26-percent risk of neurodevelopmental morbidity in monochorionic twins compared with 2 percent in dichorionic twins. They also found that this morbidity was related to gestational age at the death of the cotwin. If the death occurred between 28 and 33 weeks’ gestation, monochorionic twins had an almost eightfold risk of neurodevelopmental morbidity compared with dichorionic twins of the same gestational age. With fetal death after 34 weeks, the likelihood dramatically decreased—odds ratio 1.48.

The acuity of hypotension following the death of one twin with twin-twin-transfusion syndrome makes successful intervention for the survivor nearly impossible. Even with delivery immediately after a cotwin demise is recognized, the hypotension that occurs at the moment of death has likely
Diagnosis. There have been dramatic changes in the criteria used to diagnose and classify varying severities of twin-twin transfusion syndrome. Previously, weight discordancy and hemoglobin differences in monochorionic twins were calculated. However, it was soon appreciated that in many cases these were late-onset findings. According to the Society for Maternal-Fetal Medicine (2013), TTTS is diagnosed based on two criteria: (1) presence of a monochorionic diamnionic pregnancy, and (2) hydramnios defined if the largest vertical pocket is > 8 cm in one twin and oligohydramnios defined if the largest vertical pocket is < 2 cm in the other twin. Only 15 percent of pregnancies complicated by lesser degrees of fluid imbalance progress to TTTS (Huber, 2006).

Once identified, TTTS is typically staged by the Quintero (1999) staging system:

- **Stage I**—discordant amniotic fluid volumes as described above, but urine is still visible sonographically within the bladder of the donor twin.
- **Stage II**—criteria of stage I, but urine is not visible within the donor bladder.
- **Stage III**—criteria of stage II and abnormal Doppler studies of the umbilical artery, ductus venosus, or umbilical vein.
- **Stage IV**—ascites or frank hydrops in either twin.
- **Stage V**—demise of either fetus.

In addition to these criteria, there is evidence that cardiac function of the recipient twin correlates with fetal outcome (Crombleholme, 2007). Although fetal echocardiographic findings are not part of the staging system above, many centers routinely perform fetal echocardiography for TTTS. It has been theorized that early diagnosis of cardiomyopathy in the recipient twin may identify pregnancies that would benefit from early intervention. One system for evaluating cardiac function—the **myocardial performance index (MPI)** or **Tei index**—is a Doppler index of ventricular function calculated for each ventricle (Michelfelder, 2007). Although scoring systems that include assessment of cardiac function have been developed, their usefulness in prediction of outcomes remains controversial (Simpson, 2013).

At Parkland Memorial Hospital, evaluation before and during treatment includes anatomical and neurological fetal assessment using echocardiography, MPI calculation, Doppler velocimetry, and MR imaging; genetic counseling and amniocentesis; and placental mapping.

Management and Prognosis. The prognosis for multifetal gestations complicated by TTTS is related to Quintero stage and gestational age at presentation. More than three fourths of stage I cases remain stable or regress without intervention. Conversely, outcomes in those identified at stage III or higher are much worse, and the perinatal loss rate is 70 to 100 percent without intervention (Simpson, 2013). Several therapies are currently used for TTTS, including amnioreduction, laser ablation of vascular anastomoses, selective feticide, and septostomy (intentional creation of a communication in the dividing amnionic membrane). Comparative data from randomized trials for some of these techniques are discussed below.

The Eurofetus trial included 142 women with severe TTTS diagnosed before 26 weeks. Participants were randomly assigned to laser ablation of vascular anastomoses or to serial amnioreduction (Senat, 2004). These investigators reported an increased survival rate to age 6 months for at least one twin with laser ablation compared with serial amnioreduction—76 versus 51 percent, respectively. Moreover, analyses of randomized studies confirm better neonatal outcomes with laser therapy compared with selective amnioreduction (Roberts, 2008; Rossi,
In contrast, Crombleholme and associates (2007), in a randomized trial of 42 women, found equivalent rates of 30-day survival of one or both twins treated with either amnioreduction or selective fetoscopic laser ablation—75 versus 65 percent, respectively. Furthermore, evaluation of twins from the Eurofetus trial through 6 years of age did not demonstrate any additional survival benefit beyond 6 months or improved neurological outcomes in those treated with laser (Salomon, 2010).

At this time, laser ablation of anastomoses is preferred for severe TTTS (stages II-IV), although optimal therapy for stage I disease is controversial. After laser therapy, close ongoing surveillance is necessary. Robyr and colleagues (2006) reported that a fourth of 101 pregnancies treated with laser required additional invasive therapy because of either recurrent TTTS, or middle cerebral artery Doppler evidence of anemia or polycythemia. Recently, in a comparison of selective laser ablation of individual anastomoses versus ablation of the entire surface of chorionic plate along the vascular equator, Baschat and coworkers (2013) found that equatorial photocoagulation reduced the likelihood of recurrence.

Moise and associates (2005) compared amnioreduction and septostomy in a multicentered randomized trial of 73 women. Repeated procedures were performed for symptoms or if the greatest vertical pocket of amniotic fluid met the original inclusion criteria of 8 to 12 cm, depending on gestational age. Perinatal outcomes were the same in each group, with at least one survivor in 80 percent of pregnancies. The average number of additional procedures was two in each group. Much of this is moot, however, because intentional septostomy has largely been abandoned as treatment (Simpson, 2013).

Selective reduction has generally been considered if severe amniotic fluid and growth disturbances develop before 20 weeks. In such cases, both fetuses typically will die without intervention. Selection of which twin is to be terminated is based on evidence of damage to either fetus and comparison of their prognoses. Any substance injected into one twin may affect the other twin because of shared circulations. Therefore, feticidal techniques include methods to occlude the circulation of the chosen fetal umbilical vein or by umbilical cord occlusion using radiofrequency ablation, fetoscopic ligation, or coagulation with laser, monopolar, or bipolar cauterization (Challis, 1999; Chang, 2009; Donner, 1997). Even after these procedures, however, the risks to the remaining fetus are still appreciable (Rossi, 2009).

**Twin Anemia Polycythemia Sequence (TAPS)**

This form of chronic fetofetal transfusion is characterized by significant hemoglobin differences between donor and recipient twins without the discrepancies in amniotic fluid volumes typical of twin-twin-transfusion syndrome (Slaghekke, 2010). It is diagnosed antenatally by middle cerebral artery (MCA) peak systolic velocity (PSV) > 1.5 multiples of the median (MoM) in the donor an < 1.0 MoM in the recipient twin (Simpson, 2013). The spontaneous form reportedly complicates 1 to 5 percent of monochorionic pregnancies, and it occurs in up to 13 percent of pregnancies after laser photocoagulation. Spontaneous TAPS usually occurs after 26 weeks and iatrogenic TAPS develops within 5 weeks of a procedure (Lewi, 2013). Although a staging system has been proposed by Slaghekke and colleagues (2010), further studies are necessary to better understand the natural history of TAPS and its management.

**Twin-Reversed Arterial Perfusion (TRAP) Sequence**

Also known as an acardiac twin, this is a rare—1 in 35,000 births—but serious complication of monochorionic multifetal gestation. In the TRAP sequence, there is usually a normally formed donor twin that has features of heart failure and a recipient twin that lacks a heart (acardius) and
other structures. It has been hypothesized that the TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt (Fig. 45-23). Within the single, shared placenta, arterial perfusion pressure of the donor twin exceeds that in the recipient twin, who thus receives reverse blood flow of deoxygenated arterial blood from its cotwin (Lewi, 2013). This “used” arterial blood reaches the recipient twin through its umbilical arteries and preferentially goes to its iliac vessels. Thus, only the lower body is perfused, and disrupted growth and development of the upper body results. Failure of head growth is called *acardius acephalus*; a partially developed head with identifiable limbs is called *acardius myelacephalus*; and failure of any recognizable structure to form is *acardius amorphous*, which is shown in Figure 45-24 (Faye-Petersen, 2006). Because of this vascular connection, the normal donor twin must not only support its own circulation but also pump its blood through the underdeveloped acardiac recipient. This may lead to cardiomegaly and high-output heart failure in the normal twin (Fox, 2007).

**FIGURE 45-23** Twin reversed-arterial-perfusion sequence. In the TRAP sequence, there is usually a normally formed donor twin that has features of heart failure, and a recipient twin that lacks a heart. It has been hypothesized that the TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt. Within the single, shared placenta, perfusion pressure of the donor twin overpowers that in the recipient twin, who thus receives reverse blood flow from its twin sibling. The “used” arterial blood (*colored blue*) that reaches the recipient twin preferentially goes to its iliac vessels and thus perfuses only the lower body. This disrupts growth and development of the upper body.
FIGURE 45-24 Photograph of an acardiac twin weighing 475 grams. The underdeveloped head is indicated by the black arrow, and its details are shown in the inset. A yellow clamp is seen on its umbilical cord. Its viable donor cotwin was delivered vaginally at 36 weeks and weighed 2325 grams. (Photograph contributed by Dr. Michael D. Hnat.)

Lewi and coworkers (2010) reviewed 26 cases of TRAP sequence identified in the first trimester. In one third, the pump twin died before planned intervention at 16 to 18 weeks. In more than half of all the cases, there was spontaneous cessation of flow to the acardiac twin, and such flow arrest was associated with subsequent death or neurological injury in 85 percent of the normal twins. Quintero and associates (1994, 2006) have reviewed methods of in utero treatment of acardiac twinning in which the goal is interruption of aberrant vascular communication between the twins. Of these methods, Lee (2007), Lewi (2010), Livingston (2007), and their colleagues found an approximate 90-percent survival rate following second-trimester radiofrequency ablation. This method cauterizes umbilical vessels in the malformed recipient twin to terminate blood flow from the donor. In a review of 118 complicated monochorionic twin gestations that underwent bipolar cord coagulation, Lanna and associates (2012) reported a fetal loss rate in those treated before 19 weeks of 45 percent compared with 3 percent in those treated after 19 weeks. Prompted by the high mortality rate of TRAP sequence in the first trimester, small case series of early intervention have been reported (O’Donoghue, 2008; Scheier, 2012). Importantly, efficacy and safety of intervention before fusion of the amnion and chorion has not been demonstrated convincingly (Lewi, 2013).
Complete Hydatidiform Mole with Coexisting Normal Fetus

Also termed a twin molar pregnancy, this is due to a complete diploid molar pregnancy comprising one conceptus, whereas the cotwin is a normal fetus. Reported prevalence rates range from 1 in 22,000 to 1 in 100,000 pregnancies (Dolapcioglu, 2009). It must be differentiated from a partial molar pregnancy in which an anomalous singleton fetus—usually triploid—is accompanied by molar tissue (Chap. 20, p. 398).

Optimal management is not known for this twin gestation. Diagnosis is usually made in the first half of pregnancy, and termination at that time would remove the mole but also the normal fetus. However, pregnancy progression exposes the woman to the later postpartum dangers of persistent trophoblastic disease that requires chemotherapy and may be fatal. Despite this, pregnancy continuation is increasingly being recommended in cases with a karyotypically normal and nonanomalous twin, no early preeclampsia, and declining hCG levels (Sebire, 2002).

If observation and pregnancy progression is chosen, preterm delivery is frequently required because of persistent and heavy bleeding or severe preeclampsia. Dolapcioglu and coworkers (2009) reviewed 159 reported cases and reported a live birth in 35 percent. Preeclampsia and preterm birth each developed in a third. Niemann and colleagues (2007) reported that persistent trophoblastic disease rates following such a twin gestation were not increased compared with those after a singleton complete mole.

DISCORDANT GROWTH OF TWIN FETUSES

Size inequality of twin fetuses, which can be a sign of pathological growth restriction in one fetus, is calculated using the larger twin as the index. Generally, as the weight difference within a twin pair increases, the perinatal mortality rate increases proportionately. Because the single placenta is not always equally shared in monochorionic twins, these twins have greater rates of discordant growth outside of TTTS than dichorionic twins. It develops in approximately 15 percent of twin gestations (Lewi, 2013; Miller, 2012). As discussed further in Chapter 44 (p. 879), restricted growth of one twin fetus usually develops late in the second and early third trimester. Earlier discordancy indicates higher risk for fetal demise in the smaller twin. Specifically, when discordant growth is identified before 20 weeks, fetal death occurs in about 20 percent (Lewi, 2013). Importantly, differences in crown-rump length (CRL) are associated with fetal structural and chromosomal anomalies but are not reliable predictors for birthweight discordance (Miller, 2012).

Etiopathogenesis

The cause of birthweight inequality in twin fetuses is often unclear, but the etiology in monochorionic twins likely differs from that in dichorionic twins. Discordancy in monochorionic twins is usually attributed to placental vascular anastomoses that cause hemodynamic imbalance between the twins. Reduced pressure and perfusion of the donor twin can cause diminished placental and fetal growth. Even so, unequal placental sharing is probably the most important determinant of discordant growth in monochorionic twins (Lewi, 2013). Occasionally, monochorionic twins are discordant in size because they are discordant for structural anomalies.

Discordancy in dichorionic twins may result from various factors. Dizygotic fetuses may have
different genetic growth potential, especially if they are of opposite genders. Alternatively, because the placentas are separate and require more implantation space, one placenta might have a suboptimal implantation site. Bagchi and associates (2006) observed that the incidence of severe discordancy is twice as great in triplets as it is in twins. This finding lends credence to the view that in utero crowding is a factor in fetal-growth restriction. Placental pathology may play a role as well. Kent and coworkers (2012) evaluated placental abnormalities in 668 twin gestations. They observed a strong relationship between histological placental abnormalities and birthweight discordancy with associated growth restriction in dichorionic, but not monochorionic, twin pregnancies.

**Diagnosis**

Size discordancy between twins can be determined sonographically in several ways. One common method uses sonographic fetal biometry to compute an estimated weight for each twin (Chap. 10, p. 198). The weight of the smaller twin is then compared with that of the larger twin. Thus, percent discordancy = weight of larger twin minus weight of smaller twin, divided by weight of larger twin. Alternatively, considering that growth restriction is the primary concern and that abdominal circumference (AC) reflects fetal nutrition, some use the sonographic AC value of each twin. With these methods, some specify discordance if the AC measurements differ more than 20 mm or if the estimated fetal weight difference is 20 percent or more.

That said, several different weight disparities between twins have been used to define discordancy. Accumulated data suggest that weight discordancy greater than 25 to 30 percent most accurately predicts an adverse perinatal outcome. Hollier and coworkers (1999) retrospectively evaluated 1370 twin pairs delivered at Parkland Hospital and stratified twin weight discordancy in 5-percent increments within a range of 15 to 40 percent. They found that the incidence of respiratory distress, intraventricular hemorrhage, seizures, periventricular leukomalacia, sepsis, and necrotizing enterocolitis increased directly with the degree of weight discordancy. These conditions increased substantially if discordancy was greater than 25 percent. The relative risk of fetal death increased significantly to 5.6 if there was more than 30-percent discordancy. It increased to 18.9 if there was greater than 40-percent discordancy.

**Management**

Sonographic monitoring of growth within a twin pair and calculating discordancy has become a mainstay in management. Other sonographic findings, such as oligohydramnios, may be helpful in gauging fetal risk. Monochorionic twins are generally monitored more frequently. This is because their risk of death is higher—3.6 percent versus 1.1 percent—and the risk of neurological damage in the surviving twin is substantial compared with those risks in dichorionic twins (Hillman, 2011; Lee, 2008). Thorson and colleagues (2011) retrospectively analyzed 108 monochorionic twin pregnancies and found that a sonographic surveillance interval of greater than 2 weeks was associated with detection of higher-stage twin-twin transfusion syndrome. These findings have led some to recommend serial sonographic surveillance every 2 weeks in monochorionic twins (Simpson, 2013; Society for Maternal-Fetal Medicine, 2013). However, there have been no randomized trials of the optimal frequency of sonographic surveillance in monochorionic twin pregnancies. At Parkland Hospital, monochorionic twins undergo sonographic evaluation to assess interval growth every 4 weeks. Dichorionic twins are evaluated every 6 weeks. Depending on the degree of discordancy and the gestational age, fetal surveillance may be indicated, especially if
one or both fetuses exhibit restricted growth. Nonstress testing, biophysical profile scores, and umbilical artery Doppler assessment have all been recommended in the management of twins, but none have been evaluated in appropriately sized prospective trials (Miller, 2012).

The American College of Obstetricians and Gynecologists (2010) recommends that antepartum testing be performed in multifetal gestations for the same indications as in singleton fetuses (Chap 17, p. 345). At Parkland Hospital, all women with twin discordance of 25 percent or greater undergo daily monitoring as an inpatient. There are limited data to establish the optimal timing of delivery of twins. Delivery is usually not prompted by size discordancy alone, except occasionally at advanced gestational ages. The Royal College of Obstetricians and Gynecologists (2008) advocates delivery by 37 weeks’ gestation in monochorionic twins and by 38 weeks in dichorionic twins.

**FETAL DEMISE**

At any time during multifetal pregnancy, one or more fetuses may die, either simultaneously or sequentially. The causes and incidence of fetal death are related to zygosity, chorionicity, and growth concordance.

**Death of One Fetus**

In some pregnancies, one fetus dies remote from term, but pregnancy continues with one or more live fetuses. When this occurs early in pregnancy, it may manifest as a *vanishing twin* discussed on page 892. Fetal death in a slightly more advanced gestation may go undetected until delivery of a normal-appearing live infant along with a dead fetus that is barely identifiable. It may be compressed appreciably—*fetus compressus*, or it may be flattened remarkably through desiccation—*fetus papyraceus* (Fig. 45-25).
This fetus papyraceus is a tan ovoid mass compressed against the fetal membranes. Anatomical parts can be identified as marked. Demise of this twin had been noted during sonographic examination performed at 17 weeks’ gestation. Its viable cotwin delivered at 40 weeks. (Photograph contributed by Dr. Michael V. Zaretsky.)

In a review of 9822 Japanese twin pregnancies, Morikawa and associates (2012) reported that 2.5 percent of monochorionic diamnionic twins greater than 22 weeks’ gestation had a death of one or both twins compared with 1.2 percent of dichorionic twins. As shown in Figure 45-26, the risk of stillbirth is related to gestational age in all twins, but is much higher for monochorionic twin pregnancies before 32 weeks. In this same review, women with monochorionic diamnionic twins who lost one twin were 16 times more likely to experience death of the cotwin than women with dichorionic twins who lost one twin (Morikawa, 2012). Similarly, in their analysis of 1094 twin pregnancies, Mahony and associates (2011) identified a threefold increased risk of death of one or both fetuses in monochorionic twins compared with dichorionic pairs. Last, in their systematic review and metaanalyses, Hillman and colleagues (2011) concluded that after one twin dies, the odds of cotwin demise was five times higher in monochorionic twins compared with dichorionic twins experiencing the same fate. Analyses of 701 triplets identified mortality rates to be 2.1 percent, 3.2 percent, and 5.3 percent in trichorionic triamnionic, dichorionic triamnionic, and monochorionic triamnionic triplets, respectively (Kawaguchi, 2013).
Other factors that affect the prognosis for the surviving twin include gestational age at the time of the demise and duration between the demise and delivery of the surviving twin. With demise of the vanishing twin discussed earlier, after the first trimester, the risk of death is not increased for the survivor. However, when one fetus dies in the second trimester or later, the effect of gestational age at the time of death and the mortality risk to the cotwin is less clear. In the analysis by Hillman and colleagues (2011), cotwin demise rates were unaffected regardless of whether the first death occurred at 13 to 27 weeks or at 28 to 34 weeks. In cases with the death of one twin after the first trimester, however, the odds of spontaneous and iatrogenic preterm delivery of the remaining living twin were increased (Hillman, 2011). Preterm birth was five times more likely in monochorionic twin gestations complicated by demise of one twin between 28 and 33 weeks’ gestation. If the fetus died after 34 weeks, preterm delivery rates were similar.

The neurological prognosis for a surviving cotwin depends almost exclusively on chorionicity. In their comprehensive review, Ong and coworkers (2006) found an 18-percent rate of neurological abnormality in twins with monochorionic placentation compared with only 1 percent in those with dichorionic placentation. In another review, in twin pregnancies complicated by a single fetal demise before 34 weeks, a fivefold increased risk of neurodevelopmental morbidity was identified in monochorionic twins compared with dichorionic twins. If the one fetus died after 34 weeks, the likelihood of neurological deficits was essentially the same between monochorionic and dichorionic twin pregnancies (Hillman, 2011).

Later in gestation, the death of one of multiple fetuses could theoretically trigger coagulation defects in the mother. Only a few cases of maternal coagulopathy after a single fetal death in a twin pregnancy have been reported. This is probably because the surviving twin is usually delivered within a few weeks of the demise (Eddib, 2006). That said, we have observed transient, spontaneously corrected consumptive coagulopathy in multifetal gestations in which one fetus died and was retained in utero along with its surviving twin. The plasma fibrinogen concentration
initially decreased but then increased spontaneously, and the level of serum fibrinogen-fibrin degradation products increased initially but then returned to normal levels. At delivery, the portions of the placenta that supplied the living fetus appeared normal. In contrast, the part that had once provided for the dead fetus was the site of massive fibrin deposition. This is further discussed and illustrated in Chapter 41 (p. 811).

**Management**

Decisions should be based on gestational age, the cause of death, and the risk to the surviving fetus. As mentioned previously, if the loss occurs early in the first trimester, a vanishing twin is considered harmless to the survivor. If the loss occurs after the first trimester, the risk of death or damage to the survivor is largely limited to monochorionic twin gestations. Morbidity in the monochorionic twin survivor is almost always due to vascular anastomoses, which often cause the demise of one twin followed by sudden hypotension in the other. If one fetus of a monochorionic twin gestation dies after the first trimester but before viability, pregnancy termination can be considered (Blickstein, 2013). Occasionally, death of one but not all fetuses results from a maternal complication such as diabetic ketoacidosis or severe preeclampsia with abruption. Pregnancy management is based on the diagnosis and the status of both the mother and surviving fetus. If the death of one dichorionic twin is due to a discordant congenital anomaly, its death should not affect its surviving twin.

**Single fetal death during late second and early third trimester presents the greatest risk to the surviving twin.** Although the risks of subsequent death or neurological damage to the survivor are comparatively increased for monochorionic twins at this gestational age, the risk of preterm birth is equally increased in mono- and dichorionic twins (Ong, 2006). Delivery generally occurs within 3 weeks of diagnosis of fetal demise, thus antenatal corticosteroids for survivor lung maturity should be considered (Blickstein, 2013). Regardless, unless there is a hostile intrauterine environment, the goal should be to prolong pregnancy.

Timing of elective delivery after conservative management of a late second or early third trimester single fetal death is a matter of debate. Dichorionic twins can probably be safely delivered at term. Monochorionic twin gestations are more difficult to manage and are often delivered between 34 and 37 weeks’ gestation (Blickstein, 2013). In cases of single fetal death at term, especially when the etiology is unclear, most opt for delivery instead of expectant management.

**Impending Death of One Fetus**

Abnormal antepartum test results of fetal health in one twin fetus, but not the other, pose a particular dilemma. Delivery may be the best option for the compromised fetus yet may result in death from immaturity of the cotwin. If fetal lung maturity is confirmed, salvage of both the healthy fetus and its jeopardized sibling is possible. Unfortunately, ideal management if twins are immature is problematic but should be based on the chances of intact survival for both fetuses. Often the compromised fetus is severely growth restricted or anomalous. Thus, performing amniocentesis for fetal karyotyping in women of advanced maternal age carrying twin pregnancies is advantageous, even for those who would continue their pregnancies regardless of the diagnosis. Aneuploidy identification in one fetus allows rational decisions regarding interventions.
Primary goals of prenatal management of multifetal pregnancy are to provide close observation of the mother and her fetuses to prevent or interdict complications as they develop. A major imperative is to prevent preterm delivery of markedly immature neonates. At Parkland Hospital, women with multifetal gestations are seen every 2 weeks beginning at 22 weeks’ gestation, and a digital cervical examination is performed at each visit. Identification of other unique complications discussed above may also lead to interventions including early delivery. We routinely perform sonographic studies to assess fetal growth and amnionic fluid every 4 weeks in monochorionic twins or 6 weeks in dichorionic pairs.

### Diet

Along with more frequent prenatal visits, it must be ensured that the maternal diet provides additional requirements for calories, protein, minerals, vitamins, and essential fatty acids. Achievement of BMI-specific weight gain goals, supplementation with macro- and micronutrients to meet the increased needs associated with a twin gestation, and carbohydrate-controlled diets have been recommended (Goodnight, 2009). The Institute of Medicine guidelines for twin pregnancy recommend a 37- to 54-lb weight gain for women with a normal BMI. In their extensive review of the topic, Goodnight and Newman (2009) recommend supplementation of micronutrients such as calcium, magnesium, zinc, and vitamins C, D, and E based on upper intake levels from the Food and Nutrition Board of the Institute of Medicine. The daily recommended increased caloric intake for women with twins is 40 to 45 kcal/kg/d, composed of 20 percent protein, 40 percent carbohydrate, and 40 percent fat divided into three meals and three snacks daily.

### Surveillance of Fetal Growth and Health

Because a cornerstone of fetal assessment in twin pregnancy is identification of abnormal fetal growth or discordancy, serial sonographic examinations are usually performed throughout the third trimester. Assessment of amnionic fluid volume is also important. Associated oligohydramnios may indicate uteroplacental pathology and should prompt further evaluation of fetal well-being. That said, quantifying amnionic fluid volume in multifetal gestation is sometimes difficult. Some measure the deepest vertical pocket in each sac or assess the fluid subjectively. Measurement of the amnionic fluid index (AFI) may also be helpful. Using data from 488 diamnionic twins with birthweight between the 10th and 90th percentiles, Hill and associates (2000) described a protocol for measuring the AFI in twin gestations. Each amnionic sac was divided into quadrants that extended along a vertical, horizontal, or oblique axis. The deepest vertical pocket free of umbilical cord in each quadrant was measured. They found a slightly lower median value in twins than singletons. The AFI was highest at 26 to 28 weeks’ gestation and declined until delivery. Magann and coworkers (2000) compared subjective assessment and several objective methods of assessing amnionic fluid in 23 sets of twins. They found all methods to be equally poor in predicting abnormal volumes in diamnionic twins. At Parkland Hospital, the single deepest vertical pocket is measured in each sac. A measurement < 2 cm is considered oligohydramnios and a measurement ≥ 8 cm is considered hydramnios (Hernandez, 2012).

### Tests of Fetal Well-Being

As described throughout Chapter 17, there are several methods of assessing fetal health in singleton pregnancies. The nonstress test or biophysical profile is commonly used in management
of twin or higher-order multifetal gestations. Because of the complex complications associated with multifetal gestations and the potential technical difficulties in differentiating fetuses during antepartum testing, the usefulness of these methods appears limited. According to DeVoe (2008), the few exclusive studies of nonstress testing in twins suggest that the method performs the same as in singleton pregnancies. Elliott and Finberg (1995) used the biophysical profile as the primary method for monitoring higher-order multifetal gestations. They reported that four of 24 monitored pregnancies had a poor outcome despite reassuring biophysical profile scores. Although biophysical testing is commonly performed in multifetal gestations, there are insufficient data to determine its efficacy (DeVoe, 2008).

In an early study of 272 twin sets, Giles and colleagues (1990) reported that availability of umbilical artery Doppler velocimetry led to a reduced perinatal mortality rate. In a later randomized trial of 526 twin pregnancies by the same group, the addition of umbilical artery Doppler velocimetry to management compared with fetal testing based on fetal-growth parameters alone resulted in no perinatal outcome improvement (Giles, 2003). Hack and associates (2008) investigated the utility of umbilical artery Doppler velocimetry in 67 uncomplicated monochorionic twin gestations. They found similar mortality rates in those with abnormal pulsatility indices of the umbilical artery compared with those with normal indices. Differences in neonatal morbidity were explained by gestational age at delivery.

All testing schemes have high false-positive rates in singletons, and data suggest that testing in multifetal gestations performs no better. In cases of abnormal testing in one twin and normal results in another, iatrogenic preterm delivery remains a major concern.

**Pulmonary Maturation**

According to Robinson and coworkers (2012), beyond a strategy of planned delivery of uncomplicated monochorionic twins at 38 weeks, a secondary strategy is amniocentesis to verify pulmonary maturity before delivery between 36 and 38 weeks. In cases of complicated twin gestations, amniocentesis may be performed earlier. As measured by determination of the lecithin-sphingomyelin ratio, pulmonary maturation is usually synchronous in twins (Leveno, 1984). Moreover, although this ratio usually does not exceed 2.0 until 36 weeks in singleton pregnancies, it often exceeds this value by approximately 32 weeks in multifetal pregnancies. McElrath and colleagues (2000) reported similar increased values of surfactant in twins after 31 weeks’ gestation. In a comparison of respiratory morbidity in 100 twins and 241 singleton newborns delivered by cesarean before labor, Ghi and associates (2013) found less neonatal respiratory morbidity in twins, especially those delivered ≤ 37 weeks’ gestation. In some cases, however, pulmonary function may be markedly different, and the smallest, most stressed twin fetus is typically more mature.

**PRETERM BIRTH**

Preterm labor is common in multifetal pregnancies and may complicate up to 50 percent of twin, 75 percent of triplet, and 90 percent of quadruplet pregnancies (Elliott, 2007). The proportion of preterm births in multifetal gestations, however, varies widely. For example, the preterm birth rate is 42 percent in Ireland but is 68 percent in Austria (Giuffre, 2012). These differences likely reflect different clinical approaches to management. Several techniques have been applied in attempts to prolong these pregnancies. Methods include bed rest—especially through hospitalization, prophylactic administration of β-mimetic drugs or progestins, prophylactic...
Prediction of Preterm Birth

A major goal of multifetal pregnancy prenatal care is accurate prediction of women likely to experience preterm delivery, with prediction followed by prevention. This has been an elusive goal, but some advances have been made. Goldenberg and coworkers (1996) prospectively screened 147 twin pregnancies for more than 50 potential preterm birth risk factors. These investigators found that cervical length and fetal fibronectin concentration in the cervical canal were predictive of preterm birth (Chap. 42, p. 843). At 24 weeks, a cervical length ≤ 25 mm was the best predictor of birth before 32 weeks. At 28 weeks, an elevated fetal fibronectin level was the best predictor. Similarly, To and associates (2006) sonographically measured cervical length in 1163 twin pregnancies at 22 to 24 weeks. Rates of preterm delivery before 32 weeks were 66 percent in those with cervical lengths of 10 mm; 24 percent for lengths of 20 mm; 12 percent for 25 mm; and only 1 percent for 40 mm. McMahon and colleagues (2002) found that women with multifetal gestations at 24 weeks who had a closed internal os on digital cervical examination, a normal cervical length by sonographic examination, and a negative fetal fibronectin test result had a low risk to deliver before 32 weeks. Interestingly, a closed internal os by digital examination was as predictive of early delivery as the combination of normal sonographically measured cervical length and negative fetal fibronectin test results.

In a systematic review and metaanalysis of transvaginal cervical length for the prediction of preterm birth, Conde-Agudelo and coworkers (2010) concluded that cervical length between 20 and 24 weeks was a good predictor of spontaneous preterm birth in asymptomatic women with twin pregnancies. These authors found that a cervical length ≤ 20 mm was most accurate for predicting birth < 34 weeks, with a specificity of 97 percent and positive likelihood ratio of 9.0.

Prevention of Preterm Birth

Several schemes have been evaluated to prevent preterm labor and delivery. In recent years, some have been shown to decrease the risk of preterm delivery in small subgroups of singleton pregnancies. Unfortunately, most have been disappointingly ineffective.

Bed Rest

Most evidence suggests that routine hospitalization is not beneficial in prolonging multifetal pregnancy. In a metaanalysis of seven trials of hospitalization with bed rest, Crowther and Har (2010) concluded that the practice did not reduce the risk of preterm birth or perinatal mortality. Also at Parkland Hospital, elective hospitalization was compared with outpatient management, and no advantages were found (Andrews, 1991). Importantly, however, almost half of the women required admission for specific indications such as hypertension or threatened preterm delivery.

Limited physical activity, early work leave, more frequent health care visits and sonographic examinations, and structured maternal education regarding preterm delivery risks have been advocated to reduce preterm birth rates in women with multiple fetuses. Unfortunately, there is little evidence that these measures substantially change outcome.

Prophylactic Tocolysis

Tocolytic therapy in multifetal pregnancies has not been extensively studied. In a Cochrane review...
of five randomized trials of prophylactic oral β-mimetic therapy that included 374 twin pregnancies, Yamasmit and coworkers (2012) concluded that treatment did not reduce the rate of twins delivering before 37 or before 34 weeks. Especially in light of the recent Food and Drug Administration warning against the use of oral terbutaline, prophylactic use of β-mimetics in multifetal gestations seems especially unwarranted.

**Intramuscular Progesterone Therapy**

Although somewhat effective in reducing recurrent preterm birth in women with a singleton pregnancy, weekly injections of 17α-hydroxyprogesterone caproate (17-OHPC) are not effective for multifetal gestations (Caritis, 2009; Rouse, 2007). These results were corroborated in a more recent randomized trial in 240 twin pregnancies (Combs, 2011). Moreover, women carrying twins and identified with a cervical length < 36 mm (25th percentile) did not benefit despite their increased risk for preterm birth (Durnwald, 2010). Senat and colleagues (2013) randomly assigned 165 asymptomatic women with twins and a cervical length < 25 mm to 17-OHPC and also found no reduction in delivery before 37 weeks.

Caritis and associates (2012), in an evaluation of plasma drug concentrations in a Maternal-Fetal Medicine Units (MFMU) Network trial, reported that higher concentrations of 17-OHPC were associated with earlier gestational age at delivery. They concluded that 17-OHPC may adversely lower the gestational age at delivery in women with twin gestations. When taken together, administration of intramuscular 17-OHPC to women with twin pregnancies, even to those with a shortened cervix, does not lower the preterm birth risk.

**Vaginal Progesterone Therapy**

Micronized progesterone administered vaginally to women with twins is of uncertain benefit. Cetingoz and coworkers (2011) gave 100 mg of micronized progesterone intravaginally daily from 24 to 34 weeks. These authors reported that this practice reduced rates of delivery before 37 weeks from 79 to 51 percent in 67 women with twins. In contrast, several studies have failed to demonstrate any preterm birth rate reduction in women receiving various formulations of vaginal progesterone. Norman and colleagues (2009) randomly assigned 494 women with twins to 10 weeks of daily 90-mg intravaginal progesterone and failed to show reduced rates of delivery before 34 weeks. In the multicenter Prevention of Preterm Delivery in Twin Gestations (PREDICT) trial, Rode and associates (2011) randomly assigned 677 women with twins to receive prophylactic, 200-mg progesterone pessaries or placebo pessaries. These investigators also failed to demonstrate a reduction in delivery rates before 34 weeks. In a subgroup analysis of this trial that included only women with a short cervix or a history of prior preterm birth, Klein and associates (2011) also did not demonstrate a benefit. At Parkland Hospital, management of women with multifetal gestations does not typically include progesterone in any formulation.

**Cervical Cerclage**

Prophylactic cerclage has not been shown to improve perinatal outcome in women with multifetal pregnancies. Studies have included women who were not specially selected and those who were selected because of a shortened cervix that was identified sonographically (Dor, 1982; Elimian, 1999; Newman, 2002; Rebarber, 2005). In the latter group, cerclage may actually worsen outcomes (Berghella, 2005).

**Pessary**
A vaginal pessary that encircles and theoretically compresses the cervix, alters the inclination of the cervical canal, and relieves direct pressure on the internal cervical os has been proposed as an alternative to cerclage. The most popular is the silicone Arabin pessary. In a study of pessary use in women with a short cervix between 18 and 22 weeks, a subgroup analysis of 23 women with twins showed a significant reduction in the delivery rate before 32 weeks compared with the rate in 23 control pregnancies (Arabin, 2003). Liem and coworkers (2013) recently reported on the open-label Pessaries in Multiple Pregnancy as a Prevention of Preterm Birth (ProTWIN) trial completed at 40 centers throughout the Netherlands. These researchers randomized 813 unselected women with twins to receive either the Arabin pessary between 12 and 20 weeks or no treatment. The pessary failed to reduce preterm birth overall but did decrease delivery rates before 32 weeks in a subset of women with a cervical length < 38 mm—29 versus 14 percent. At this time, before such treatment can be recommended, beneficial effects of pessary use in women with a short cervix need to be confirmed.

### Treatment of Preterm Labor

Although many advocate their use, therapy with tocolytic agents to forestall preterm labor in multifetal pregnancy has not resulted in measurably improved neonatal outcomes (Chauhan, 2010; Gyetvai, 1999). They are similarly ineffective in singleton pregnancy as discussed in further detail in Chapter 42 (p. 851). Another caveat is that tocolytic therapy in women with a multifetal pregnancy entails higher risk than in singleton pregnancy. This is in part because of the augmented pregnancy-induced hypervolemia and its increased cardiac demands and susceptibility to iatrogenic pulmonary edema. Gabriel and colleagues (1994) compared outcomes of 26 twin and six triplet pregnancies with those of 51 singletons—all treated with a β-mimetic drug for preterm labor. Women with a multifetal gestation had significantly more cardiovascular complications—43 versus 4 percent—including three with pulmonary edema. In a recent retrospective analysis, Derbent and coworkers (2011) evaluated nifedipine tocolysis in 58 singleton and 32 twin pregnancies. These authors reported higher incidences of side effects such as maternal tachycardia in women with twins—19 versus 9 percent.

### Glucocorticoids for Lung Maturation

Administration of corticosteroids to stimulate fetal lung maturation has not been well studied in multifetal gestation. However, these drugs logically should be as beneficial for multiples as they are for singletons (Roberts, 2006). Battista and colleagues (2008) compared the efficacy of betamethasone therapy in 60 preterm twin pregnancies to 60 preterm singleton pregnancies. These researchers found no differences in neonatal morbidity, including respiratory distress. Moreover, Gyamfi and associates (2010) evaluated betamethasone concentrations in maternal and umbilical cord blood in 30 singleton and 15 twin pregnancies receiving weekly antenatal corticosteroids. They found no differences in levels between twins and singletons. These treatments are discussed in Chapter 42 (p. 850). At this time, guidelines for the use of these agents are not different from those for singleton gestations (American College of Obstetricians and Gynecologists, 2010).

### Preterm Premature Membrane Rupture

The frequency of preterm premature rupture of membranes (PPROM) increases with increasing plurality. In a population-based retrospective cohort study of more than 290,000 live births in
Ohio, Pakrashi and coworkers (2013) reported the proportion of preterm birth complicated by premature rupture was 13.2 percent in singletons. This rate was compared with 17, 20, 20, and 100 percent in twins, triplets, quadruplets, and higher-order multiples, respectively. Multifetal gestations with PPROM are managed expectantly much like singleton pregnancies (Chap. 42, p. 846). Ehsanipoor and colleagues (2012) compared outcomes of 41 twin and 82 singleton pregnancies, both with ruptured membranes between 24 and 32 weeks. They found the median latency was overall shorter for twins—3.6 days compared with 6.2 days for singletons. This difference was significant in pregnancies after 30 weeks—1.7 days and 6.9 days. Importantly, latency beyond 7 days approximated 40 percent in both groups.

### Delayed Delivery of Second Twin

Infrequently, after preterm birth of the presenting fetus, it may be advantageous for undelivered fetus(es) to remain in utero. Trivedi and Gillett (1998) reviewed the English literature and described 45 case reports of asynchronous birth in multifetal gestation. Although likely biased, those pregnancies with a surviving retained twin or triplet continued for an average of 49 days. No advantage was gained by management with tocolytics, prophylactic antimicrobials, or cerclage. In their 10-year experience, Roman and associates (2010) reported a median latency of 16 days in 13 twin and five triplet pregnancies with delivery of the first fetus between 20 and 25 weeks. Survival of the firstborn infant was 16 percent. Although 54 percent of the retained fetuses survived, only 37 percent of survivors did so without major morbidity. Livingston and coworkers (2004) described 14 pregnancies in which an active attempt was made to delay delivery of 19 fetuses after delivery of the first neonate. Only one fetus survived without major sequelae, and one mother developed sepsis syndrome with shock. Arabin and van Eyck (2009) reported better outcomes in a few of the 93 twin and 34 triplet pregnancies that qualified for delayed delivery in their center during a 17-year period.

If asynchronous birth is attempted, there must be careful evaluation for infection, abruption, and congenital anomalies. The mother must be thoroughly counseled, particularly regarding the potential for serious, life-threatening infection. The range of gestational age in which the benefits outweigh the risks for delayed delivery is likely narrow. Avoidance of delivery from 23 to 26 weeks would seem most beneficial. In our experience, good candidates for delayed delivery are rare.

### LABOR AND DELIVERY

There is a litany of complications that may be encountered during labor and delivery of multiple fetuses. In addition to preterm labor and delivery as already discussed, there are increased rates of uterine contractile dysfunction, abnormal fetal presentation, umbilical cord prolapse, placenta previa, placental abruption, emergent operative delivery, and postpartum hemorrhage from uterine atony. All of these must be anticipated and thus certain precautions and special arrangements are prudent. These should include:

1. An appropriately trained obstetrical attendant should remain with the mother throughout labor. Continuous external electronic monitoring is preferable. If membranes are ruptured and the cervix dilated, the presenting fetus is monitored internally.
2. An intravenous infusion system capable of delivering fluid rapidly is established. In the
absence of hemorrhage, lactated Ringer or an aqueous dextrose solution is infused at a rate of 60 to 125 mL/hr.

3. Blood for transfusion is readily available if needed.
4. An obstetrician skilled in intrauterine identification of fetal parts and in intrauterine manipulation of a fetus should be present.
5. A sonography machine is readily available to evaluate the presentation and position of the fetuses during labor and to image the remaining fetus(es) after delivery of the first.
6. An anesthesia team is immediately available in the event that emergent cesarean delivery is necessary or that intrauterine manipulation is required for vaginal delivery.
7. For each fetus, at least one attendant who is skilled in resuscitation and care of newborns and who has been appropriately informed of the case should be immediately available.
8. The delivery area should provide adequate space for the nursing, obstetrical, anesthesia, and pediatric team members to work effectively. Equipment must be on site to provide emergent anesthesia, operative intervention, and maternal and neonatal resuscitation.

**Evaluation upon Admission**

**Fetal Presentation**

In addition to the standard preparations for the conduct of labor and delivery discussed in Chapter 22, there are special considerations for women with a multifetal pregnancy. First, the positions and presentations of fetuses are best confirmed sonographically (American College of Obstetricians and Gynecologists, 2011). Although any possible combination of positions may be encountered, those most common at admission for delivery are cephalic-cephalic, cephalic-breech, and cephalic-transverse. At Parkland Hospital between 2008 and 2013, 71 percent of twin pregnancies had cephalic presentation of the first fetus at the time of admission to labor and delivery. Importantly, with perhaps the exception of cephalic-cephalic presentations, these are all unstable before and during labor and delivery. Accordingly, compound, face, brow, and footling breech presentations are relatively common, and even more so if fetuses are small, amniotic fluid is excessive, or maternal parity is high. Cord prolapse is also frequent in these circumstances.

After this initial evaluation, if active labor is confirmed, then a decision is made to attempt vaginal delivery or to proceed with cesarean delivery. The latter is chosen in many cases because of fetal presentations. Cephalic presentation of the first fetus in a laboring woman with twins may be considered for expectant management. Of the 547 women who presented like this at Parkland Hospital during 5 years, 32 percent delivered spontaneously. Nevertheless, the overall cesarean delivery rate in twin pregnancies during those years was 77 percent. Notably, 5 percent of cesareans performed were for emergent delivery of the second twin following vaginal delivery of the first twin. The desire to avoid this obstetrical dilemma has contributed to the increasing cesarean delivery rate in twin pregnancies across the United States (Antsaklis, 2013; Lee, 2011).

**Labor Induction or Stimulation**

According to a comparison of 891 twins with more than 100,000 singleton pregnancies included in the Consortium of Safe Labor, Leftwich and colleagues (2013) concluded that both nulliparas and multiparas with twins had slower progression of active labor. Women with twins required between 1 and 3 additional hours to complete first-stage labor. This was despite equivalent rates of labor induction or augmentation. Provided women with twins meet all criteria for oxytocin administration, it may be used as described in Chapter 26 (p. 529). Wolfe and associates (2013)
evaluated the success of labor induction in 40 sets of twins compared with 80 singletons and found that protocols for oxytocin alone or in combination with cervical ripening can safely be used in twin gestations. Taylor and coworkers (2012) reported that 100 women with twins undergoing labor induction had similar labor lengths and cesarean delivery rates compared with those of 100 matched women with singleton pregnancies. Still, in an analysis of twin births in the United States between 1995 and 2008, Lee and colleagues (2011) reported that induction rates of twin pregnancies has decreased from a maximum of 13.8 percent in 1999 to 9.9 percent in 2008.

### Analgesia and Anesthesia

During labor and delivery of multiple fetuses, decisions regarding analgesia and anesthesia may be complicated by problems imposed by preterm labor, preeclampsia, desultory labor, need for intrauterine manipulation, and postpartum uterine atony and hemorrhage.

Labor epidural analgesia is ideal because it provides excellent pain relief and can be rapidly extended cephalad if internal podalic version or cesarean delivery is required. There are special considerations for women with severe preeclampsia or with hemorrhage as discussed in their respective chapters. Because of these eventualities, most recommend that continuous epidural analgesia be performed by anesthesia personnel with special expertise in obstetrics.

If general anesthesia becomes necessary for intrauterine manipulation, then uterine relaxation can be accomplished rapidly with one of the halogenated inhalation agents discussed in Chapter 25 (p. 519). Some clinicians use intravenous or sublingual nitroglycerin to achieve uterine relaxation yet avoid the aspiration and hypoxia risks associated with general anesthetics.

### Delivery Route

Regardless of fetal presentation during labor, there must be a readiness to deal with any change of fetal position during delivery and especially following delivery of the first twin. If the first fetus is nonvertex, cesarean delivery is typically performed, whereas cephalic-cephalic twins are commonly considered for vaginal delivery (Peaceman, 2009; Rossi, 2011). Importantly, when comparing neonatal outcomes among all these options, second twins at term as a group have worse composite neonatal outcomes than those of their cotwin regardless of delivery method (Smith, 2007; Thorngren-Jerneck, 2001).

#### Cephalic-Cephalic Presentation

If the first twin presents cephalic, delivery can usually be accomplished spontaneously or with forceps. According to D’Alton (2010), there is general consensus that a trial of labor is reasonable in women with cephalic-cephalic twins. Hogle and associates (2003) performed an extensive literature review and concluded that planned cesarean delivery does not improve neonatal outcome when both twins are cephalic. The recent randomized trial by Barrett and coworkers (2013) affirms this conclusion. Muleba and colleagues (2005) identified increased rates of respiratory distress in the second twin of preterm pairs regardless of delivery mode or corticosteroid use.

#### Cephalic-Noncephalic Presentation

The optimal delivery route for cephalic–noncephalic twin pairs remains controversial (D’Alton, 2010). Patient selection is crucial, and options include cesarean delivery of both twins, or less
commonly, vaginal delivery with intrapartum external cephalic version of the second twin. Longer intertwin delivery time has been shown in some studies to be associated with poorer second twin outcome (Edris, 2006; Stein, 2008). Thus, breech extraction may be preferable to version. Least desirable, vaginal delivery of the first but cesarean delivery of the second twin may be required due to intrapartum complications such as umbilical cord prolapse, placental abruption, contracting cervix, and fetal distress. Most, but not all, studies show the worst composite fetal outcomes for this scenario (Alexander, 2008; Rossi, 2011; Wen, 2004).

Several reports attest to the safety of vaginal delivery of second noncephalic twins whose birthweight is > 1500 g. Recently, Fox and associates (2014) reported outcomes of 287 diamnionic twin pregnancies between 2005 and 2009. Cesarean delivery was routinely performed for all women with a noncephalic presenting twin fetus, a noncephalic second twin weighing < 1500 g, or a second twin estimated to be 20 percent larger than the presenting twin. All others without contraindications to labor were offered a vaginal delivery and were treated using a strict protocol of second-stage labor management. This included vaginal delivery of a second cephalic twin, breech extraction of a second noncephalic twin, and internal podalic version of an unengaged cephalic second twin followed by breech extraction. Of the 130 who planned a vaginal delivery, only 15 percent underwent cesarean delivery. There was no difference in the rate of 5-minute Apgar score < 7 or of umbilical arterial pH < 7.20 in second twins. The data are less informative concerning vaginal delivery of a second twin whose estimated fetal weight is < 1500 g. That said, however, comparable or even better fetal outcomes with vaginal delivery have been reported with these smaller infants compared with those who weigh > 1500 g (Caukwell, 2002; Davidson, 1992; Rydhström, 1990).

Other investigators advocate cesarean delivery for both members of a cephalic-noncephalic twin pair (Armson, 2006; Hoffmann, 2012). Yang and coworkers (2005a,b) studied 15,185 cephalic-noncephalic twin pairs. The risk of asphyxia-related neonatal deaths and morbidity was increased in the group in which both twins were delivered vaginally compared with the group in which both twins underwent cesarean delivery.

**Randomized Trial of Planned Cesarean versus Vaginal Delivery.** To add insight into the clinical complexities discussed above, a randomized trial was designed by the Twin Birth Study Collaborative Group from Canada. The study results described by Barrett and colleagues (2013) included 2804 women carrying a presumed diamnionic twin pregnancy with the first fetus presenting cephalic. Women were randomly assigned between 32 and 38 weeks to planned cesarean or vaginal delivery. The time from randomization to delivery—12.4 versus 13.3 days, the mean gestational age at delivery—36.7 versus 36.8 weeks, and use of regional analgesia—92 versus 87 percent was similar in both groups. Salient maternal and perinatal outcomes are shown in Table 45-4. No significant differences in outcomes were noted between the two groups of women. Although there were no increased risks to mother or fetuses with planned vaginal delivery in these circumstances, we agree with Greene (2013) that this trial will moderately affect the cesarean delivery rate of women with twins.

Breech Presentation of First Twin

Problems with the first twin presenting as a breech are similar to those encountered with a singleton breech fetus. Thus, major problems may develop if:

1. The fetus is unusually large, and the aftercoming head is larger than the birth canal.
2. The fetal body is small, and delivery of the extremities and trunk through an inadequately effaced and dilated cervix causes the relatively larger head to become trapped above the cervix. This is more likely when there is disproportion between the fetal buttocks or trunk and the head. This may be seen with preterm or growth-restricted fetuses or with a macrocephalic fetus due to hydrocephaly.
3. The umbilical cord prolapses.

If these problems are anticipated or identified, cesarean delivery is often preferred with a viable-size fetus. But even without these problems, many obstetricians perform cesarean delivery if the first twin presents as breech. This is despite data that support the safety of vaginal delivery.

Breech Presentation of First Twin

Problems with the first twin presenting as a breech are similar to those encountered with a singleton breech fetus. Thus, major problems may develop if:

1. The fetus is unusually large, and the aftercoming head is larger than the birth canal.
2. The fetal body is small, and delivery of the extremities and trunk through an inadequately effaced and dilated cervix causes the relatively larger head to become trapped above the cervix. This is more likely when there is disproportion between the fetal buttocks or trunk and the head. This may be seen with preterm or growth-restricted fetuses or with a macrocephalic fetus due to hydrocephaly.
3. The umbilical cord prolapses.

If these problems are anticipated or identified, cesarean delivery is often preferred with a viable-size fetus. But even without these problems, many obstetricians perform cesarean delivery if the first twin presents as breech. This is despite data that support the safety of vaginal delivery.
Specifically, Blickstein and associates (2000) reported experiences from 13 European centers with 613 twin pairs and the first twin presenting breech. Vaginal delivery was attempted in 373 of these cases and was successful in 64 percent. Cesarean delivery of the second twin was done in 2.4 percent. There was no difference in the rate of 5-minute Apgar score < 7 or of mortality in breech-presenting first twins who weighed at least 1500 g. Details of techniques for delivery of a breech presentation are described in Chapter 28 (p. 563).

Locked Twins. For twin fetuses to become locked together during delivery, the first must present as breech and the second as cephalic. As the breech of the first twin descends through the birth canal, the chin locks between the neck and chin of the second cephalic-presenting cotwin. This phenomenon is rare, and Cohen and coworkers (1965) described it only once in 817 twin gestations. Cesarean delivery should be considered when the potential for locking is identified.

Vaginal Delivery of the Second Twin

Following delivery of the first twin, the presenting part of the second twin, its size, and its relationship to the birth canal should be quickly and carefully ascertained by combined abdominal, vaginal, and at times, intrauterine examination. Sonography may be a valuable aid. If the fetal head or the breech is fixed in the birth canal, moderate fundal pressure is applied and membranes are ruptured. Immediately afterward, digital examination of the cervix is repeated to exclude cord prolapse. Labor is allowed to resume. If contractions do not begin within approximately 10 minutes, dilute oxytocin may be used to stimulate contractions.

In the past, the safest interval between delivery of the first and second twins was frequently cited as less than 30 minutes. Rayburn and colleagues (1984), and others, have shown that if continuous fetal monitoring is used, a good outcome is achieved even if this interval is longer. Several investigators have demonstrated a direct correlation between worsening umbilical cord blood gas values and increasing time between delivery of first and second twins (Leung, 2002; Stein, 2008). Gourheux and associates (2007) retrospectively reviewed delivery intervals in 239 twin gestations in France and determined that mean umbilical arterial pH was significantly lower after the interval exceeded 15 minutes. Thus, vigilant monitoring for nonreassuring fetal heart rate or bleeding is required. Hemorrhage may indicate clinically significant placental abruption.

If the occiput or breech presents immediately over the pelvic inlet, but is not fixed in the birth canal, the presenting part can often be guided into the pelvis by one hand in the vagina, while a second hand on the uterine fundus exerts moderate pressure caudally. Alternatively, with abdominal manipulation, an assistant can guide the presenting part into the pelvis. Sonography can aid guidance and allow heart rate monitoring. Intrapartum external version of a noncephalic second twin has also been described.

A presenting shoulder may be gently converted into a cephalic presentation. If the occiput or breech is not over the pelvic inlet and cannot be so positioned by gentle pressure or if appreciable uterine bleeding develops, delivery of the second twin can be problematic.

To obtain a favorable outcome, it is essential to have an obstetrician skilled in intrauterine fetal manipulation and anesthesia personnel skilled in providing anesthesia to effectively relax the uterus for vaginal delivery of a noncephalic second twin (American College of Obstetricians and Gynecologists, 2010). To take maximum advantage of the dilated cervix before the uterus contracts and the cervix retracts, delay must be avoided. Prompt cesarean delivery of the second fetus is preferred if no one present is skilled in the performance of internal podalic version or if anesthesia that will provide effective uterine relaxation is not immediately available.
Internal Podalic Version
With this maneuver, a fetus is turned to a breech presentation using the hand placed into the uterus (Fig. 45-27). The obstetrician grasps the fetal feet to then effect delivery by breech extraction. As mentioned earlier, Fox and colleagues (2010) described a strict protocol for management of the delivery of the second twin, which included internal podalic version. They reported that none of the 110 women who delivered the first twin vaginally underwent a cesarean delivery for the second twin. Chauhan and coworkers (1995) compared outcomes of 23 second twins delivered by podalic version and breech extraction with those of 21 who underwent external cephalic version. Breech extraction was considered superior to external version because less fetal distress developed. The technique of breech extraction is described in Chapter 28 (p. 567).

FIGURE 45-27 Internal podalic version. Upward pressure on the head by an abdominal hand is applied as downward traction is exerted on the feet.

Vaginal Birth after Cesarean Delivery
Any attempt to deliver twins vaginally in a woman who has previously undergone one or more cesarean deliveries should be carefully considered. As discussed in Chapter 31 (p. 614), some studies support the safety of attempting a vaginal birth after cesarean delivery (VBAC) for selected women with twins (Cahill, 2005; Ford, 2006; Varner, 2005). According to the American College of Obstetricians and Gynecologists (2013b), there currently is no evidence of an increased risk of uterine rupture, and women with twins and one previous cesarean delivery with a low transverse incision may be considered candidates for trial of labor. At Parkland Hospital, such women are generally offered repeat cesarean delivery.
There are several unusual intraoperative problems that can arise during cesarean delivery of twins or higher-order multiples. Supine hypotension is common, and thus these women should be positioned in a left lateral tilt to deflect uterine weight off the aorta (Chap. 4, p. 60). A low-transverse hysterotomy is preferable if the incision can be made large enough to allow atraumatic delivery of both fetuses. Piper forceps can be used if the second twin is presenting breech (Fig. 28-13, p. 568). In some cases, a vertical hysterotomy beginning as low as possible in the lower uterine segment may be advantageous. For example, if a fetus is transverse with its back down and the arms are inadvertently delivered first, it is much easier and safer to extend a vertical uterine incision upward than to extend a transverse incision laterally or to make a “T” incision vertically.

Cesarean Delivery of the Second Twin

It is not uncommon for cesarean delivery to become necessary for delivery of a second twin after the first has been delivered vaginally. As described earlier, this occurred in 32 of 770 women with twins at Parkland Hospital between 2008 and 2013. In these cases, prompt cesarean delivery is required and is frequently emergently indicated. Indications most often cited are a second fetus that is much larger than the first and is presenting breech or transverse. In other cases, the cervix promptly contracts and thickens after delivery of the first twin. This may be followed by a nonreassuring fetal status or by a cervix that fails to completely dilate again despite adequate uterine contractions.

TRIPLET OR HIGHER-ORDER GESTATION

Fetal heart rate monitoring during labor with triplet pregnancies is challenging. A scalp electrode can be attached to the presenting fetus, but it is difficult to ensure that the other two fetuses are each being monitored separately. With vaginal delivery, the first neonate is usually born with little or no manipulation. Subsequent fetuses, however, are delivered according to the presenting part. This often requires complicated obstetrical maneuvers such as total breech extraction with or without internal podalic version or even cesarean delivery. Associated with malposition of fetuses is an increased incidence of cord prolapse. Moreover, reduced placental perfusion and hemorrhage from separating placentas are more likely during delivery.

For all these reasons, many clinicians believe that pregnancies complicated by three or more fetuses are best delivered by cesarean. Vaginal delivery is reserved for those circumstances in which survival is not expected because fetuses are markedly immature or maternal complications make cesarean delivery hazardous to the mother. Others believe that vaginal delivery is safe under certain circumstances. For example, Alamia and colleagues (1998) evaluated a protocol for vaginal delivery of triplet pregnancies in which the presenting fetus was cephalic. A total of 23 sets of triplets were analyzed, and a third of these were delivered vaginally. Neonatal outcomes were the same in the vaginal and cesarean delivery groups, with no morbidity and 100-percent fetal survival. Grobman and associates (1998) and Alran and coworkers (2004) reported vaginal delivery completion rates of 88 and 84 percent, respectively, in women carrying triplets who underwent a trial of labor. Neonatal outcomes did not differ from those of a matched group of triplet pregnancies delivered by elective cesarean. Conversely, Vintzeleos and colleagues (2005) reviewed more than 7000 triplet pregnancies and found that vaginal delivery was associated with an increased perinatal mortality rate. Importantly, the overall cesarean delivery rate among triplets...
was 95 percent. At Parkland Hospital, triplet gestations are routinely delivered by cesarean.

## SELECTIVE REDUCTION OR TERMINATION

In some cases of higher-order multifetal gestation, reduction of the fetal number to two or three improves survival of the remaining fetuses. *Selective reduction* implies early pregnancy intervention, whereas *selective termination* is performed later.

### Selective Reduction

Reduction of a selected fetus or fetuses in a multichorionic multifetal gestation may be chosen as a therapeutic intervention to enhance survival of the remaining fetuses (American College of Obstetricians and Gynecologists, 2013a). There are no randomized controlled trials on the effects of such reduction. However, a metaanalysis of nonrandomized prospective studies indicates that pregnancy reduction to twins compared with expectant management is associated with lower rates of maternal complications, preterm birth, and neonatal death (Dodd, 2004, 2012). Pregnancy reduction can be performed transcervically, transvaginally, or transabdominally, but the transabdominal route is usually easiest.

Transabdominal fetal reductions are typically performed between 10 and 13 weeks. This gestational age is chosen because most spontaneous abortions have already occurred, the remaining fetuses are large enough to be evaluated sonographically, the amount of devitalized fetal tissue remaining after the procedure is small, and the risk of aborting the entire pregnancy as a result of the procedure is low. The smallest fetuses and any anomalous fetuses are chosen for reduction. Potassium chloride is then injected under sonographic guidance into the heart or thorax of each selected fetus. Care is used to not enter or traverse the sacs of fetuses selected for retention. In most cases, pregnancies are reduced to twins to increase the chances of delivering at least one viable fetus.

Evans and associates (2005) reported continued improvement in fetal outcomes with this procedure. They analyzed more than 1000 pregnancies managed in 11 centers from 1995 to 1998. The pregnancy loss rate varied from a low of 4.5 percent for triplets who were reduced to twins. The loss rate increased with each addition to the starting number of fetuses and peaked at 15 percent for six or more fetuses (Evans, 2001). Operator skill and experience are believed responsible for the low and declining rates of pregnancy loss.

### Selective Termination

With the identification of multiple fetuses discordant for structural or genetic abnormalities, three options are available: abortion of all fetuses, selective termination of the abnormal fetus, or pregnancy continuation. Because anomalies are typically not discovered until the second trimester, selective termination is performed later in gestation than selective reduction and entails greater risk. This procedure is therefore usually not performed unless the anomaly is severe but not lethal. Thus, a triplet pregnancy in which one fetus has Down syndrome might be a candidate for selective termination, whereas a twin pregnancy in which one fetus has trisomy 18 might not. In some cases, termination is considered because the abnormal fetus may jeopardize the normal one. For example, pathological hydramnios in a twin with esophageal atresia could lead to preterm birth of its...
Prerequisites to selective termination include a precise diagnosis for the anomalous fetus and absolute certainty of fetal location. Thus, if genetic amniocentesis is performed on a multifetal gestation, a map of the uterus with locations of all the fetuses clearly labeled should be made at the time of the diagnostic procedure. Unless a special procedure such as umbilical cord interruption is used, selective termination should be performed only in multichorionic multifetal gestations to avoid damaging the surviving fetuses (Lewi, 2006). Roman and coworkers (2010) compared 40 cases of bipolar umbilical cord coagulation with 20 cases of radiofrequency ablation for treatment of complicated monochorionic multifetal gestations at midpregnancy. They found similar survival rates of 87 and 88 percent, and a median gestational age > 36 weeks at delivery in both. Prefumo and colleagues (2013) reported their preliminary experience with microwave ablation of the umbilical cord for selective termination in two monochorionic twin pregnancies. One pregnancy aborted within 7 days, and the other resulted in a term singleton delivered at 39 weeks’ gestation.

Evans and coworkers (1999) have provided the most comprehensive results to date on second-trimester selective termination for fetal abnormalities. A total of 402 cases were analyzed from eight centers worldwide. Included were 345 twin, 39 triplet, and 18 quadruplet pregnancies. Selective termination using potassium chloride resulted in delivery of a viable neonate or neonates in more than 90 percent of cases, with a mean age of 35.7 weeks at delivery. The entire pregnancy was lost in 7.1 percent of pregnancies reduced to singletons and in 13 percent of those reduced to twins. The gestational age at the time of the procedure did not appear to affect the pregnancy loss rate. Several losses occurred because the pregnancy was actually monochorionic, and potassium chloride also killed the normal fetus through placental vascular anastomoses.

**Ethics**

The ethical issues associated with these techniques are almost limitless. There is a beneficence-based justification for offering selective termination in cases in which continuation of the pregnancy poses a threat to the life of coexistent fetuses. The final decision to continue the pregnancy without intervention, to terminate the entire pregnancy, or to elect selective termination is solely the patient’s (Chervenak, 2013). The interested reader is referred to the excellent reviews by Evans and coworkers (1996, 2004) and Simpson and Carson (1996).

**Informed Consent**

Before selective termination or reduction, a discussion should include the morbidity and mortality rates expected if the pregnancy is continued; the morbidity and mortality rates expected with surviving twins or triplets; and the risks of the procedure itself.

With couples seeking infertility treatment, the issue of selective reduction should ideally be discussed before conception. Grobman and associates (2001) reported that these couples were generally unaware of the risks associated with multifetal gestation, and they were less desirous of having a multifetal gestation once apprised of the risks.

Specific risks that are common to selective termination or reduction include:

1. Abortion of the remaining fetuses
2. Abortion of the wrong (normal) fetus(es)
3. Retention of genetic or structurally abnormal fetuses after a reduction in number
4. Damage without death to a fetus
5. Preterm labor
6. Discordant or growth-restricted fetuses
7. Maternal infection, hemorrhage, or possible disseminated intravascular coagulopathy because of retained products of conception.

The procedure should be performed by an operator skilled and experienced in sonographically guided procedures.

Psychological Reaction

Women and their spouses who elect to undergo selective termination or reduction find this decision highly stressful. Schreiner-Engel and colleagues (1995) retrospectively studied the emotional reactions of 100 women following selective reduction. Although 70 percent of the women mourned for their dead fetus(es), most grieved only for 1 month. Persistent depressive symptoms were mild, although moderately severe sadness and guilt continued for many of them. Fortunately, most were reconciled to the termination of some fetuses to preserve the lives of a remaining few. Indeed, 93 percent of the women would have made the same decision again.

Never penalize a woman because she is pregnant. Pregnant women are susceptible to any of the medical and surgical disorders that can affect childbearing-aged women. Some of these, especially those that are chronic, more often precede pregnancy. But, they as well as others can acutely complicate an otherwise normal pregnancy. It is difficult to accurately quantify nonobstetrical disorders that complicate pregnancy, however, some estimates can be made. For example, one managed-care population had an overall antenatal hospitalization rate of 10.1 per 100 deliveries (Gazmararian, 2002). Of these, approximately a third were for nonobstetrical conditions that included renal, pulmonary, and infectious diseases. In another study from the 2002 Nationwide Inpatient Sample, the injury hospitalization rate was found to be 4.1 women per 1000 deliveries (Kuo, 2007). Approximately 1 in every 635 pregnant women will undergo a nonobstetrical surgical procedure (Corneille, 2010; Kizer, 2011).

Many of these nonobstetrical disorders are within the purview of the obstetrician. Some, however, will warrant consultation, and still others require a multidisciplinary team. The latter may include maternal-fetal medicine specialists, internists and medical subspecialists, surgeons, anesthesiologists, and numerous other disciplines (American College of Obstetricians and Gynecologists, 2013). In these latter situations, obstetricians should have a working knowledge of
the wide range of medical disorders common to childbearing-aged women. At the same time, nonobstetricians who help care for these women and their unborn fetuses should be familiar with pregnancy-induced physiological changes and special fetal considerations. Many of these normal pregnancy perturbations have clinically significant effects on various diseases and cause seemingly aberrant changes in routine laboratory values.

It should be axiomatic that a woman should never be penalized because she is pregnant. To ensure this, a number of questions should be addressed:

• What management plan would be recommended if the woman was not pregnant?
• If the proposed management is different because the woman is pregnant, can this be justified?
• What are the risks versus benefits to the mother and her fetus, and are they counter to each other?
• Can an individualized management plan be devised that balances the benefits versus risks of any alterations?

Such an approach should allow individualization of care for women with most medical and surgical disorders complicating pregnancy. Moreover, it may be especially helpful for consideration by nonobstetrical consultants.

MATERNAL PHYSIOLOGY AND LABORATORY VALUES

Pregnancy induces physiological changes in virtually all organ systems. Some are profound and may amplify or obfuscate evaluation of coexisting conditions. Coincidentally, results of numerous laboratory tests are altered, and some values would, in the nonpregnant woman, be considered abnormal. Conversely, some may appear to be within a normal range but are decidedly abnormal for the pregnant woman. The wide range of pregnancy effects on normal physiology and laboratory values are discussed in the chapters that follow as well as throughout Chapter 4 and the Appendix.

MEDICATIONS DURING PREGNANCY

It is indeed fortunate that most medications necessary to treat the most frequently encountered illnesses complicating pregnancy can be given with relative safety. That said, there are notable exceptions, which are considered in Chapter 12.

SURGICAL PROCEDURES DURING PREGNANCY

The risk of an adverse pregnancy outcome is not appreciably increased in most women who undergo an uncomplicated surgical procedure. With complications, however, risks likely will be increased. For example, perforative appendicitis with feculent peritonitis has significant maternal and perinatal morbidity and mortality rates even if surgical and anesthetic techniques are flawless. Conversely, procedure-related complications may adversely affect outcomes. For example, a woman who has uncomplicated removal of an inflamed appendix may suffer aspiration of acidic gastric contents at the time of tracheal intubation or extubation. Still, compared with nonpregnant women undergoing similar procedures, pregnant women do not appear to have excessive
Effect of Surgery and Anesthesia on Pregnancy Outcome

The most extensive data regarding anesthetic and surgical risks to pregnancy are from the Swedish Birth Registry as described by Mazze and Källén (1989). The effects on pregnancy outcomes of 5405 nonobstetrical surgical procedures performed in 720,000 pregnant women from 1973 to 1981 were analyzed. General anesthesia was used for approximately half of these procedures and commonly involved nitrous oxide supplemented by another inhalation agent or intravenous medications. These procedures were performed in 41 percent of women in the first trimester, 35 percent in the second, and 24 percent in the third. The distribution by the type of procedure is shown in Figure 46-1. Overall, 25 percent were abdominal operations and 20 percent were gynecological or urological procedures. Laparoscopy was the most frequently performed operation, and appendectomy was the most common second-trimester procedure.

![Figure 46-1](image)

**FIGURE 46-1** Proportions of surgical procedures by trimester in 3615 women. (Data from Mazze, 1989.)

Perinatal Outcomes

Excessive perinatal morbidity associated with nonobstetrical surgery is attributable in many cases
to the disease itself rather than to adverse effects of surgery and anesthesia. The Swedish Birth Registry again provides valuable data as shown in Table 46-1 (Mazze, 1989). The incidence of neonates with congenital malformations or those stillborn was not significantly different from that of nonexposed control newborns. There were, however, significantly increased incidences of low birthweight, preterm birth, and neonatal death in infants born to women who had undergone surgery. Increased neonatal deaths were largely due to preterm birth. These investigators concluded that these adverse outcomes likely were due to a synergistic effect of the illness in concert with the surgical procedures. In another study, there was an increased preterm delivery rate in 235 women undergoing adnexal mass surgery (Hong, 2006).

NS = not significant.

Data from Mazze, 1989.

In a follow-up study of the Swedish database, Källén and Mazze (1990) scrutinized 572 operations performed at 4 to 5 weeks’ gestation and reported a nonsignificant relationship with increased neural-tube defect rates. In a similar study from a Hungarian database, Czeizel and colleagues (1998) found no evidence that anesthetic agents were teratogenic. In a review, Kuczkowski (2006) concluded that there is no robust evidence that anesthetic agents are harmful to the fetus.

LAPAROSCOPIC SURGERY DURING PREGNANCY

Laparoscopy has become the most common first-trimester procedure used for diagnosis and management of several surgical disorders (Kuczkowski, 2007). In addition to management of ectopic pregnancy (Chap. 19, p. 385), it is used preferentially during most of pregnancy for exploration and treatment of adnexal masses (Chap. 63, p. 1226), for appendectomy (Chap. 54, p. 1079), and for cholecystectomy (Chap. 55, p. 1096). In 2011, the Guidelines Committee of the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) updated its recommendations concerning laparoscopy use in pregnant women. Some of these guidelines are listed in Table 46-2.
**TABLE 46-2. Some Guidelines for the Performance of Laparoscopic Surgery in Pregnancy**

**Indications**—same as for nonpregnant women  
Adnexal mass excision  
Investigation of acute abdominal processes  
Appendectomy, cholecystectomy, nephrectomy, adrenalectomy, splenectomy  

**Timing**—all trimesters  
**Technique**  
Position: left lateral recumbent  
Entry: open technique, careful Veress needle, or optical trocar; fundal height may alter insertion site selection  
Trocars: direct visualization for placement; fundal height may alter insertion site selection  
CO\textsubscript{2} insufflation pressures: 10–15 mm Hg  
Monitoring: capnography intraoperatively, FHR assessment pre- and postoperatively  
Perioperative pneumatic compression devices and early postoperative ambulation  

CO\textsubscript{2} = carbon dioxide; FHR = fetal heart rate.  
Summarized from Pearl, 2011.

Information regarding surgical approach selection in pregnant women comes from the American College of Surgeons database (Silvestri, 2011). During the 5-year period ending in 2009, almost 1300 pregnant women who had undergone either appendectomy or cholecystectomy were studied. Open appendectomy was performed in 36 percent of 857 pregnant women compared with only 17 percent of those not pregnant. Of those undergoing cholecystectomy, an open procedure was used in 10 percent of 436 pregnant women compared with 5 percent of nonpregnant women.

There are no randomized trials comparing laparoscopic with open surgery, however, most reviews report equally satisfactory outcomes (Bunyavejchevin, 2013; Fatum, 2001; Lachman, 1999). The most frequently performed procedures were cholecystectomy, adnexal surgery, and appendectomy. Laparoscopic adnexal mass surgery in pregnancy is preferred, and its relative safety is attested to by several investigators (Biscette, 2011; Hoover, 2011; Koo, 2011, 2012). At first, 26 to 28 weeks became the upper gestational-age limit recommended, but as experience has continued to accrue, many now describe laparoscopic surgery performed in the third trimester (Donkervoort, 2011; Kizer, 2011). In one report of 59 pregnant women undergoing laparoscopic cholecystectomy or appendectomy, a third were > 26 weeks pregnant (Rollins, 2004). There were no serious adverse sequelae to these procedures. There are now reports of laparoscopic splenectomy, adrenalectomy, and nephrectomy done in pregnant women (Aubrey-Bassier, 2012; Gernsheimer, 2007; Kosaka, 2006; Miller, 2012; Stroup, 2007).

**Hemodynamic Effects**

Abdominal insufflation for laparoscopy causes hemodynamic changes that are similar in pregnant and nonpregnant women, and these are summarized in Table 46-3. Reedy and associates (1995) studied baboons at the human equivalent of 22 to 26 weeks’ gestation. There were no substantive physiological changes with 10 mm Hg insufflation pressures, but 20 mm Hg caused significant...
maternal cardiovascular and respiratory changes after 20 minutes. These included increased respiratory rate, respiratory acidosis, diminished cardiac output, and increased pulmonary artery and capillary wedge pressures.

|------------------------------------------|---------------------------------|----------------------------------|
| **System**                             | **Effects**                     | **Mechanisms**                   | **Possible Maternal-Fetal Effects** |
| Respiratory                            | P<sub>CO₂</sub> increases, pH decreases | CO₂ absorption                   | Hypercarbia, acidosis              |
| Cardiovascular                         | Increased—heart rate; systemic vascular resistance; pulmonary, central venous, and mean arterial pressures | Hypercarbia and increased intraabdominal pressure | Uteroplacental hypoperfusion— possible fetal hypoxia, acidosis, and hypoperfusion<sup>b</sup> |
|                                         | Decreased—cardiac output         | Decreased venous return           |                                    |
| Blood flow                             | Decreased splanchnic flow with hypoperfusion of liver, kidneys, and gastrointestinal organs | Increased intraabdominal pressure | As above                          |
|                                         | Decreased venous return from lower extremities | Increased intraabdominal pressure | As above                          |
|                                         | Increased cerebral blood flow    | Hypercarbia possibly from shunting due to splanchnic tamponade | Increased CSF pressure<sup>b</sup> |

<sup>a</sup>Effects intensified when insufflation pressure > 20 mm Hg in baboons (Reedy, 1995).  
<sup>b</sup>Data primarily from animal studies.  
CO₂ = carbon dioxide; CSF = cerebrospinal fluid; P<sub>CO₂</sub> = partial pressure of CO₂.  
Data from O’Rourke, 2006; Reynolds, 2003.

In women, cardiorespiratory changes are generally not severe if insufflation pressures are kept below 20 mm Hg. With noninvasive hemodynamic monitoring in women at midpregnancy, the cardiac index decreased 26 percent by 5 minutes of insufflation and 21 percent by 15 minutes (Steinbrook, 2001). Despite this, mean arterial pressures, systemic vascular resistance, and heart rate did not change significantly.

**Perinatal Outcomes**

Because precise effects of laparoscopy in the human fetus are unknown, animal studies are informative. In early studies of pregnant ewes, various investigators reported that uteroplacental blood flow decreased when intraperitoneal insufflation pressure exceeded 15 mm Hg (Barnard, 1995; Hunter, 1995). This was the result of decreased perfusion pressure and increased placental vessel resistance (see Table 46-3). The previously cited baboon studies by Reedy and coworkers (1995) produced similar findings. Since then, other studies in sheep have corroborated these observations (O’Rourke, 2006; Reynolds, 2003).
Pregnancy outcomes in women are limited to observations. Reedy and colleagues (1997) used the updated Swedish Birth Registry database to analyze a 20-year period and more than 2 million deliveries. There were 2181 laparoscopic procedures, most of which were performed during the first trimester. Perinatal outcomes for these women were compared with those of all women in the database as well as those undergoing open surgical procedures. These investigators confirmed the earlier findings of an increased risk of low birthweight, preterm delivery, and fetal-growth restriction in pregnancies of women in both operative groups compared with controls. There were no differences, however, when outcomes of women undergoing laparoscopy versus laparotomy were compared. Similar findings were reported from an observational study of 262 women undergoing surgery for an adnexal mass (Koo, 2012).

**Technique**

Preparation for laparoscopy differs little from that used for laparotomy. Bowel cleansing empties the large intestine and may aid visualization. Nasogastric or orogastric decompression reduces the risk of stomach trocar puncture and aspiration. Aortocaval compression is avoided by a left-lateral tilt. Positioning of the lower extremities in boot-type stirrups maintains access to the vagina for fetal sonographic assessment or manual uterine displacement. Vaginally placed instruments that enter the cervix or uterus for uterine manipulation should not be used during pregnancy.

Most reports describe the use of general anesthesia after tracheal intubation with monitoring of end-tidal carbon dioxide—EtCO\(_2\) (Hong, 2006; Ribic-Pucelj, 2007). With controlled ventilation, EtCO\(_2\) is maintained at 30 to 35 mm Hg.

Beyond the first trimester, technical modifications of standard pelvic laparoscopic entry are required to avoid uterine puncture or laceration. Many recommend open entry techniques to avoid perforations of the uterus, pelvic vessels, and adnexa (Kizer, 2011; Koo, 2012). The abdomen is incised at or above the umbilicus, and the peritoneal cavity entered under direct visualization. At this point, the cannula is then connected to the insufflation system, and a 12-mm Hg pneumoperitoneum is created. The initial insufflation should be conducted slowly to allow for prompt assessment and reversal of any untoward pressure-related effects. Gas leakage around the cannula is managed by tightening the surrounding skin with a towel clamp. Insertion of secondary trocars into the abdomen is most safely performed under direct laparoscopic visual observation through the primary port. Single-port surgery has also been described (Dursun, 2013).

In more advanced pregnancies, direct entry through a left upper quadrant port in the midclavicular line, 2 cm beneath the costal margin, has been described (Donkervoort, 2011; Stepp, 2004). Known as Palmer point, this entry site is used in gynecological laparoscopy because visceroparietal adhesions uncommonly form here (Vilos, 2007).

**Gasless Laparoscopy**

This is a less commonly used alternative approach that uses a rod with intraabdominal fan-blade-shaped retractors. When opened, these allow the abdominal wall to be lifted upward. It avoids the typical laparoscopic cardiovascular changes because the pneumoperitoneum is created by retraction rather than insufflation (Phupong, 2007).

**Complications**

Risks inherent to any abdominal endoscopy are possibly increased slightly during pregnancy. The
obvious unique complication is perforation of the pregnant uterus with either a trocar or Veress needle (Azevedo, 2009; Kizer, 2011). That said, reported complications are infrequent (Fatum, 2001; Joumblat, 2012; Koo, 2012). After a Cochrane database review, it was determined that randomized trials would be necessary to deduce comparative benefits and risks of laparoscopy versus laparotomy during pregnancy (Bunyavejchevin, 2013). Pragmatically, this seems unfeasible, and common sense should dictate the approach used.

**IMAGING TECHNIQUES**

Imaging modalities that are used as adjuncts for diagnosis and therapy during pregnancy include sonography, radiography, and magnetic resonance (MR) imaging. Of these, radiography is the most problematic. Inevitably, some radiographic procedures are performed before recognition of early pregnancy, usually because of trauma or serious illness. Fortunately, most diagnostic radiographic procedures are associated with minimal fetal risks. As with drugs and medications, however, these procedures may lead to litigation if there is an adverse pregnancy outcome. And x-ray exposure may lead to a needless therapeutic abortion because of patient or physician anxiety.

Beginning 2007, the American College of Radiology (ACR) has addressed the growing concern of radiation dose in all fields of medicine. Some of the goals were to limit exposure through radiation safety practices and promote lifelong accumulated records of exposures in any given patient (Amis, 2007). Task Force recommendations included additional considerations for special radiosensitive populations, such as children and pregnant and potentially pregnant women. The Task Force also suggested that the College should encourage radiologists to record all ionizing radiation times and exposures, compare them with benchmarks, and evaluate outliers as part of ongoing quality assurance programs. At the present time at Parkland Hospital, special recommendations are made for the pregnant woman. Radiation exposure values and duration are recorded in high-exposure areas such as computed tomography (CT) and fluoroscopy. Moreover, quality assurance mechanisms are in place to monitor these parameters.

An excellent review of ionizing radiation exposure during pregnancy was performed following the recent Fukushima nuclear plant disaster in Japan (Groen, 2012). This review reinforces considerations during pregnancy that are discussed subsequently.

**Ionizing Radiation**

The term radiation is poorly understood. Literally, it refers to energy transmission and thus is often applied not only to x-rays, but also to microwaves, ultrasound, diathermy, and radio waves. Of these, x-rays and gamma rays have short wavelengths with very high energy and are ionizing radiation forms. The other four energy forms have rather long wavelengths and low energy (Brent, 1999b, 2009).

The biological effects of x-rays are caused by an electrochemical reaction that can damage tissue. According to Brent (1999a, 2009), x- and gamma-radiation at high doses can create two types of biological effects and reproductive risks in the fetus:

1. **Deterministic effects**—these may cause congenital malformations, fetal-growth restriction, mental retardation, and abortion. Although controversial, this so-called NOAEL—No Observed Adverse Effect Level—suggests that there is a threshold dose (0.05 gray or 5 rad) below which there is no risk. It also suggests that the threshold for gross fetal malformations is more likely to
be 0.2 gray (20 rad).

2. *Stochastic effects*—these are randomly determined probabilities, which may cause genetic diseases and carcinogenesis. In this case, cancer risk is increased, and hypothetically, at even very low doses.

In this sense, ionizing radiation refers to waves or particles—photonsof significant energy that can change the structure of molecules such as those in DNA, or that can create free radicals or ions capable of causing tissue damage (Hall, 1991; National Research Council, 1990). Methods of measuring the effects of x-rays are summarized in Table 46-4. The standard terms used are *exposure* (in air), *dose* (to tissue), and *relative effective dose* (to tissue). In the range of energies for diagnostic x-rays, the dose is now expressed in grays (Gy), and the relative effective dose is now expressed in sieverts (Sv). These can be used interchangeably. For consistency, all doses discussed subsequently are expressed in contemporaneously used units of gray (1 Gy = 100 rad) or sievert (1 Sv = 100 rem). To convert, 1 Sv = 100 rem = 100 rad.

**X-Ray Dosimetry**

When calculating the ionizing radiation dose, such as that from x-rays, several factors to be considered include: (1) type of study, (2) type and age of equipment, (3) distance of target organ from radiation source, (4) thickness of the body part penetrated, and (5) method or technique used for the study (Wagner, 1997).

Estimates of dose to the uterus and embryo for various frequently used radiographic examinations are summarized in Table 46-5. Studies of maternal body parts farthest from the uterus, such as the head, result in a very small dose of radiation scatter to the embryo or fetus. The size of the woman, radiographic technique, and equipment performance are variable factors. Thus, data in the table serve only as guidelines. When the radiation dose for a specific individual is required, a medical physicist should be consulted. Brent (2009) recommends consulting the Health Physics Society website (www.hps.org) to view some examples of questions and answers posed by patients exposed to radiation.
Deterministic Effects of Ionizing Radiation

One potential harmful effect of radiation exposure is deterministic, which may result in abortion, growth restriction, congenital malformations, microcephaly, or mental retardation. These deterministic effects are threshold effects, and the level below which they are induced is the NOAEL (Brent, 2009).

The harmful deterministic effects of ionizing radiation have been extensively studied for cell damage with resultant embryogenesis dysfunction. These have been assessed in animal models, as well as in Japanese atomic bomb survivors and the Oxford Survey of Childhood Cancers (Sorahan, 1995). Additional sources have confirmed previous observations and provided more information (Groen, 2012). One is the 2003 International Commission on Radiological Protection publication, which describes biological fetal effects from prenatal irradiation. Another is the Biological Effects of Ionizing Radiation—BEIR VII Phase 2 report of the National Research Council (2006), which discusses health risks from exposure to low levels of ionizing radiation.

Animal Studies

In the mouse model, the lethality risk is highest during the preimplantation period—up to 10 days postconception. This is likely due to blastomere destruction caused by chromosomal damage (Hall, 1991). The NOAEL for lethality is 0.15 to 0.2 Gy. Genomic instability can be induced by...
some mouse models at levels of 0.5 Gy (50 rad), which greatly exceeds levels with diagnostic studies (International Commission on Radiological Protection, 2003).

During organogenesis, high-dose radiation—1 gray or 100 rad—is more likely to cause malformations and growth restriction and less likely to have lethal effects in the mouse. Acute low-dose ionizing radiation appears to have no deleterious effects (Howell, 2013). Studies of brain development suggest that there are effects on neuronal development and a window of cortical sensitivity in early and midfetal periods. During this, the threshold ranges from 0.1 to 0.3 Gy or 10 to 30 rad (International Commission on Radiological Protection, 2003).

Human Data
Data on adverse human effects of high-dose ionizing radiation have most often been derived from atomic bomb survivors from Hiroshima and Nagasaki (Greskovich, 2000; Otake, 1987). The International Commission on Radiological Protection (2003) confirmed initial studies showing that the increased risk of severe mental retardation was greatest between 8 and 15 weeks (Fig. 46-2). There may be a lower-threshold dose of 0.3 Gy—30 rad—a range similar to the window of cortical sensitivity in the mouse model discussed above. The mean decrease in intelligence quotient (IQ) scores was 25 points per Gy or 100 rad. There appears to be linear dose response but it is not clear whether there is a threshold dose. Most estimates err on the conservative side by assuming a linear nonthreshold hypothesis. From their review, Strzelczyk and coworkers (2007) conclude that limitations of epidemiological studies at low-level exposures, along with new radiobiological findings, challenge the hypothesis that any amount of radiation causes adverse effects. In one such study describing fetuses exposed to low radiation doses, Choi and colleagues (2012) did not find an increased risk for congenital anomalies.
Follow-up of subjects from Hiroshima and Nagasaki after the atomic bomb explosion in 1945. Subsequent severe mental retardation caused by exposure to ionizing in utero radiation at two gestational age epochs to 1 Gy, that is, 100 rad. Mean values and 90-percent confidence levels are estimated from dosimetry calculated by two methods—T65DR and D586—used by the Radiation Effects Research Foundation of the Japanese Ministry of Health and National Academy of Sciences of the United States. (Data from Otake, 1987, with permission.)

Finally, there is no documented increased risk of mental retardation in humans less than 8 weeks’ or greater than 25 weeks’ gestation, even with doses exceeding 0.5 Gy or 50 rad (Committee on Biological Effects, BEIR V, 1990; International Commission on Radiological Protection, 2003).

There are reports that have described high-dose radiation used to treat women for malignancy, menorrhagia, and uterine myomas. Dekaban (1968) described 22 infants with microcephaly, mental retardation, or both following exposure in the first half of pregnancy to an estimated 2.5 Gy or 250 rad. Malformations in other organs were not found unless they were accompanied by microcephaly, eye abnormalities, or growth restriction (Brent, 1999b).

The implications of these findings seem straightforward. From 8 to 15 weeks, the embryo is most susceptible to radiation-induced mental retardation. It has not been resolved whether this is a threshold or nonthreshold linear function of dose. The Committee on Biological Effects (1990) estimates the risk of severe mental retardation to be as low as 4 percent for 0.1 Gy (10 rad) and as
high as 60 percent for 1.5 Gy (150 rad). But recall that these doses are 2 to 100 times higher than those considered maximal from diagnostic radiation. Importantly, cumulative doses from multiple procedures may reach the harmful range, especially at 8 to 15 weeks. At 16 to 25 weeks, the risk is less. And again, there is no proven risk before 8 weeks or after 25 weeks.

Embryo-fetal risks from low-dose diagnostic radiation appear to be minimal. Current evidence suggests that there are no increased risks for malformations, growth restriction, or abortion from a radiation dose of less than 0.05 Gy (5 rad). Indeed, Brent (2009) concluded that gross congenital malformations would not be increased with exposure to less than 0.2 Gy (20 rad). Because diagnostic x-rays seldom exceed 0.1 Gy (10 rad), Strzelczyk and associates (2007) concluded that these procedures are unlikely to cause deterministic effects. As emphasized by Groen and coworkers (2012), 0.1 Gy is the radiation equivalent to that from more than 1000 chest x-rays!

### Stochastic Effects of Ionizing Radiation

This refers to random, presumably unpredictable oncogenic or mutagenic effects of radiation exposure. They concern associations between fetal diagnostic radiation exposure and increased risk of childhood cancers or genetic diseases. According to Doll and Wakeford (1997), as well as the National Research Council (2006) BEIR VII Phase 2 report, excess cancers can result from in utero exposure to doses as low as 0.01 Sv or 1 rad. Stated another way by Hurwitz and colleagues (2006), the estimated risk of childhood cancer following fetal exposure to 0.03 Gy or 3 rad doubles the background risk of 1 in 600 to that of 2 in 600.

In one report, in utero radiation exposure was determined for 10 solid cancers in adults from age 17 to 45 years. There was a dose-response relationship as previously noted at the 0.1 Sv or 10 rem threshold. Intriguingly, nine of 10 cancers were found in females (National Research Council, 2006). These likely are associated with a complex series of interactions between DNA and ionizing radiation. They also make it more problematic to predict cancer risk from low-dose radiation of less than 0.1 Sv or 10 rem. Importantly, below doses of 0.1 to 0.2 Sv, there is no convincing evidence of a carcinogenic effect (Brent, 2009; Preston, 2008; Strzelczyk, 2007).

### Therapeutic Radiation

In an earlier report, the Radiation Therapy Committee Task Group of the American Association of Physics in Medicine found that approximately 4000 pregnant women annually undergo cancer therapy in the United States (Stovall, 1995). Their recommendations, however, stand to date. The Task Group emphasizes careful individualization of radiotherapy for the pregnant woman (Chap. 63, p. 1220). For example, in some cases, shielding of the fetus and other safeguards can be employed (Fenig, 2001; Nuyttens, 2002). In other instances, the fetus will be exposed to dangerous radiation doses, and a carefully designed plan must be improvised (Prado, 2000). One example is the model to estimate the fetal dose with maternal brain radiotherapy, and another is the model to calculate the fetal dose with tangential breast irradiation (Mazonakis, 1999, 2003). The impact of radiotherapy on future fertility and pregnancy outcomes was reviewed by Wo and Viswanathan (2009) and others, and this is discussed in detail in Chapter 63 (p. 1220).

### Diagnostic Radiation

To estimate fetal risk, approximate x-ray dosimetry must be known. According to the American College of Radiology no single diagnostic procedure results in a radiation dose significant enough
Radiographs
Dosimetry for standard radiographs is presented in Table 46-5. In pregnancy, the AP-view chest radiograph is the most commonly used study, and fetal exposure is exceptionally small—0.0007 Gy or 0.07 mrad. With one abdominal radiograph, because the embryo or fetus is directly in the x-ray beam, the dose is higher—0.001 Gy or 100 mrad. The standard intravenous pyelogram may exceed 0.005 Gy or 500 mrad because of several films. The one-shot pyelogram described in Chapter 53 (p. 1056) is useful when urolithiasis or other causes of obstruction are suspected but unproven by sonography. Most “trauma series,” such as radiographs of an extremity, skull, or rib series, deliver low doses because of the fetal distance from the target area.

Fetal indications for radiographic studies are limited. In some countries, x-ray pelvimetry is done for a breech presentation (Chap. 28, p. 562).

Fluoroscopy and Angiography
Dosimetry calculations are much more difficult with these procedures because of variations in the number of radiographs obtained, total fluoroscopy time, and fluoroscopy time in which the fetus is in the radiation field. As shown in Table 46-6, the range is variable. The Food and Drug Administration limits the exposure rate for conventional fluoroscopy such as barium studies, however, special-purpose systems such as angiography units have the potential for much higher exposure.

| TABLE 46-6. Estimated X-Ray Doses to the Uterus/Embryo from Common Fluoroscopic Procedures |
Endoscopy is the preferred method of gastrointestinal tract evaluation in pregnancy (Chap. 54, p. 1069). Occasionally, an upper gastrointestinal series or barium enema may be performed before a pregnancy is recognized. Most would likely be done during preimplantation or early organogenesis.

Angiography and vascular embolization may occasionally be necessary for serious maternal disorders, especially renal disease, and for trauma (Wortman, 2013). As before, the greater the distance from the embryo or fetus, the less the exposure and risk.

**Computed Tomography**

This is usually performed by obtaining a spiral of 360-degree images that are postprocessed in multiple planes. Of these, the axial image remains the most commonly obtained. Multidetector CT (MDCT) images are now standard for common clinical indications. The most recent detectors have 16 or 64 channels, and MDCT protocols may result in increased dosimetry compared with traditional CT imaging. A number of imaging parameters have an effect on exposure (Brenner, 2007). These include pitch, kilovoltage, tube current, collimation, number of slices, tube rotation, and total acquisition time. If a study is performed with and without contrast, the dose is doubled because twice as many images are obtained. Fetal exposure is also dependent on factors such as maternal size as well as fetal size and position. And as with plain radiography, the closer the target area is to the fetus, the greater the delivered dose.

PTCA = percutaneous transluminal coronary angioplasty; SD = standard deviation.
Cranial CT scanning is the most commonly requested study in pregnant women. It is used in women with neurological disorders as discussed in Chapter 60 (p. 1187) and with eclampsia as noted in Chapter 40 (p. 744). Nonenhanced CT scanning is commonly used to detect acute hemorrhage within the epidural, subdural, or subarachnoid spaces. Because of the distance from the fetus, radiation dosage is negligible (Goldberg-Stein, 2012).

Abdominal procedures are more problematic. Hurwitz and associates (2006) employed a 16-MDCT to calculate fetal exposure at 0 and 3 months’ gestation using a phantom model (Table 46-7). Calculations were made for three commonly requested procedures in pregnant women. The pulmonary embolism protocol has the same dosimetry exposure as the ventilation-perfusion (V/Q) lung scan discussed below. Because of the pitch used, the appendicitis protocol has the highest radiation exposure, however, it is very useful clinically (Fig. 46-3). Using a similar protocol in 67 women with suspected appendicitis, Lazarus and coworkers (2007) reported sensitivity of 92 percent, specificity of 99 percent, and a negative-predictive value of 99 percent. Here dosimetry was markedly decreased compared with standard appendiceal imaging because of a different pitch. For suspected urolithiasis, the MDCT-scan protocol shown in Figure 46-4 is used if sonography is nondiagnostic. Using a similar protocol, White and colleagues (2007) identified urolithiasis in 13 of 20 women at an average of 26.5 weeks. Finally, and as discussed in Chapter 47 (p. 954), abdominal tomography should be performed if indicated in the pregnant woman with severe trauma.

Data from Hurwitz, 2006.
Most experience with chest CT-scanning is with suspected pulmonary embolism. The most recent recommendations for its use in pregnancy from the Prospective Investigation of Pulmonary Embolism Diagnosis—PIOPED—II investigators were summarized by Stein and associate (2007). They found that pulmonary scintigraphy—the V/Q scan—was recommended for pregnan
women by 70 percent of radiologists and chest CT angiography by 30 percent. And scintigraphy is still recommended by the American Thoracic Society in pregnant women with a normal chest x-ray (Leung, 2012). But most agree that MDCT angiography has improved accuracy because of increasingly faster acquisition times. Others have reported a higher use rate for CT angiography and emphasize that dosimetry is similar to that with V/Q scintigraphy (Brenner, 2007; Hurwitz, 2006; Matthews, 2006). At Parkland and UT Southwestern University Hospitals, we prefer MDC’ scanning initially for suspected pulmonary embolism (Chap. 52, p. 1042).

CT pelvimetry is used by some before attempting breech vaginal delivery (Chap. 28, p. 562). The fetal dose approaches 0.015 Gy or 1.5 rad, but use of a low-exposure technique may reduce this to 0.0025 Gy or 0.25 rad.

Nuclear Medicine Studies

These studies are performed by “tagging” a radioactive element to a carrier that can be injected, inhaled, or swallowed. For example, the radioisotope technetium-99m may be tagged to red blood cells, sulfur colloid, or pertechnetate. The method used to tag the agent determines fetal radiation exposure. The amount of placental transfer is obviously important, but so is renal clearance because of fetal proximity to the maternal bladder. Measurement of radioactive technetium is based on its decay, and the units used are the curie (Ci) or the becquerel (Bq). Dosimetry is usually expressed in millicuries (mCi). As shown in Table 46-4, the effective tissue dose is expressed in sievert units (Sv) with conversion as discussed: 1 Sv = 100 rem = 100 rad.

Depending on the physical and biochemical properties of a radioisotope, an average fetal exposure can be calculated (Wagner, 1997; Zanzonico, 2000). Commonly used radiopharmaceuticals and estimated absorbed fetal doses are given in Table 46-8. The radionuclide dose should be kept as low as possible (Adelstein, 1999). Exposures vary with gestational age and are greatest earlier in pregnancy for most radiopharmaceuticals. One exception is the later effect of iodine-131 on the fetal thyroid (Wagner, 1997). The International Commission on Radiological Protection (2001) has compiled dose coefficients for radionuclides. Stather and coworkers (2002) detailed the biokinetic and dosimetric models used by the Commission to estimate fetal radiation doses from maternal radionuclide exposure.

\(^a\)mCi = millicuries. To convert to mrad, multiply by 100.

\(^b\)Exposures are generally greater prior to 12 weeks compared with increasing gestational ages.

\(^c\)Some measurements account for placental transfer.

\(^d\)The uptake and exposure of \(^{131}\)I increases with gestational age.

DPTA = diethylenetriaminepentaacetic acid; Ga = gallium; HIDA = hepatobiliary iminodiacetic acid; I = iodine; mCi = millicurie; mSv = millisievert; Tc = technetium; TcO\(_4\) = pertechnetate; Tl = thallium.

Data from Adelstein, 1999; Schwartz, 2003; Stather, 2002; Wagner, 1997; Zanzonico, 2000.
As discussed above, MDCT-angiography is being used preferentially for suspected pulmonary embolism during pregnancy. Until recently, the imaging modality was the ventilation-perfusion lung scan in this setting. It is used if CT angiography is nondiagnostic (Chap. 52, p. 1043). Perfusion is measured with injected $^{99}$Tc-macroaggregated albumin, and ventilation is measured with inhaled xenon-127 or xenon-133. Fetal exposure with either is negligible (Chan, 2002; Mountford, 1997).

Thyroid scanning with iodine-123 or iodine-131 seldom is indicated in pregnancy. With trace doses used, however, fetal risk is minimal. Importantly, therapeutic radioiodine in doses to treat Graves disease or thyroid cancer may cause fetal thyroid ablation and cretinism.

The sentinel lymphoscintigram, which uses $^{99m}$Tc-sulfur colloid to detect the axillary lymph node most likely to have metastases from breast cancer, is a commonly used preoperative study in nonpregnant women (Newman, 2007; Spanheimer, 2009; Wang, 2007). As shown in Table 46-8, the calculated dose is approximately 0.014 mSv or 1.4 mrad, which should not preclude its use during pregnancy.

**SONOGRAPHY**

Of all of the major advances in obstetrics, the development of sonography for study of the fetus and mother certainly is one of the greater achievements. The technique has become virtually indispensable in everyday practice. The wide range of clinical uses of sonography in pregnancy is further discussed in Chapter 10 and in most other sections of this book.

**MAGNETIC RESONANCE IMAGING**

Magnetic resonance technology does not use ionizing radiation, and its application is cited throughout this book. Advantages include high soft-tissue contrast, ability to characterize tissue, and acquisition of images in any plane—particularly axial, sagittal, and coronal. An entire section in Chapter 10 (p. 222) is devoted to mechanisms that generate MR images.

### Safety

The most recent update of the Blue Ribbon Panel on MR safety of the American College of Radiology was summarized by Kanal and colleagues (2007). The panel concluded that there are no reported harmful human effects from MR imaging. Chew and associates (2001) found no differences in blastocyst formation exposure of early murine embryos to MR imaging with 1.5 T strength. Vadeyar and coworkers (2000) noted no demonstrable fetal heart rate pattern changes during MR imaging in women. Chung (2002) has reviewed these safety issues.

Contraindications to MR imaging include internal cardiac pacemakers, neurostimulators, implanted defibrillators and infusion pumps, cochlear implants, shrapnel or other metal in biologically sensitive areas, some intracranial aneurysm clips, and any metallic foreign body in the eye. Of more than 51,000 nonpregnant patients scheduled for MR imaging, Dewey and colleagues (2007) found that only 0.4 percent had an absolute contraindication to the procedure.
Contrast Agents

Several elemental gadolinium chelates are used to create paramagnetic contrast. Some are gadopentetate, gadodiamide, gadoteridol, and gadoterate. These cross the placenta and are found in amniotic fluid. In doses approximately 10 times the human dose, gadopentetate caused slight developmental delay in rabbit fetuses. There is little experience with gadolinium in humans (Wang, 2012). In one study, De Santis and associates (2007) described 26 women given a gadolinium derivative in the first trimester without adverse fetal effects. Currently, according to Briggs and coworkers (2011), as well as the Panel, these contrast agents are not recommended unless there are overwhelming benefits.

Maternal Indications

In some cases, MR imaging may be complementary to CT, and in others, MR imaging is preferable. Maternal central nervous system abnormalities, such as brain tumors or spinal trauma, are more clearly seen with MR imaging. As discussed in Chapter 40 (p. 743), MR imaging has provided valuable insights into the pathophysiology of eclampsia and to calculate cerebrovascular blood flow in preeclampsia (Twickler, 2007; Zeeman, 2003, 2004a,b, 2009). It is invaluable in the diagnosis of neurological emergencies (Edlow, 2013). MR imaging is a superb technique to evaluate the maternal abdomen and retroperitoneal space. It is chosen by many to determine the degree and extent of placenta accreta and its variants in women who have had a prior cesarean delivery (Chap. 41, p. 806). It has been employed for detection and localization of adrenal tumors, renal lesions, gastrointestinal lesions, and pelvic masses in pregnancy. It has particular value in evaluating neoplasms of the chest, abdomen, and pelvis in pregnancy (Boyd, 2012; Oto, 2007; Tica, 2013). MR urography has been used successfully for renal urolithiasis (Mullins, 2012). MR imaging may be selected to confirm pelvic and vena caval thrombosis—a common source of pulmonary embolism in pregnant women (Fig. 46-5). As discussed in Chapter 37 (p. 688), CT and MR imaging is useful for evaluation of puerperal infections, but MR imaging provides better visualization of the bladder flap area following cesarean delivery (Brown, 1999; Twickler, 1997). MR imaging now includes evaluation of right lower quadrant pain in pregnancy, specifically appendicitis (Baron, 2012; Dewhurst, 2013; Pedrosa, 2007, 2009). Investigators have also found other disorders of the gastrointestinal tract to be easily diagnosed with MR imaging (Chap. 54, p. 1069).
FIGURE 46-5 Magnetic-resonance images of a pelvic vein thrombosis in a 15-week pregnant woman who presented with left leg pain but no symptoms of a pulmonary embolus. A. Reconstructed magnetic resonance venogram demonstrates partial chronic occlusion of the left common iliac vein (large arrow) and thrombosis and complete occlusion of the left internal iliac vein (small arrows). B. From the axial images, there is normal flow in the right (arrow) and no flow in the left internal iliac vein (curved arrow). (Image contributed by Dr. R. Douglas Sims.)

**Fetal Indications**

Fetal MR imaging provides a complement to sonography (De Wilde, 2005; Laifer-Narin, 2007 Sandrasegaran, 2006). According to Zaretsky and colleagues (2003a), MR imaging can be used to image almost all elements of the standard fetal anatomical survey. The most frequent fetal indications for MR imaging are evaluation of complex abnormalities of the brain, chest, and genitourinary system. Bauer (2009), Reichel (2003), Twickler (2002), Weisz (2009), and their associates have validated its use for fetal central nervous system anomalies and biometry (Fig. 46-6). Caire and coworkers (2003) reported its merits for fetal genitourinary anomalies. Hawkins and colleagues (2008) described MR imaging in 21 fetuses with renal anomalies and oligohydramnios. Zaretsky and associates (2003b) noted that fetal-weight estimation was more accurate using MR imaging than with sonography. Fast-acquisition sequencing has solved problems with fetal movement to improve imaging. The technique is termed HASTE—Half-Fourier Acquisition Single slow Turbo spin Echo, or SSFSE—Single Shot Fast Spin Echo. A more extensive discussion of fetal indications and findings of MR imaging are discussed in Chapter 10 and throughout this book.

GUIDELINES FOR DIAGNOSTIC IMAGING DURING PREGNANCY

The American College of Obstetricians and Gynecologists (2009) has reviewed the effects of radiographic, sonographic, and magnetic-resonance exposure during pregnancy. Its suggested guidelines are shown in Table 46-9.

### Table 46-9. Guidelines for Diagnostic Imaging During Pregnancy

1. Women should be counseled that x-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. Specifically, exposure to less than 5 rads has not been associated with an increase in fetal anomalies or pregnancy loss.
2. Concern about possible effects of high-dose ionizing radiation exposure should not prevent medically indicated diagnostic x-ray procedures from being performed on a pregnant woman. During pregnancy, other imaging procedures not associated with ionizing radiation, e.g., ultrasonography, and MRI, should be considered instead of x-rays when appropriate.
3. Ultrasonography and MRI are not associated with known adverse fetal effects.
4. Consultation with an expert in dosimetry calculation may be helpful in calculating estimated fetal dose when multiple diagnostic x-rays are performed on a pregnant patient.
5. The use of radioactive isotopes of iodine is contraindicated for therapeutic use during pregnancy.
6. Radiopaque and paramagnetic contrast agents are unlikely to cause harm and may be of diagnostic benefit, but these agents should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Summarized from the American College of Obstetricians and Gynecologists, 2009.

An endless number of medical, surgical, and obstetrical complications may be encountered in pregnancy or the puerperium. Those that are more complex and life threatening can be particularly challenging, especially when a multidisciplinary team is necessary for optimal care. It is axiomatic that obstetricians and other members of the health-care team have a working knowledge of the unique considerations for pregnant women. Some of those discussed in Chapter 46 include pregnancy-induced physiological changes, alterations in normal laboratory values, and finally and importantly, consideration for the second patient—the fetus. Because these severely ill women are usually young and in good health, their prognosis is generally better than that of many other patients admitted to intensive care units.

In the United States each year, 1 to 3 percent of pregnant women require critical care services, and the risk of death during such admission ranges from 2 to 11 percent (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Those with pregnancy-associated complications—especially hemorrhage and hypertension—have the greatest need for intensive care (Baskett, 2009; Kuklina, 2009; Madan, 2008). That said, many antepartum admissions are for nonobstetrical reasons, and in our experiences from Parkland Hospital, these include diabetes, pneumonia or asthma, heart disease, chronic hypertension, pyelonephritis, or thyrotoxicosis (Zeeman, 2006). In addition to antenatal treatment, intrapartum and postpartum
critical care for hypertensive disorders, hemorrhage, sepsis, or cardiopulmonary complications may be required for many. In instances of life-threatening hemorrhage, surgical procedures may be necessary, and close proximity to a delivery-operating room is paramount. For women who are undelivered, fetal well-being is also better served by this close proximity.

### Organization of Critical Care

The concept and development of critical care for all aspects of medicine and surgery began in the 1960s. The National Institutes of Health held a Consensus Conference (1983) and the Society of Critical Care Medicine (1988, 1999) subsequently established guidelines for intensive care units (ICUs). Especially pertinent to obstetrics, costly ICUs prompted evolution of a step-down intermediate care unit. These units were designed for patients who did not require intensive care, but who needed a higher level of care than that provided on a general ward. The American College of Critical Care Medicine and the Society of Critical Care Medicine (1998) published guidelines for these units (Table 47-1).

#### TABLE 47-1. Guidelines for Conditions That Could Qualify for Intermediate Care

| Cardiac: | evaluation for possible infarction, stable infarction, stable arrhythmias, mild-to-moderate congestive heart failure, hypertensive urgency without end-organ damage |
| Pulmonary: | stable patients for weaning and chronic ventilation, patients with potential for respiratory failure who are otherwise stable |
| Neurological: | stable central nervous system, neuromuscular, or neurosurgical conditions that require close monitoring |
| Drug overdose: | hemodynamically stable |
| Gastrointestinal: | stable bleeding, liver failure with stable vital signs |
| Endocrine: | diabetic ketoacidosis, thyrotoxicosis that requires frequent monitoring |
| Surgical: | postoperative from major procedures or complications that require close monitoring |
| Miscellaneous: | early sepsis, patients who require closely titrated intravenous fluids, pregnant women with severe preeclampsia or other medical problems |

From Nasraway, 1998.

### Obstetrical Critical Care

Although the evolution of critical care for obstetrical patients has generally followed developments described above, there are no specific guidelines. Most hospitals employ a blend of these concepts, and in general, units can be divided into three types.

1. Medical or Surgical ICU—in most hospitals, severely ill women are transferred to a unit operated by medical and surgical “intensivists.” Admissions or transfers to these units are situation-specific and based on the acuity of care needed and on the ability of the facility to provide it. For example, in most institutions, pregnant women who require ventilatory support, invasive monitoring, or pharmacological support of circulation are transferred to an ICU. Another example is the neurological ICU (Sheth, 2012). A review of more than 25 tertiary-care
referral institutions indicated that approximately 0.5 percent of obstetrical patients are transferred to these types of ICUs (Zeeman, 2006).

2. Obstetrical Intermediate Care Unit—sometimes referred to as a High-Dependency Care Unit (HDU)—an example of this system is the one at Parkland Hospital. Located within the labor and delivery unit, it has designated rooms and experienced personnel. The two-tiered system incorporates the guidelines for intermediate and intensive care. Care is provided by maternal-fetal medicine specialists and nurses with experience in critical care obstetrics. As needed, this team is expanded to include other obstetricians and anesthesiologists, gynecological oncologists, pulmonologists, cardiologists, surgeons, and other medical and surgical subspecialists. Many tertiary-care centers have developed similar intermediate care units and use selected triage to ICUs. Guidelines for such transfers must follow the federal Emergency Medical Treatment and Labor Act (EMTALA) guidelines. According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012), the minimal monitoring required for a critically ill patient during transport includes continuous pulse oximetry, electrocardiography, and regular assessment of vital signs. All critically ill patients must have secure venous access before transfer. Those who are mechanically ventilated must have their endotracheal tube position confirmed and secured before transfer. Left uterine displacement and supplemental oxygen should be applied routinely during transport of antepartum patients. The utility of continuous fetal heart rate or tocodynamic monitoring is unproven, therefore, its use should be individualized.

3. Obstetrical Intensive Care Unit—these units are full-care ICUs as described above, but are operated by obstetrical and anesthesia personnel in the labor and delivery unit. Very few units have these capabilities (Zeeman, 2003, 2006).

For smaller hospitals, transfer to a medical or surgical ICU may be preferable, and sometimes transfer to another hospital is necessary. As discussed, indications for admission to these various types of critical care units are highly variable. Shown in Table 47-2 are some examples. The American College of Obstetricians and Gynecologists (2011a) has summarized critical obstetrical care implementation depending on hospital size and technical facilities. Somewhat related, the concept has been explored of a medical emergency team—MET—for rapid response to emergent obstetrical situations (Gosman, 2008).

Pulmonary Artery Catheter

Data obtained during pregnancy with the pulmonary artery catheter (PAC) have contributed immensely to the understanding of normal pregnancy hemodynamics and pathophysiology of common obstetrical conditions. These include preeclampsia-eclampsia, acute respiratory distress syndrome (ARDS), and amnionic-fluid embolism (Clark, 1988, 1995, 1997; Cunningham, 1986, 1987; Hankins, 1984, 1985). Because of these studies, most have concluded that such monitoring is seldom necessary (American College of Obstetricians and Gynecologists, 2013; Dennis, 2012).

In nonobstetrical patients, randomized trials of nearly 5000 subjects have shown no benefits with pulmonary artery catheter monitoring (Harvey, 2005; Richard, 2003; Sandham, 2003). A randomized trial by the National Heart, Lung, and Blood Institute (2006b) assessed catheter-guided therapy in 1000 patients with ARDS. Invasive monitoring did not improve outcomes and had more complications. According to a recent Cochrane Database review, there have been no randomized trials using this for preeclampsia management (Li, 2012). Overall mechanisms, benefits, and risks were reviewed by Vincent (2011).

Hemodynamic Changes in Pregnancy

Formulas for deriving some hemodynamic parameters are shown in Table 47-3. These measurements can be corrected for body size by dividing by body surface area (BSA) to obtain

In a landmark investigation, Clark and colleagues (1989) used pulmonary artery catheterization to obtain cardiovascular measurements in healthy pregnant women and again in these same women when nonpregnant. These values are shown in Chapter 4 (Table 4-4, p. 60) and are also plotted on a ventricular function curve (Fig. 4-9, p. 59). Because increased blood volume and cardiac output are compensated by decreased vascular resistance and increased pulse rate, ventricular performance remains within the normal range at term. A working knowledge of these changes is paramount to understanding the pathophysiology of pregnancy complications discussed later in this chapter and throughout the book.

### ACUTE PULMONARY EDEMA

The incidence of pulmonary edema complicating pregnancy averages 1 in 500 to 1000 deliveries at tertiary referral centers. The two general causes are: (1) **cardiogenic**—hydrostatic edema caused by high pulmonary capillary hydraulic pressures and (2) **noncardiogenic**—permeability edema caused by capillary endothelial and alveolar epithelial damage. In pregnancy, noncardiogenic pulmonary edema is more common. Taken in toto, studies in pregnant women indicate that more than half who develop pulmonary edema have some degree of sepsis syndrome in conjunction with tocolysis, severe preeclampsia, or obstetrical hemorrhage combined with vigorous fluid therapy (Thornton, 2011). To categorize these differences, Dennis and Solnordal (2012) proposed a classification to include those women who are normotensive or hypotensive versus those with hypertension.

Although cardiogenic pulmonary edema is less frequent, common precipitating causes include resuscitation for hemorrhage and vigorous treatment of preterm labor. The causes in 51 women with pulmonary edema were cardiac failure, tocolytic therapy, iatrogenic fluid overload, or preeclampsia, approximately a fourth each (Sciscione, 2003). In another study, more than half of
cases were associated with preeclampsia, and there was equal distribution of the other three causes (Hough, 2007). Although used less commonly today, tocolytic therapy with β-mimetic drugs at one time was the cause of up to 40 percent of pulmonary edema cases (DiFederico, 1998; Jenkins, 2003).

Noncardiogenic Increased Permeability Edema

Endothelial activation is the common denominator that is associated with preeclampsia, sepsis syndrome, and acute hemorrhage—or frequently combinations thereof—and they are the most common predisposing factors to pulmonary edema (Table 47-4). As discussed, these clinical scenarios are often associated with corticosteroids given to hasten fetal lung maturation along with vigorous fluid replacement and tocolytic therapy (Thornton, 2011). Although parenteral β-agonists are undisputedly linked to pulmonary edema, indictment of magnesium sulfate is less convincing. In one study in which pulmonary edema developed in 8 percent of nearly 800 women given magnesium sulfate for preterm labor, half of these were also given terbutaline (Samol, 2005). In our extensive experiences at Parkland Hospital with the use of magnesium sulfate for neuroprophylaxis for severe preeclampsia, we remain dubious that magnesium per se causes pulmonary edema. Similar conclusions were reached following a review by Martin and Foley (2006).

Cardiogenic Hydrostatic Edema

Ventricular failure causing pulmonary edema in pregnancy is usually associated with some form of gestational hypertension. Although it can be due to congenital or acquired anatomical defects, diastolic dysfunction is frequently from chronic hypertension, obesity, or both (Jessup, 2003; Kenchaiah, 2002). In these women, acute systolic hypertension exacerbates diastolic dysfunction and causes pulmonary edema (Dennis, 2012; Gandhi, 2001). Of note, concentric and eccentric hypertrophy is two- to threefold more common in black women compared with white women.
Despite an underlying cardiomyopathy, heart failure is commonly precipitated by preeclampsia, hypertension, hemorrhage and anemia, and puerperal sepsis (Cunningham, 1986; Sibai, 1987). In many of these, when echocardiography is done later, systolic function is normal as measured by ejection fraction, but evidence for diastolic dysfunction can often be found (Aurigemma, 2004). The use of brain natriuretic peptide (BNP) has not been evaluated extensively in pregnancy (Chap. 4, p. 61 and Appendix, p. 1291). This neurohormone is secreted from ventricle myocytes and fibroblasts with distention seen in heart failure. In nonpregnant patients, values < 100 pg/mL have an excellent negative-predictive value, and levels > 500 pg/mL have an excellent positive-predictive value. It is problematic that levels frequently are 100 to 500 pg/mL, and thus nondiagnostic (Ware, 2005). Values for N-terminal BNP and atrial natriuretic peptide (ANP) are both elevated with preeclampsia (Tihtonen, 2007).

Management

Acute pulmonary edema requires emergency management. Furosemide is given in 20- to 40-mg intravenous doses along with therapy to control dangerous hypertension. Further treatment depends on whether a woman is ante- or postpartum and whether the fetus is alive or not. A live fetus prohibits the use of cardioactive drugs that might lower peripheral resistance and in turn severely diminish uteroplacental circulation. The cause of cardiogenic failure is determined by echocardiography, which will help direct further therapy. Acute pulmonary edema is not, per se, an indication for emergency cesarean delivery. Indeed, in most cases, these women are better served by vaginal delivery.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute lung injury that causes a form of severe permeability pulmonary edema and respiratory failure is termed acute respiratory distress syndrome (ARDS). This is a pathophysiological continuum from mild pulmonary insufficiency to dependence on high inspired oxygen concentrations and mechanical ventilation. Because there are no uniform criteria for its diagnosis, the incidence is variably reported. One review computed it to be 1 in 3000 to 6000 deliveries, and this comports with our experiences at Parkland Hospital (Catanzarite, 2001). In its most extreme form requiring ventilatory support, there is an associated mortality rate of 45 percent. This rate can be as high as 90 percent if caused or complicated by sepsis (Phua, 2009). Although they are younger and usually healthier than the overall population, pregnant women still have mortality rates of 25 to 40 percent (Catanzarite, 2001; Cole, 2005). Finally, if ARDS develops antepartum there is a correspondingly high perinatal mortality rate.

Definitions

Physiological criteria required for diagnosis of acute respiratory distress syndrome are study dependent. In general, less precise terms are used for clinical care. Most investigators have defined ARDS as radiographically documented pulmonary infiltrates, a ratio of arterial oxygen tension to the fraction of inspired oxygen (P\text{ao}_2:F\text{io}_2) < 200, and no evidence of heart failure (Mallampalli, 2010). Recently, the international consensus-revised Berlin Definition was
reported by the ARDS Definition Task Force (2012). It describes categories of mild (200 mm Hg < Pa\textsubscript{o}2/Fi\textsubscript{o}2 ≤ 300 mm Hg); moderate (100 mm Hg < Pa\textsubscript{o}2/Fi\textsubscript{o}2 ≤ 200 mm Hg); and severe (Pa\textsubscript{o}2/Fi\textsubscript{o}2 ≤ 100 mm Hg). To date, for most interventional studies, however, a working diagnosis of acute lung injury is made when the Pa\textsubscript{o}2:Fi\textsubscript{o}2 ratio is < 300 along with dyspnea, tachypnea, oxygen desaturation, and radiographic pulmonary infiltrates (Wheeler, 2007).

### Etiopathogenesis

ARDS is a pathophysiological description that begins with acute lung injury from various causes. Several disorders have been implicated as causes of acute pulmonary injury and permeability edema during pregnancy (Table 47-5). Although many are coincidental, some are more common in pregnant women. For example, in nonpregnant patients, sepsis and diffuse infectious pneumonia are the two most common single-agent causes and together account for 60 percent of cases. In pregnancy, however, pyelonephritis, chorioamnionitis, and puerperal pelvic infection are the most frequent causes of sepsis. As discussed previously, severe preeclampsia and obstetrical hemorrhage are also commonly associated with permeability edema. Importantly, more than half of pregnant women with acute respiratory distress syndrome have some combination of sepsis, shock, trauma, and fluid overload. With acute hemorrhage, the contribution of transfusion-related acute lung injury (TRALI) is unclear in obstetrical patients (Kopko, 2002). This entity is discussed further in Chapter 41 (p. 818).

Endothelial injury in the lung capillaries releases cytokines that recruit neutrophils to the site of inflammation. Here, they elaborate more cytokines to worsen tissue injury. There are three stages
of ARDS development. First, the **exudative phase** follows widespread injury to microvascular endothelium, including the pulmonary vasculature, and there is also alveolar epithelial injury. These result in increased pulmonary capillary permeability, surfactant loss or inactivation, diminished lung volume, and vascular shunting with resultant arterial hypoxemia. Next, the **fibroproliferative phase** usually begins 3 to 4 days later and lasts up to day 21. Last, the **fibrotic phase** results from healing, and despite this, the long-term prognosis for pulmonary function is surprisingly good (Herridge, 2003; Levy, 2012).

### Clinical Course

With pulmonary injury, the clinical condition depends largely on the insult magnitude, the ability to compensate for it, and the disease stage. For example, soon after the initial injury, there commonly are no physical findings except perhaps hyperventilation. And at first, arterial oxygenation usually is adequate. Pregnancy-induced mild metabolic alkalosis may be accentuated by hyperventilation. With worsening, clinical and radiological evidence for pulmonary edema, decreased lung compliance, and increased intrapulmonary blood shunting become apparent. Progressive alveolar and interstitial edema develop with extravasation of inflammatory cells and erythrocytes.

Ideally, pulmonary injury is identified at this early stage, and specific therapy is directed at the insult if possible. Further progression to acute respiratory failure is characterized by marked dyspnea, tachypnea, and hypoxemia. Additional lung volume loss results in worsening of pulmonary compliance and increased shunting. There are now diffuse abnormalities by auscultation, and a chest radiograph characteristically demonstrates bilateral lung involvement (Fig. 47-1). At this phase, the injury ordinarily would be lethal in the absence of high inspired-oxygen concentrations and positive airway pressure by mask or by intubation. When shunting exceeds 30 percent, severe refractory hypoxemia develops along with metabolic and respiratory acidosis that can result in myocardial irritability, dysfunction, and cardiac arrest.
Management

In cases of severe acute lung injury, attempts are made to provide adequate oxygenation of peripheral tissues while ensuring that therapeutic maneuvers do not further aggravate lung injury. At least intuitively, increasing oxygen delivery should produce a corresponding increase in tissue uptake, but this is difficult to measure (Evans, 1999). Support of systemic perfusion with intravenous crystalloid and blood is imperative. As discussed on page 941, the trial conducted by the National Heart, Lung, and Blood Institute (2006b) showed that pulmonary artery catheterization did not improve outcomes. Because sepsis is commonplace in lung injury, vigorous antimicrobial therapy is given for infection, along with debridement of necrotic tissues. Oxygen delivery can be greatly improved by correction of anemia—each gram of hemoglobin carries 1.25 mL of oxygen when 90-percent saturated. By comparison, increasing the arterial $P_o_2$ from 100 to 200 mm Hg results in the transport of only 0.1 mL of additional oxygen for each 100 mL of blood.

Reasonable goals in caring for the woman with severe lung injury are to attain a $P_a_o_2$ of 60 mm Hg or 90-percent saturation at an inspired oxygen content of < 50 percent and with positive end-expiratory pressures < 15 mm Hg. With regard to the pregnancy, it remains controversial whether delivery of the fetus improves maternal oxygenation (Cole, 2005; Mallampalli, 2010).

Mechanical Ventilation

Positive pressure ventilation by face mask may be effective in some women in early stages of
pulmonary insufficiency (Roy, 2007). In an attempt to maximize the fetal environment, early intubation is preferred in the pregnant woman if respiratory failure is more likely than not, and especially if it appears imminent. There are many successful formulas for mechanical ventilation management (Levy, 2012). High-frequency oscillation ventilation (HFOV) has not been shown effective in ARDS (Ferguson, 2013; Slutsky, 2013; Young, 2013). Adjustments are made to obtain a \( \text{Pao}_2 > 60 \text{ mm Hg} \) or a hemoglobin saturation of \( \geq 90 \text{ percent} \) and a \( \text{Pa}_\text{co}_2 \) of 35 to 45 mm Hg. Lower levels for \( \text{Pao}_2 \) should be avoided, because placental perfusion may be impaired (Levinson, 1974).

For women who require ventilation for any length of time, the maternal mortality rate is approximately 20 percent. In a study of 51 such women, of whom almost half had severe preeclampsia, most required intubation postpartum. Eleven were delivered while being ventilated, and another six were discharged undelivered (Jenkins, 2003). There were two maternal deaths, including a woman who died as a complication of tocolytic treatment. In two other reports, maternal mortality rates were 17 and 25 percent (Chen, 2003; Schneider, 2003). None of these investigators concluded that delivery improved maternal outcome.

**Positive End-Expiratory Pressure.** With severe lung injury and high intrapulmonary shunt fractions, it may not be possible to provide adequate oxygenation with usual ventilatory pressures, even with 100-percent oxygen. Positive end-expiratory pressure is usually successful in decreasing the shunt by recruiting collapsed alveoli. At low levels of 5 to 15 mm Hg, positive pressure can typically be used safely. At higher levels, impaired right-sided venous return can result in decreased cardiac output, decreased uteroplacental perfusion, alveolar overdistention, falling compliance, and barotrauma (Slutsky, 2013).

**Extracorporeal Membrane Oxygenation**

As discussed in Chapter 33 (p. 638), extracorporeal membrane oxygenation (ECMO) has been successfully used for neonatal meconium aspiration syndrome. Preliminary observation suggests that it may be useful in adults (Brodie, 2011; Levy, 2012; Peek, 2009). ECMO has been used in pregnant women. In one study, 12 women with influenza-induced lung failure were treated with ECMO, and of four maternal deaths, three were due to anticoagulation-related hemorrhage (Nair, 2011). In other reports, ECMO was used to allow time for lung healing in five pregnant women, and the duration of support in the four survivors was 2 to 28 days (Cunningham, 2006). Technical aspects of ECMO were recently reviewed by Brodie and Bacchetta (2011).

**Fetal Oxygenation**

The propensity of the hemoglobin molecule to release oxygen is described by the [oxyhemoglobin dissociation curve](#). For clinical purposes, the curve can be divided into an upper oxygen association curve representing the alveolar-capillary environment and a lower oxygen dissociation portion representing the tissue-capillary environment. Shifts of the curve have their greatest impact at the steep portion because they affect oxygen delivery. A rightward shift is associated with decreased hemoglobin affinity for oxygen and hence increased tissue-capillary oxygen interchange. Rightward shifts are produced by hypercapnia, metabolic acidosis, fever, and increased 2,3-diphosphoglycerate levels. During pregnancy, the erythrocyte concentration of 2,3-diphosphoglycerate is increased by approximately 30 percent. This favors oxygen delivery to both the fetus and maternal peripheral tissues (Rorth, 1971).
FIGURE 47-2 Oxyhemoglobin dissociation curve. With higher oxygen tension (\(P_{aO_2}\)) in the pulmonary alveoli, adult hemoglobin is maximally saturated compared with that at the lower oxygen tension in the tissue capillaries. Note that at any given oxygen tension, fetal hemoglobin carries more oxygen than adult hemoglobin, as indicated by percent saturation.

Fetal hemoglobin has a higher oxygen affinity than adult hemoglobin. As seen in Figure 47-2, its curve is positioned to the left of the adult curve. To achieve 50-percent hemoglobin saturation in the mother, the \(P_{aO_2}\) must be 27 mm Hg compared with only 19 mm Hg in the fetus. Under normal physiological conditions, the fetus is constantly on the dissociation, or tissue, portion of the curve. Even with severe maternal lung disease and very low \(P_{aO_2}\) levels, oxygen displacement to fetal tissues is favored. Another example of this comes from pregnant women who live at high altitudes, where despite a maternal \(P_{aO_2}\) of only 60 mm Hg, the fetal \(P_{aO_2}\) is equivalent to that of fetuses at sea level (Subrevilla, 1971).

Intravenous Fluids

Although mortality outcomes are similar, conservative versus liberal fluid management is associated with fewer days of mechanical ventilation (Wiedemann, 2006). There are some pregnancy-induced physiological changes that predispose to a greater risk of permeability edema from vigorous fluid therapy. Colloid oncotic pressure (COP) is determined by serum albumin concentration—1 g/dL exerts approximately 6 mm Hg pressure. As discussed in Chapter 4 (p. 67), serum albumin concentrations normally decrease in pregnancy. This results in a decline in oncotic pressure from 28 mm Hg in the nonpregnant woman to 23 mm Hg at term and to 17 mm Hg in the puerperium (Benedetti, 1979; Dennis, 2012). With preeclampsia, endothelial activation with leakage causes extravascular albumin loss and decreased serum albumin levels. As a result in
these cases, oncotic pressure averages only 16 mm Hg antepartum and 14 mm Hg postpartum (Zinaman, 1985). These changes have a significant clinical impact on the colloid oncotic pressure/wedge pressure gradient. Normally, this gradient exceeds 8 mm Hg, however, when it is 4 mm Hg or less, there is an increased risk for pulmonary edema. These associations were recently reviewed by Dennis and Solnordal (2012).

### Other Therapy

There were no benefits from artificial or replacement surfactant therapy in 725 nonpregnant patients with sepsis-induced lung failure (Anzueto, 1996). Although inhalation of nitric oxide was found to cause early improvement, mortality rates were unchanged in two studies (Taylor, 2004; Wheeler, 2007). In a trial conducted by the National Heart, Lung, and Blood Institute (2006a) prolonged methylprednisolone therapy did not reduce mortality rates.

### Long-Term Outcomes

There are no long-term follow-up studies of pregnant women who recover from respiratory distress syndrome. In nonpregnant subjects, there are significant risks for impaired global cognitive function at 3 and 12 months (Pandharipande, 2013). Data from nonpregnant patients indicate a 1- to 2-year hiatus before basic normal activity is restored in all. In a 5-year follow-up study, Herridge and associates (2011) reported normal lung function but significant exercise limitation, physical and psychological sequelae, decreased physical quality of life, and increased costs and use of health-care services.

### SEPSIS SYNDROME

Sepsis is derived from the ancient Greek sepein, “to rot.” The sepsis syndrome is induced by a systemic inflammatory response to bacteria or viruses or their by-products such as endotoxins or exotoxins. The severity of the syndrome is a continuum or spectrum (Fig. 47-3). Infections that most commonly cause the sepsis syndrome in obstetrics are pyelonephritis (Chap. 53, p. 1054), chorioamnionitis and puerperal sepsis (Chap. 37, p. 683), septic abortion (Chap. 18, p. 356), and necrotizing fasciitis (Chap. 37, p. 686). The mortality rate in nonpregnant patients is 20 to 35 percent with severe sepsis and 40 to 60 percent with septic shock (Angus, 2013; Munford, 2012). Mabie and coworkers (1997) reported a 28-percent mortality rate in 18 pregnant women with sepsis and shock. That said, the maternal mortality risk from sepsis is significantly underestimated (Acosta, 2013).
FIGURE 47-3 The sepsis syndrome begins with a systemic inflammatory response syndrome (SIRS) in response to infection that may progress to septic shock.

**Etiopathogenesis**

Most of what is known concerning sepsis pathogenesis comes from study of lipopolysaccharide—LPS or endotoxin (Munford, 2012). The lipid A moiety is bound by mononuclear blood cells becomes internalized, and stimulates release of mediators and a series of complex downstream perturbations. Clinical aspects of the sepsis syndrome are manifest when cytokines are released that have endocrine, paracrine, and autocrine effects (Angus, 2013).

Although the sepsis syndrome in obstetrics may be caused by several pathogens, most cases represent a small group. For example, pyelonephritis complicating pregnancy caused by *Escherichia coli* and *Klebsiella* species commonly is associated with bacteremia and sepsis syndrome (Cunningham, 1987; Mabie, 1997). And although pelvic infections are usually polymicrobial, bacteria that cause severe sepsis syndrome are frequently endotoxin-producing Enterobacteriaceae, most commonly *E coli*. Other pelvic pathogens are aerobic and anaerobic streptococci, *Bacteroides* species, and *Clostridium* species. Some strains of group A β-hemolytic streptococci and *Staphylococcus aureus*—including community-acquired methicillin-resistant strains (CA-MRSA)—produce a superantigen that activates T cells to rapidly cause all features of
the sepsis syndrome—*toxic shock syndrome* (Moellering, 2011; Soper, 2011). This is discussed further in Chapter 37 (p. 690).

There are also potent bacterial *exotoxins* that can cause severe sepsis syndrome. Examples include exotoxins from *Clostridium perfringens*, toxic-shock-syndrome toxin-1 (TSST-1) from *S. aureus*, and toxic shock-like exotoxin from group A β-hemolytic streptococci (Daif, 2009; Soper, 2011). These last exotoxins cause rapid and extensive tissue necrosis and gangrene, especially of the postpartum uterus, and may cause profound cardiovascular collapse and maternal death (Nathan, 1993; Sugiyama, 2010). In a review discussed subsequently, the maternal mortality rate from these infections was 58 percent (Yamada, 2010).

Thus, the sepsis syndrome begins with an inflammatory response that is directed against microbial endotoxins and exotoxins (Angus, 2013). CD4 T cells and leukocytes are stimulated to produce proinflammatory compounds that include tumor necrosis factor-α (TNF-α), several interleukins, other cytokines, proteases, oxidants, and bradykinin that result in a “cytokine storm” (Que, 2005; Russell, 2006). Many other cellular reactions then follow that include stimulation of pro- and antiinflammatory compounds, procoagulant activity, gene activation, receptor regulation, and immune suppression (Filbin, 2009; Moellering, 2011). It is also likely that IL-6 mediates myocardial suppression (Pathan, 2004).

The pathophysiological response to this cascade is selective vasodilation with maldistribution of blood flow. Leukocyte and platelet aggregation cause capillary plugging. Worsening endothelial injury causes profound permeability capillary leakage and interstitial fluid accumulation (Fig. 47-4). Depending on the degree of injury and inflammatory response, there is a pathophysiological and clinical continuum as depicted in Figure 47-3. The clinical syndrome begins with subtle signs of sepsis from infection and terminates with *septic shock*, which is defined by hypotension unresponsive to intravenous hydration. In its early stages, clinical shock results primarily from decreased systemic vascular resistance that is not compensated fully by increased cardiac output. Hypoperfusion results in lactic acidosis, decreased tissue oxygen extraction, and end-organ dysfunction that includes acute lung and kidney injury.
FIGURE 47-4 Endothelial permeability. The normal interendothelial interface is shown in the left inset. Cytokines and other inflammatory mediators disassemble the cellular junctions, resulting in microvascular leaks (right). (Modified from Lee, 2010.)

Clinical Manifestations

The sepsis syndrome has myriad clinical manifestations that, at least in part, are dependent on the specific invading microorganism and its particular endo- or exotoxins. Some of the general effects of LPS are as follows:

1. Central nervous system: confusion, somnolence, coma, combative- ness, fever, or hypoxemia
2. Cardiovascular: tachycardia, hypotension
3. Pulmonary: tachypnea, arteriovenous shunting with dysoxia and hypoxemia, exudative infiltrates from endothelial-alveolar damage, pulmonary hypertension
4. Gastrointestinal: gastroenteritis—nausea, vomiting, and diarrhea; hepatocellular necrosis—jaundice, hyperglycemia
5. Renal: prerenal oliguria, acute kidney injury
6. Hematological: leukocytosis or leukopenia, thrombocytopenia, activation of coagulation with disseminated intravascular coagulation

Thus, although capillary leakage initially causes hypovolemia, if intravenous crystalloid is given at this point, then sepsis hemodynamically can be described as a high cardiac output, low systemic vascular resistance condition (Fig. 47-5). Concomitantly, pulmonary hypertension develops, and despite the high cardiac output, severe sepsis likely also causes myocardial
depression (Ognibene, 1988). This is often referred to as the warm phase of septic shock. These findings are the most common cardiovascular manifestations of early sepsis, but they can be accompanied by some of the other clinical or laboratory aberrations listed above.

The response to initial intravenous hydration may be prognostic. Most pregnant women who have early sepsis show a salutary response with crystalloid and antimicrobial therapy, and if indicated, debridement of infected tissue. Conversely, if hypotension is not corrected following vigorous fluid infusion, then the prognosis is more guarded. At this juncture, if there also is no response to β-adrenergic inotropic agents, this indicates severe and unresponsive extracellular...
fluid extravasation with vascular insufficiency, overwhelming myocardial depression, or both. Oliguria and continued peripheral vasoconstriction characterize a secondary, cold phase of septic shock that is rarely survived. Another poor prognostic sign is continued renal, pulmonary, and cerebral dysfunction once hypotension has been corrected (Angus, 2013). The average risk of death increases by 15 to 20 percent with failure of each organ system. With three systems, mortality rates are 70 percent (Martin, 2003; Wheeler, 1999).

Management

In 2004 an internationally directed consensus effort was launched as the Surviving Sepsis Campaign (Dellinger, 2008). The cornerstone of management is early goal-directed management, and it stresses prompt recognition of serious bacterial infection and close monitoring of vital signs and urine flow. Institution of this protocol has improved survival rates (Angus, 2013; Barochia, 2010).

An algorithm for management of sepsis syndrome is shown in Figure 47-6. The three basic steps are performed as simultaneously as possible and include evaluation of the sepsis source and its sequelae, cardiopulmonary function assessment, and immediate management. The most important step in sepsis management is rapid infusion of 2 L and sometimes as many as 4 to 6 L of crystalloid fluids to restore renal perfusion in severely affected women (Vincent, 2013). Simultaneously, appropriately chosen broad-spectrum antimicrobials are begun. There is hemoconcentration because of the capillary leak. Thus, if anemia coexists with severe sepsis, then blood is given along with crystalloid to maintain the hematocrit at approximately 30 percent (Munford, 2012; Rivers, 2001). The use of colloid solution such as hetastarch is controversial, and we as well as others do not recommend its use (Angus, 2013; Ware, 2000). Indeed, a recent Scandinavian randomized trial comparing hydroxyethyl starch and Ringer acetate reported a higher mortality rate with the starch solution (Perner, 2012). Another recent study found equivalent results with 6-percent hydroxyethyl starch compared with normal saline (Myburgh, 2012). In vasopressor-dependent shock, some recommend albumin infusions (Angus, 2013; Vincent, 2013).

Aggressive volume replacement ideally is promptly followed by urinary output of at least 30 and preferably 50 mL/hr, as well as other indicators of improved perfusion. If not, then consideration is given for vasoactive drug therapy. Mortality rates are high when sepsis is further complicated by respiratory or renal failure. With severe sepsis, damage to pulmonary capillary endothelium and alveolar epithelium causes alveolar flooding and pulmonary edema. This may occur even with low or normal pulmonary capillary wedge pressures, as with the acute respiratory distress syndrome discussed on page 943 and depicted in Figure 47-1.

Broad-spectrum antimicrobials are chosen empirically based on the source of infection. They are given promptly in maximal doses after appropriate cultures are taken of blood, urine, or exudates not contaminated by normal flora. In severe sepsis, appropriate empirical coverage results in better survival rates (Barochia, 2010; MacArthur, 2004). Acute pyelonephritis is usually caused by Enterobacteriaceae as discussed in Chapter 53 (p. 1054). For pelvic infections, empirical coverage with regimens such as ampicillin plus gentamicin plus clindamycin generally suffices (Chap. 37, p. 685). Associated incisional and other soft-tissue infections are increasingly likely to be caused by methicillin-resistant *S aureus*, thus vancomycin therapy is added (Kleven, 2007; Rotas, 2007). With a septic abortion, a Gram-stained smear may be helpful in identifying *Clostridium perfringens* or group A streptococcal organisms. This is also true for deep fascial infections.

**Surgical Treatment**

Continuing sepsis may prove fatal, and debridement of necrotic tissue or drainage of purulent material is crucial (Angus, 2013; Mabie, 1997). In obstetrics, the major causes of sepsis are infected abortion, pyelonephritis, and puerperal pelvic infections that include infection of perineal lacerations or of hysterotomy or laparotomy incisions. With an infected abortion, uterine contents must be removed promptly by curettage as described in Chapter 18 (p. 356). Hysterectomy is seldom indicated unless gangrene has resulted.

For women with pyelonephritis, continuing sepsis should prompt a search for obstruction caused by calculi or by a perinephric or intrarenal phlegmon or abscess. Renal sonography or “one-shot” pyelography may be used to diagnose obstruction and calculi. Computed tomography (CT) may be helpful to identify a phlegmon or abscess. With obstruction, ureteral catheterization, percutaneous nephrostomy, or flank exploration may be lifesaving (Chap. 53, p. 1057).

Most cases of puerperal pelvic sepsis are clinically manifested in the first several days postpartum, and intravenous antimicrobial therapy without tissue debridement is generally curative. There are several exceptions. First is massive uterine myonecrosis caused by group A β-hemolytic streptococcal or clostridial infections (Soper, 2011; Sugiyama, 2010; Yamada, 2010). Those with early-onset disease have presenting findings listed in Table 47-6. The mortality rate in these women with gangrene as shown in Figure 47-7 is high, and prompt hysterectomy may be lifesaving (Mabie, 1997; Nathan, 1993). Group A β-hemolytic streptococci and clostridial colonization or infection also cause toxic-shock syndrome without obvious gangrene as reviewed by Mason and Aronoff (2012). These are due to either streptococcal toxic-shock syndrome-like toxin or clostridial exotoxin that evolved from *S aureus* (Chap. 37, p. 690). In many of these cases, there is bacteremia and widespread tissue invasion, but an intact uterus and abdominal incisions. If uterine necrosis can be excluded—usually by CT scanning—then in our experiences, as well as in
others, hysterectomy may not be necessary (Soper, 2011). Still, these infections are highly lethal (Yamada, 2010).

Data from Yamada, 2010.

**FIGURE 47-7** A fatal case of group A β-hemolytic *Streptococcus pyogenes* puerperal infection following an uncomplicated vaginal delivery at term. The infection caused uterine gangrene and overwhelming sepsis syndrome. Arrows point to overtly “ballooned-out” black gangrenous areas of the postpartum uterus at the time of laparotomy for hysterectomy.
A second exception is necrotizing fasciitis of the episiotomy site or abdominal surgical incision. As described by Gallup and coworkers (2002), these infections are a surgical emergency and are aggressively managed as discussed in Chapter 37 (p. 686).

Third, persistent or aggressive uterine infection with necrosis, uterine incision dehiscence, and severe peritonitis may lead to sepsis (Chap. 37, p. 688). Thus, women following cesarean delivery who are suspected of having peritonitis should be carefully evaluated for uterine incisional necrosis or bowel perforation. These infections tend to be less aggressive than necrotizing group A streptococcal infections and develop later postpartum. CT imaging of the abdomen and pelvis can frequently determine if either of these has eventuated. If either is suspected, then prompt surgical exploration is indicated. With incisional necrosis, hysterectomy is usually necessary (Fig. 37-4, p. 688). Last, peritonitis and sepsis much less commonly may result from a ruptured parametrial, intraabdominal, or ovarian abscess (Chap. 37, p. 687).

**Adjunctive Therapy**

**Vasoactive Drugs and Corticosteroids.** As shown in Figure 47-6, a septic woman is supported with continuing crystalloid infusion, blood transfusions, and ventilation. In some cases, other measures may be necessary. Of options, vasoactive drugs are not given unless aggressive fluid treatment fails to correct hypotension and perfusion abnormalities. First-line vasopressors are norepinephrine, epinephrine, dopamine, dobutamine, or phenylephrine (Vincent, 2013). Low-dose vasopressin combined with norepinephrine infusion did not improve survival (Russell, 2008).

The use of corticosteroids remains controversial. Serum cortisol levels are typically elevated in sepsis, and higher levels are associated with increased mortality rates (Sam, 2004). Some but not all studies show a salutary effect of corticosteroid administration. It is thought that *critical illness-related corticosteroid insufficiency*—CIRCI—may play a role in recalcitrant hypotension. Thus, corticosteroids may be considered for use in vasopressor-dependent patients (Angus, 2013; Dellinger, 2008).

**Coagulopathy.** Endotoxin stimulates endothelial cells to upregulate tissue factor and thus procoagulant production (Chap. 41, p. 808). At the same time, it decreases the anticoagulant action of activated protein C. Several agents developed to block coagulation, however, did not improve outcomes—some include antithrombin III, platelet-activating factor antagonist, and tissue factor pathway inhibitor (Abraham, 2003; Suffredini, 2011; Warren, 2001). A 10-year dalliance with recombinant activated protein C—drotrecogin alfa—followed after results of an early trial were promising. However, subsequent randomized trials have shown no survival benefits (Ranieri, 2012; Wenzel, 2012). Experience with its use in pregnancy had been limited to case reports (Eppert, 2011; Gupta, 2011; Medve, 2005).

**Other Therapies.** There are several other therapies that have proven ineffective. Some of these include antiendotoxin antibody and E5 murine monoclonal IgM antiendotoxin antibody; anticytokine antibodies to IL-1, TNF-α, and bradykinin; and a nitric oxide synthase inhibitor (Munford, 2012; Russell, 2006).

**TRAUMA**

Traumatic injuries such as homicide and similar violent events are a leading cause of death in young women. Depending on definitions used, up to 20 percent of pregnant women suffer physical...
trauma (American College of Obstetricians and Gynecologists, 2010; Romero, 2012). Injury-related deaths are the most commonly identified nonobstetrical cause of maternal mortality (Brown, 2009; Horon, 2001). In a California study of 4.8 million pregnancies, almost 1 in 350 women were hospitalized for injuries from assaults (El Kady, 2005). In an audit from Parkland Hospital, motor vehicle accidents and falls accounted for 85 percent of injuries sustained by 1682 pregnant women (Hawkins, 2007). Homicides and suicides are also a major cause of pregnancy-associated deaths (Lin, 2011; Shadigian, 2005). From the National Violent Death Reporting System, Palladino and colleagues (2011) found that there were 2.0 pregnancy-associated suicides per 100,000 live births. The rate was 2.9 per 100,000 for pregnancy-associated homicides. And interrelated, intimate partner violence may be linked to these suicides (Martin, 2007).

### Blunt Trauma

#### Physical Abuse—Intimate Partner Violence

According to the United States Department of Justice (2013), women aged 16 to 24 years have the highest per capita rates of intimate partner violence—19.4 per 1000. As many as 10 million women each year are physically assaulted, sexually assaulted, or stalked by an intimate partner (Centers for Disease Control and Prevention, 2013a). One goal in violence prevention for Healthy People 2010 was the reduction of physical abuse directed at women by male partners. The Pregnancy Risk Assessment Monitoring Systems—PRAMS—report showed some improvement in these areas (Suellentrop, 2006).

Even more appalling is that physical violence directed at women continues during pregnancy. Most data have been accrued by public institutions, and abuse rates range from 1 to 20 percent during pregnancy (American College of Obstetricians and Gynecologists, 2011b). In Phoenix more than 13 percent of women who enrolled for prenatal services had a history of physical or sexual abuse (Coonrod, 2007). Abuse is linked to poverty, poor education, and use of tobacco, alcohol, and illicit drugs (Centers for Disease Control and Prevention, 2008). Unfortunately abused women tend to remain with their abusers, and the major risk factor for intimate partner homicide is prior domestic violence (Campbell, 2007). Finally, women seeking pregnancy termination have a higher incidence of intimate partner violence (Bourassa, 2007).

The woman who is physically abused tends to present late, if at all, for prenatal care. In the study cited above, pregnant women hospitalized in California as a result of assault had significantly increased perinatal morbidity rates (El Kady, 2005). Immediate sequelae included uterine rupture, preterm delivery, and maternal and perinatal death. Subsequent outcomes included increased rates of placental abruption, preterm and low-birthweight infants, and other adverse outcomes. Silverman and associates (2006) reported similar results from PRAMS, which included more than 118,000 pregnancies in 26 states. Others have cited increased preterm birth and depression (Rodriguez, 2008).

Preventively, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend universal screening for intimate partner violence at the initial prenatal visit, during each trimester, and again at the postpartum visit (Chap. 9, p. 174). Others recommend a case-finding approach based on clinical suspicion (Robertson-Blackmore, 2013; Wathen, 2003).

#### Sexual Assault

According to the Centers for Disease Control and Prevention (2012), 20 percent of adult women
will be sexually assaulted sometime during their lives. More than 90 percent of the nearly 200,000 rape victims in the United States in 2006 were women; 80 percent were younger than 30 years; and 44 percent were younger than 18. Satin and coworkers (1992) reviewed more than 5700 female sexual assault victims in Dallas County and reported that 2 percent were pregnant. Associated physical trauma is common (Sugar, 2004). From a forensic standpoint, evidence collection protocol is not altered (Linden, 2011).

In addition to attention to physical injuries, exposure to sexually transmitted diseases must be considered. The Centers for Disease Control and Prevention (2010) recommends antimicrobial prophylaxis against gonorrhea, chlamydial infection, and trichomoniasis (Table 47-7). If the woman is not pregnant, another very important aspect is emergency contraception, as recommended by the American College of Obstetricians and Gynecologists (2012) and discussed in detail in Chapter 38 (p. 714).

| TABLE 47-7. Guidelines for Prophylaxis against Sexually Transmitted Disease in Victims of Sexual Assault |
The importance of psychological counseling for the rape victim and her family cannot be overemphasized. There is a 30- to 35-percent lifetime risk each for posttraumatic stress disorder, major depression, and suicide contemplation (Linden, 2011).

### Automobile Accidents
At least 3 percent of pregnant women are involved in motor vehicle accidents each year in the United States. Using data from PRAMS, Sirin and colleagues (2007) estimated that 92,500 pregnant women are injured annually. Motor-vehicle crashes are the most common causes of serious, life-threatening, or fatal blunt trauma during pregnancy (Brown, 2009; Luley, 2013; Patteson, 2007; Vladutiu, 2013). Mattox and Goetzl (2005) report these accidents to be the leading

cause of traumatic fetal deaths as well, and this was also true for Parkland Hospital (Hawkins, 2007). As with all motor vehicle crashes, alcohol use is commonly associated. But sadly, as many as half of accidents occur without seat-belt use, and many of these deaths would likely be preventable by the three-point restraints shown in Figure 47-8 (Klinich, 2008; Luley, 2013; Metz, 2006). Seat belts prevent contact with the steering wheel, and they reduce abdominal impact pressure (Motozawa, 2010).

![Figure 47-8](image)

**FIGURE 47-8** Illustration showing correct use of three-point automobile restraint. The upper belt is *above* the uterus, and the lower belt fits snugly across the upper thighs and well *below* the uterus.

Original concerns regarding injuries caused by airbag deployment have been somewhat allayed (Matsushita, 2014). One study included 30 such women from 20 to 37 weeks’ gestation whose airbag deployed in accidents with a median speed of 35 mph (Metz, 2006). A third were not using seat belts, and there was one fetal death from the single case of placental abruption. Almost 75 percent had contractions, half had abdominal pain, and in 20 percent, there were abnormal fetal heart rate tracings. In a retrospective cohort study that included 2207 pregnant women in crashes
with airbag deployment, perinatal outcomes were not clinically different from 1141 controls without airbags (Schiff, 2010). Importantly, 96 percent of both groups used seat belts.

**Other Blunt Trauma**

Some other common causes of blunt trauma are falls and aggravated assaults. In the California review reported by El Kady and associates (2005), intentionally inflicted injuries were present in approximately a third of pregnant women who were hospitalized for trauma. Less common are blast or crush injury (Sela, 2008). With blunt trauma, there can be serious intraabdominal injuries. Even so, bowel injuries are less frequent because of the protective effect of a large uterus. Still, diaphragmatic, splenic, liver, and kidney injuries may also be sustained. Particularly worrisome is the specter of amnionic-fluid embolism, which has been reported with even mild trauma (Ellingsen, 2007; Pluymakers, 2007). Retroperitoneal hemorrhage is possibly more common than in nonpregnant women (Takehana, 2011).

Orthopedic injuries are also encountered with some regularity (Desai, 2007). From the Parkland Hospital trauma unit, 6 percent of 1682 pregnant women evaluated had orthopedic injuries. This subset was also at increased risk for placental abruption, preterm delivery, and perinatal mortality (Cannada, 2008). In a review of 101 pelvic fractures during pregnancy, there was a 9-percent maternal and 35-percent fetal mortality rate (Leggon, 2002). In another study of pelvic and acetabular fractures during 15 pregnancies, there was one maternal death, and four of 16 fetuses died (Almog, 2007). Finally, head trauma and neurosurgical care raise unique issues (Qaiser, 2007).

**Fetal Injury and Death**

Perinatal death rates increase with the severity of maternal injuries. Fetal death is more likely with direct fetoplacental injury, maternal shock, pelvic fracture, maternal head injury, or hypoxia (Ikossi, 2005; Pearlman, 2008). Motor vehicle accidents caused 82 percent of fetal deaths from trauma. Death was caused by placental injury in half, and by uterine rupture in 4 percent (Weiss, 2001). Patteson and coworkers (2007) reported similar findings.

Although uncommon, fetal skull and brain injuries are more likely if the head is engaged and the maternal pelvis is fractured (Palmer, 1994). Conversely, fetal head injuries, presumably from a contrecoup effect, may be sustained in unengaged vertex or nonvertex presentations. Fetal skull fractures are rare and best seen using CT imaging (Sadro, 2012). Sequelae include intracranial hemorrhage (Green-Thompson, 2005). A newborn with paraplegia and contractures associated with a motor vehicle accident sustained several months before birth was described by Weyerts and colleagues (1992). Other injuries have included fetal decapitation or incomplete midabdominal fetal transection at midpregnancy (Rowe, 1996; Weir, 2008).

**Placental Injuries—Abruptio Placentae or Tear**

Catastrophic events that occur with blunt trauma include placental injuries—abruption or placental tear or “fracture”—and uterine rupture (Fig. 47-9 and 47-10). Placental separation from trauma is likely caused by deformation of the elastic myometrium around the relatively inelastic placenta (Crosby, 1968). This may result from a deceleration injury as the large uterus meets the immovable steering wheel or seat belt. Some degree of abruption complicates 1 to 6 percent of “minor” injuries and up to 50 percent of “major” injuries (Pearlman, 1990; Schiff, 2002). Abruption was found to be more likely if vehicle speed exceeded 30 mph (Reis, 2000).
Acute deceleration injury occurs when the elastic uterus meets the steering wheel. As the uterus stretches, the inelastic placenta shears from the decidua basalis. Intrauterine pressures as high as 550 mm Hg are generated.
Clinical findings with traumatic abruption may be similar to those for spontaneous placental abruption (Chap. 41, p. 796). Kettel and coworkers (1988) emphasized that traumatic abruption may be occult and unaccompanied by uterine pain, tenderness, or bleeding. Stettler and associates (1992) reviewed our experiences with 13 such women at Parkland Hospital. Of these, 11 had uterine tenderness, but only five had vaginal bleeding. Because traumatic abruption is more likely to be concealed and generate higher intrauterine pressures, associated coagulopathy is more likely than with nontraumatic abruption. Partial separation may also generate uterine activity as described more fully on page 955. Other features are evidence of fetal compromise such as fetal
tachycardia, late decelerations, and acidosis and fetal death.

If there is considerable abdominal force associated with trauma, then the placenta can be torn, or “fractured” (see Fig. 47-10). If so, then life-threatening fetal hemorrhage may be encountered either into the amnionic sac or by fetomaternal hemorrhage (Pritchard, 1991). The tear is linear or stellate such as shown in Figure 47-11 and is caused by rapid deformation and reformation. Especially if there is ABO compatibility, fetomaternal hemorrhage is quantified using a Kleihauer-Betke stain of maternal blood (see Fig. 47-11). A small amount of fetal-maternal bleeding has been described in up to a third of trauma cases, and in 90 percent of these, the volume is < 15 mL (Goodwin, 1990; Pearlman, 1990). Nontraumatic placental abruption is much less often associated with significant fetomaternal hemorrhage because there usually is only minimal fetal bleeding into the intervillous space. With traumatic abruption, however, massive fetomaternal hemorrhage may coexist (Stettler, 1992). In one study there was a 20-fold risk of associated uterine contractions and preterm labor if there is evidence for a fetomaternal bleed (Muench, 2004).

**FIGURE 47-11** **A.** Partial placental abruption in which the adherent blood clot has been removed. Note the laceration of the placenta (arrow), which caused fetal death from massive fetomaternal hemorrhage. **B.** Kleihauer–Betke stain of a peripheral smear of maternal blood. The dark cells that constituted 4.5 percent of red blood cells are fetal in origin, whereas the empty cells are maternal.

**Uterine Rupture**

Blunt trauma results in uterine rupture in < 1 percent of severe cases (American College of Obstetricians and Gynecologists, 2010). Rupture is more likely in a previously scarred uterus and is usually associated with a direct impact of substantial force. Decelerative forces following a 25-mph collision can generate up to 500 mm Hg of intrauterine pressure in a properly restrained woman (Crosby, 1968). Clinical findings may be identical to those for placental abruption with an intact uterus, and maternal and fetal deterioration are soon inevitable. Pearlman and Cunningham (1996) described uterine fundal “blowout” with fetal decapitation in a 20-week pregnancy following a high-speed collision. Similarly, Weir and colleagues (2008) described supracaevical
uterine avulsion and fetal transection at 22 weeks. CT scanning may be useful to diagnose uterine rupture with a dead fetus or placental separation (Kopelman, 2013; Manriquez, 2010; Sadro, 2012; Takehana, 2011).

**Penetrating Trauma**

In a study of 321 pregnant women with abdominal trauma, Petrone (2011) reported a 9-percent incidence of penetrating injuries—77 percent were gunshot wounds and 23 percent were stab wounds. The incidence of maternal visceral injury with penetrating trauma is only 15 to 40 percent compared with 80 to 90 percent in nonpregnant individuals (Stone, 1999). When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be seriously injured. Indeed, although the fetus sustains injury in two thirds of cases with penetrating uterine injuries, maternal visceral injuries are seen in only 20 percent. Still, their seriousness is underscored in that maternal-fetal mortality rates are significantly higher than those seen with blunt abdominal injuries in pregnancy. Specifically, maternal mortality was 7 versus 2 percent, and fetal mortality was 73 versus 10 percent, respectively.

**Management of Trauma**

Maternal and fetal outcomes are directly related to the severity of injury. That said, commonly used methods of severity scoring do not take into account significant morbidity and mortality rates related to placental abruption and thus to pregnancy outcomes. In a study of 582 pregnant women hospitalized for injuries, the injury severity score did not accurately predict adverse pregnancy outcomes (Schiff, 2005). Importantly, relatively minor injuries were associated with preterm labor and placental abruption. Others have reached similar conclusions (Biester, 1997; Ikossi, 2005). In a study of 317 pregnant women at 24 weeks’ gestation or more who had “minor trauma,” 14 percent had clinically significant uterine contractions requiring extended fetal evaluation past 4 hours (Cahill, 2008).

With few exceptions, treatment priorities in injured pregnant women are directed as they would be in nonpregnant patients (Barraco, 2010; Mirza, 2010). Primary goals are evaluation and stabilization of maternal injuries. Attention to fetal assessment during the acute evaluation may divert attention from life-threatening maternal injuries (American College of Obstetricians and Gynecologists, 2010; Brown, 2009). Basic rules of resuscitation include ventilation, arrest of hemorrhage, and treatment of hypovolemia with crystalloid and blood products. Importantly, the large uterus is positioned off the great vessels to diminish its affect on vessel compression and decreased cardiac output.

Following emergency resuscitation, evaluation is continued for fractures, internal injuries, bleeding sites, and placental, uterine, and fetal trauma. Radiography is not proscribed, but special attention is given to indications. One report observed that pregnant trauma victims had less radiation exposure than nonpregnant controls (Ylagan, 2008). Brown and colleagues (2005) advocated screening abdominal sonography followed by CT scanning for positive sonographic findings. Procedures used include the FAST scan—focused assessment with sonography for trauma. This is a 5-minute, four- to six-view imaging study that evaluates perihepatic, perisplenic, pelvic, and pericardial views (Rose, 2004). In general, if fluid is seen in any of these views, then the volume is > 500 mL. However, this amount has not been corroborated for pregnancy. In some cases, open peritoneal lavage may be informative (Tsuei, 2006).

Penetrating injuries in most cases must be evaluated using radiography. Because clinical
response to peritoneal irritation is blunted during pregnancy, an aggressive approach to exploratory laparotomy is pursued. Whereas exploration is mandatory for abdominal gunshot wounds, some clinicians advocate close observation for selected stab wounds. Diagnostic laparoscopy has also been used (Chap. 46, p. 928).

**Cesarean Delivery**
The necessity for cesarean delivery of a live fetus depends on several factors. Laparotomy itself is not an indication for hysterotomy. Some considerations include gestational age, fetal condition, extent of uterine injury, and whether the large uterus hinders adequate treatment or evaluation of other intraabdominal injuries (Tsuei, 2006).

**Electronic Monitoring**
As for many other acute or chronic maternal conditions, fetal well-being may reflect the status of the mother. Thus, fetal monitoring is another “vital sign” that helps to evaluate the extent of maternal injuries. Even if the mother is stable, electronic monitoring may suggest placental abruption. In a study by Pearlman and coworkers (1990), no woman had an abruption if uterine contractions were less often than every 10 minutes within the 4 hours after trauma was sustained. Almost 20 percent of women who had contractions more frequently than every 10 minutes in the first 4 hours had an associated placental abruption. In these cases, abnormal tracings were common and included fetal tachycardia and late decelerations. Conversely, no adverse outcomes were reported in women who had normal monitor tracings (Connolly, 1997). Importantly, if tocolytics are used for these contractions, they may obfuscate findings, and we do not recommend them.

Because placental abruption usually develops early following trauma, fetal monitoring is begun as soon as the mother is stabilized. The ideal duration of posttrauma monitoring is not precisely known. From data cited above, observation for 4 hours is reasonable with a normal tracing and no other sentinel findings such as contractions, uterine tenderness, or bleeding. Certainly, monitoring should be continued as long as there are uterine contractions, nonreassuring fetal heart patterns, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes (American College of Obstetricians and Gynecologists, 2010). In rare cases, placental abruption has developed days after trauma (Higgins, 1984).

**Fetal-Maternal Hemorrhage**
It is unclear whether routine use of the Kleihauer-Betke or an equivalent test in pregnant trauma victims might modify adverse outcomes associated with fetal anemia, cardiac arrhythmias, and death (Pak, 1998). In a retrospective review of 125 pregnant women with blunt injuries, the Kleihauer-Betke test was reported to have a sensitivity of 56 percent, a specificity of 71 percent, and an accuracy of 27 percent (Towery, 1993). These investigators concluded that the test was of little value during acute trauma management. They also concluded that electronic fetal monitoring or sonography or both were more useful in detecting fetal or pregnancy-associated complications than the Kleihauer-Betke test. Others have reached similar conclusions, although a positive test with fetal cells of 0.1 percent was predictive of uterine contractions or preterm labor (Connolly, 1997; Muench, 2003, 2004).

For the woman who is D-negative, administration of anti-D immunoglobulin should be considered. This may be omitted if a test for fetal bleeding is negative. Even with anti-D immunoglobulin, alloimmunization may still develop if the fetal-maternal hemorrhage exceeds 15
mL of fetal cells (Chap. 15, p. 311).

Another important aspect of care for the pregnant trauma patient is to ensure that her tetanus immunization is current. When indicated, a dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) is preferred for its neonatal pertussis immunity benefits described in Chapter 9 (p. 184) (Centers for Disease Control and Prevention, 2013b). If unavailable, tetanus toxoid (TT) or tetanus and diphtheria toxoids (Td) are suitable alternatives.

THERMAL INJURY

Treatment of burned pregnant women is similar to that for nonpregnant patients (Pacheco, 2005). With treatment, it is generally agreed that pregnancy does not alter maternal outcome from thermal injury compared with that of nonpregnant women of similar age. As perhaps expected, maternal and fetal survival parallels the percentage of burned surface area. Karimi and colleagues (2009) reported higher mortality rates for both with suicidal attempts and with inhalational injuries. The composite mortality for more than 200 women from six studies increased in a linear fashion as the percent body-surface area burned increased (Fig. 47-12). For 20-, 40-, and 60-percent burns, the maternal mortality rates were approximately 4, 30, and 93 percent, respectively. The corresponding fetal mortality rates were 20, 48, and 96 percent, respectively. With severe burns, the woman usually enters labor spontaneously within a few days to a week and often delivers a stillborn. Contributory factors are hypovolemia, pulmonary injury, septicemia, and the intensely catabolic state associated with these burns (Radosevich, 2013).

![Maternal and fetal mortality rates by burn severity in 211 women. (Data from Akhtar, 1994; Amy, 1985; Mabrouk, 1977; Maghsoudi, 2006; Rayburn, 1984; Rode, 1990.)](image)

Following serious abdominal burns, skin contractures that develop may be painful during a subsequent pregnancy and may even require surgical decompression and split-skin autografts (Matthews, 1982; Widgerow, 1991). In a follow-up study of seven women with severe circumferential truncal burns sustained at a mean age of 7.7 years, all of 14 subsequent pregnancies were delivered at term without major complications (McCauley, 1991). Loss or distortion of nipples may cause problems in breast feeding (Fig. 47-13). Interestingly, normal
abdominal tissue expansion due to pregnancy appears to be an excellent source for obtaining skin grafts postpartum to correct scar deformities at other body sites (Del Frari, 2004).

**FIGURE 47-13** This 22-year-old nullipara sustained severe burns at age 12 years, and massive scarring followed. Both breasts were replaced by scar tissue. Following delivery, a few drops of colostrum were expressed from the left nipple, but no breast engorgement was noted. (Photograph contributed by Drs. A. R. Mahale and A. P. Sakhare, Maharashtra, India.)

### Electrical and Lightning Injuries

Earlier case reports suggested a high fetal mortality rate with electric shock (Fatovich, 1993). In a prospective cohort study, however, Einarson and coworkers (1997) showed similar perinatal outcomes in 31 injured women compared with those of noninjured controls. They concluded that traditional 110-volt North American electrical current likely is less dangerous than 220-volt currents available in Europe. A woman with iliofemoral thrombosis at 29 weeks’ gestation that may have been related to a mild electrical shock at 22 weeks was described (Sozen, 2004). Thermal burns may be extensive and require expert wound care.

The pathophysiological effects of lightning injuries can be devastating. García Gutiérrez and associates (2005) reviewed 12 case reports of injuries during pregnancy and added their own.
Cardiac arrest is rare during pregnancy. General topics regarding planning and equipment have been reviewed by the American College of Obstetricians and Gynecologists (2011a). There are special considerations for cardiopulmonary resuscitation (CPR) conducted in the second half of pregnancy, and these are outlined in the American Heart Association 2010 guidelines (Vanden Hoek, 2010). The committee acknowledges the following as standards for critically ill pregnant women: (1) relieve possible vena caval compression by left lateral uterine displacement, (2) administer 100-percent oxygen, (3) establish intravenous access above the diaphragm, (4) assess for hypotension that warrants therapy, which is defined as systolic blood pressure < 100 mmHg or < 80 percent of baseline, and (5) review possible causes of critical illness and treat conditions as early as possible.

In nonpregnant women, external chest compression results in a cardiac output approximately 30 percent of normal. In late pregnancy, this may be even less with CPR because of uterine aortocaval compression (Clark, 1997). Thus, it is paramount to accompany other resuscitative efforts with uterine displacement. Displacement can be accomplished by tilting the operating table laterally, by placing a wedge under the right hip—an example is the Cardiff resuscitation wedge, or by pushing the uterus to the left manually (Rees, 1988). If no equipment is available, such as in an out-of-hospital arrest, an individual may kneel on the floor with the maternal back on his or her thighs to form a “human wedge” (Whitty, 2002).

**Cesarean Delivery**

During maternal resuscitation, because of pregnancy-induced hindrances on CPR efforts, emergent perimortem cesarean delivery for fetal salvage and improved maternal resuscitation may be considered (Vanden Hoek, 2010). Some have stated that cesarean delivery is indicated with 4 to 5 minutes of beginning CPR if the fetus is viable (Moise, 1997). There is an undeniably inverse correlation between neurologically intact neonatal survival and the cardiac arrest-to-delivery interval in women delivered by perimortem cesarean (Katz, 2012). Specifically, of newborns delivered within 5 minutes of arrest, 98 percent are neurologically intact; within 6 to 15 minutes, 83 percent are intact; within 16 to 25 minutes, 33 percent are intact; and within 26 to 35 minutes, only 25 percent are intact (Clark, 1997). This, coupled with some evidence that delivery may also enhance maternal resuscitation, has led the American College of Obstetricians and Gynecologists (2011a) to recommend consideration for cesarean delivery within 4 minutes of cardiac arrest in these cases.

This serious and sometimes contentious issue is far from evidence based. To wit, Katz and associates (2005) reviewed 38 perimortem cesarean deliveries with a “large selection bias.” They concluded that these reports supported—but “fell far from proving”—that perimortem cesarean delivery within 4 minutes of maternal cardiac arrest improves maternal and fetal outcomes. Even so, as emphasized by Clark and coworkers (1997), and in our experiences, these goals rarely can be met in actual practice. For example, most cases of cardiac arrest occur in uncontrolled circumstances, and thus, the time to CPR initiation alone would exceed the first 5 minutes. Thus “crash” cesarean delivery would supersede resuscitative efforts, be necessarily done without appropriate anesthesia or surgical equipment, and more likely than not, would lead to maternal death. Moreover, the distinction between a perimortem versus postmortem cesarean operation is imperative (Katz, 2012). Last, in the balance, any choice may favor survival of the mother over the fetus, or vice versa, and thus there are immediate unresolvable ethical concerns. Katz (2012) has recently provided a scholarly review of perimortem cesarean delivery.
Maternal Brain Death

Occasionally, a pregnant woman with a supposedly healthy intact fetus will be kept on somatic support to await fetal viability or maturity. This is discussed in Chapter 60 (p. 1199).

Envenomation

According to their review, Brown and colleagues (2013) reported that clinically significant envenomations in pregnant women are from snakes, spiders, scorpions, jellyfish, and hymenoptera such as bees, wasps, hornets, and ants. Adverse outcomes are related to maternal effects. They conclude that limited evidence supports the use of a venom-specific approach that includes symptomatic care, antivenom administration when appropriate, anaphylaxis treatment, and fetal assessment.

Excessive weight is a major health problem in the United States and other affluent societies. For a number of years, obesity was said to be epidemic—strictly defined, this implies a temporary widespread outbreak of greatly increased frequency and severity. Unfortunately, obesity more correctly is endemic—a condition that is habitually present. By 1991, approximately a third of adults in the United States were overweight, and thus a stated goal of Healthy People 2000 was to reduce the prevalence of overweight people to 20 percent or less by the end of the 20th century (Public Health Service, 1990). Not only was this goal not achieved, but by 2000, more than half of the population was overweight. In 2010, a third of all adults were obese (Ogden, 2012).

The adverse health aspects of obesity are staggering. Obesity-related diseases include diabetes, heart disease, hypertension, stroke, and osteoarthritis. Obese women who become pregnant—and their fetuses—are predisposed to various serious pregnancy-related complications. Moreover, long-term maternal and fetal effects include significant and increased morbidity and mortality rates.

GENERAL CONSIDERATIONS

Definitions

A number of systems have been used to define and classify obesity. The body mass index (BMI), also known as the Quetelet index, is currently most often used. The BMI is calculated as weight in kilograms divided by the square of the height in meters (kg/m²). Calculated BMI values are available in various chart and graphic forms, such as the one shown in Figure 48-1. The National Institutes of Health (2000) classifies adults according to BMI as follows: normal (18.5 to 24.9 kg/m²); overweight (25 to 29.9 kg/m²); and obese (≥ 30 kg/m²). Obesity is further divided into: class 1 (30 to 34.9 kg/m²); class 2 (35 to 39.9 kg/m²); and class 3 (≥ 40 kg/m²).
FIGURE 48-1 Chart for estimating body mass index (BMI). To find the BMI category for a particular subject, locate the point at which the height and weight intersect.

Prevalence
By 2000, 28 percent of men and 33 percent of women were obese (Ogden, 2012). For the period 2009 to 2010, among men and women these percentages were almost identical at approximately 35 percent. Shown in Figure 48-2 are the prevalences of obesity among girls and women. Obesity increases with age as well as with ethnic minority, and almost 60 percent of black women were obese in 2010. This is also true among indigent individuals (Drewnowski, 2004).
Adipose Tissue as an Organ System

Fat tissue is much more complex than its energy storage function. Many cell types in fat tissue communicate with all other tissues via endocrine and paracrine factors—*adipokines*, or *adipocytokines*. Some of those with metabolic functions include adiponectin, leptin, tumor necrosis factor-α (TNF-α), interleukin 6 (IL-6), resistin, visfatin, apelin, vascular endothelium growth factor (VEGF), lipoprotein lipase, and insulin-like growth factor (Briana, 2009; Scherer, 2006). A principal adipokine is adiponectin, which is a 30-kDa protein. It enhances insulin sensitivity, blocks hepatic release of glucose, and has cardioprotective effects on circulating plasma lipids. An adiponectin deficit leads to diabetes, hypertension, endothelial cell activation, and cardiovascular disease.

Adipocytokines in Pregnancy

Cytokines that result in insulin resistance—leptin, resistin, TNF-α, and IL-6—are increased during pregnancy. Indeed, these may be the primary stimulant of insulin resistance. Secretion of the remaining adipokines is either unchanged or decreased. Specific patterns have been variously described with gestational diabetes, preeclampsia, and fetal-growth restriction (Briana, 2009). In a longitudinal study of 55 pregnant women, Meyer and associates (2013) confirmed that higher BMIs are associated with lower adiponectin but higher leptin levels.

Metabolic Syndrome
Given its multifaceted endocrine and paracrine functions, it is not surprising that excessive fat tissue is detrimental (Cornier, 2011). One major drawback is that obesity interacts with inherited factors to cause insulin resistance and in some cases, the metabolic syndrome. This resistance is characterized by impaired glucose metabolism and a predisposition to type 2 diabetes. Insulin resistance also causes several subclinical abnormalities that predispose to cardiovascular disease and accelerate its onset. The most important among these are type 2 diabetes, dyslipidemia, and hypertension, which define the metabolic syndrome.

Criteria used by the National Institutes of Health (2001) to define the metabolic syndrome are shown in Table 48-1. Virtually all obese women with hypertension demonstrate elevated plasma insulin levels. These are even higher in women with excessive fat in the abdomen—an apple shape—compared with those whose fat is in the hips and thighs—a pear shape (American College of Obstetricians and Gynecologists, 2003).

</tr>
</tbody>
</table>

<sup>a</sup>Those with normal values while taking medications are considered to meet these criteria.

**Prevalence**

Ford and colleagues (2002) did a follow-up study of men and women enrolled in the Third National Health and Nutrition Survey (NHANES III). They found an overall prevalence of the metabolic syndrome in 24 percent of women and 22 percent of men. As expected, prevalence increased with age. For women, prevalence was approximately 6 percent in those 20 to 29 years; 14 percent in those 30 to 39 years; 20 percent in those 40 to 49 years; and 30 percent for women older than 50 years. Jordan and colleagues (2012) reported similar figures in adults in New York City in 2004.

**Nonalcoholic Fatty Liver Disease (NAFLD)**

Generally speaking, visceral adiposity correlates with hepatic fat content (Cornier, 2011). With obesity, excessive fat accumulates in the liver—hepatic steatosis. Specifically, in persons with the metabolic syndrome, steatosis can progress to nonalcoholic steatohepatitis (NASH) and cirrhosis. Indeed, a fourth of cases of chronic liver disease in Western countries are caused by nonalcoholic fatty liver disease (NAFLD) (Targher, 2010). Moreover, NAFLD either is a marker for cardiovascular disease or is involved in its pathogenesis. This may be related to an inherited prothrombotic state (Verrijken, 2014).
Experience with NAFLD in pregnancy is limited (Page, 2011). It also appears that the increased insulin resistance it imposes causes excess gestational diabetes (Forbes, 2011). In addition, insulin resistance mobilizes free fatty acids to increase their plasma levels. In nonpregnant adults, hepatic fat content normally is 1 to 5 percent of liver mass, however, this has not been studied in pregnant women (Browning, 2004). However, Meyer and associates (2013) found that overweight and obese gravidas had a higher proportion of low-density lipoprotein III (LDL-III) compared with that of normal-weight women. LDL-III predominance is a hallmark of ectopic liver fat accumulation that is typical of NAFLD. At Parkland Hospital, with increasing frequency we are encountering obese women who have NAFLD with evidence of steatohepatitis manifest by elevated serum hepatic aminotransferase levels. In some cases, liver biopsy is necessary to exclude other causes.

MORBIDITY AND MORTALITY ASSOCIATED WITH OBESITY

Obese individuals are at increased risk for an imposing number of complications (Table 48-2). The direct link between obesity and type 2 diabetes mellitus is well known. Ninety percent of type 2 diabetes cases are attributable to excess weight, and 75 percent of these diabetics have the metabolic syndrome (Hossain, 2007). Heart disease due to obesity—adipositas cordis—is caused by hypertension, hypervolemia, and dyslipidemia. Higher rates of abnormal left ventricular function, heart failure, myocardial infarction, and stroke have been noted (Chinali, 2004; Kenchaiah, 2002; Targher, 2010).

| TABLE 48-2. Long-Term Complications of Obesity |
Excessive weight is associated with increased rates of early mortality, as shown by Peeters (2003) and Fontaine (2003) and their colleagues in follow-up studies from both the Framingham Heart Study and the NHANES III cohort. Mortality results from pooled data from 19 prospective studies are shown in Figure 48-3. In these and other studies, mortality risk from cardiovascular disease and cancer increased directly with increasing BMI.

TREATMENT OF OBESITY

Weight loss is tremendously difficult for obese individuals. If achieved, long-term maintenance poses equivalent or even more daunting difficulties. Even the most legitimate nonsurgical methods are fraught with frequent failure. If they are successful, slow and inexorable return to preintervention weight usually follows (Yanovski, 2005). Successful weight loss approaches include behavioral, pharmacological, and surgical techniques or a combination of these methods (Eckel, 2008; Zimmet, 2012). As such, obstetrician-gynecologists are encouraged to aid assessment and management of obesity in adult women. Weight loss and lifestyle changes have been shown to reduce the associated metabolic syndrome (Crist, 2012). When used in conjunction with bariatric surgery, there is improved glucose control with type 2 diabetes (Mingrone, 2012; Schauer, 2012).

PREGNANCY AND OBESITY

Obese women unequivocally have reproductive disadvantages. This translates into difficulty in
Obesity results in subfertility due to increased insulin resistance as in polycystic ovarian syndrome. Leptin dysregulation also results in loss of gonadotropin secretory rhythms (Maguire, 2012). Impaired fecundity has been linked to women with a BMI > 30 kg/m$^2$ (Neill, 2001). In 6500 in vitro fertilization-intracytoplasmic sperm injection cycles, Bellver and associates (2010) found that implantation, pregnancy, and livebirth rates were progressively and significantly reduced with each unit of maternal BMI. As discussed in Chapter 8 (p. 157), obesity is associated with increased risk of first-trimester and recurrent miscarriage (Lashen, 2004; Metwally, 2008). In the many overweight and obese women who achieve pregnancy, there is a litany of increased and interrelated adverse perinatal outcomes that are discussed subsequently.

### Prevalence

As expected from reviewing Figure 48-2, obesity complicating pregnancy has increased substantially in this country. Before adoption of the BMI, investigators used various definitions of obesity to assess risks during pregnancy. For example, in an earlier study from the University of Alabama at Birmingham, four definitions were used, but regardless of how obesity was defined, all groups showed at least twofold increases in prevalence during the 20-year period (Lu, 2001). Equivalent findings were reported from a 15-year study done in Cleveland (Ehrenberg, 2002). Our experience at Parkland Hospital is similar, as shown in the three epochs depicted in Figure 48-4.
Maternal Weight Gain and Energy Requirement

The Institute of Medicine (2009) updated its previous comprehensive reviews of maternal weight gain determinants in relation to biological, metabolic, and social predictors. Its recommended weight gains for various BMI categories are shown in Table 9-5 (p. 177). For overweight women, weight gain of 15 to 25 pounds is recommended. For obese women, the Institute recommends a gain of 11 to 20 pounds. This is because fat deposition is greater in women with high BMIs, and thus, energy costs are significantly lower (Butte, 2004). Kinoshita and Itoh (2006) found that during the third trimester, increases were predominantly in visceral fat. Despite these stores, maternal catabolism is—at least intuitively—not good for fetal growth and development. The American College of Obstetricians and Gynecologists (2013c) has endorsed these Institute guidelines.

These Institute guidelines for obese women have some, although minimal, foundation in scientific evidence (Rasmussen, 2010). In a study of 2080 obese women, there was no advantage to weight gain > 20 pounds (Vesco, 2011). However, Chu and coworkers (2009) reported in the United States in 2004 to 2005 that 40 percent of normal-weight and 60 percent of overweight women gained excessive weight during pregnancy. The Maternal-Fetal Medicine Units Network arrived at similar conclusions. Seventy-five percent of nearly 8300 nulliparas gained more weight than the Institute recommendations (Johnson, 2013). Additionally, women who gained more than the recommended amount had excessive postpartum weight gain at 3, 8, and 15 years after delivery (Nehring, 2011; Rooney, 2002).
Maternal Morbidity

Some of the excess perinatal morbidity due to obesity is listed in Table 48-3. In studies, various definitions of obesity in pregnant women have included 150 percent of ideal body weight, BMI > 35 kg/m², BMI > 40 kg/m², BMI > 50 kg/m², and > 150 pounds over ideal body weight (Cedergren, 2004; Crane, 2013; Denison, 2008; Kabiru, 2004; Kumari, 2001; Stamilio, 2013). In one study, Weiss and colleagues (2004) reported similar adverse outcomes and maternal morbidity in a prospective multicenter study of more than 16,000 women from the FASTER trial (First- and Second-Trimester Evaluation of Risk). As shown in Figures 48-5 and 48-6, especially striking are the marked increases in gestational diabetes and hypertension. Lipkind and associates (2013) showed obesity to be an independent risk factor for “near-miss” maternal morbidity (Chap. 1, p. 6).

bNot significantly different.

BMI = body mass index.
Data from Ovesen, 2011; Sebire, 2001.
FIGURE 48-5 Incidence of selected pregnancy outcomes in 16,102 women enrolled in the FASTER (First- and Second-Trimester Evaluation of Risk) trial according to body mass index (BMI) status. (Data from Weiss, 2004.)

FIGURE 48-6 Frequency of preeclampsia according to body mass index. (Data from the Hyperglycemia and Adverse Pregnancy Outcome [HAPO] Study Cooperative Research Group,
Not shown in Figure 48-5 are the cesarean delivery rates. These were 33.8 percent for obese and 47.4 percent for morbidly obese women compared with only 20.7 percent for the normal-weight control group (Weiss, 2004). Similar results were subsequently described by Garabedian and coworkers (2011). Haeri and colleagues (2009) also found increased rates of cesarean delivery and gestational diabetes in obese adolescents. More worrisome is that obese women also have increased rates of emergency cesarean delivery (Lynch, 2008; Poobalan, 2009). Finally, wound infections are more common. Alanis and associates (2010) reported this complication in 30 percent in women whose BMI was > 50 kg/m².

There are also reports of increased adverse pregnancy outcomes in overweight women whose BMI is 25 to 29.9 kg/m² (Hall, 2005). Shown in Table 48-3 were results of two studies that included more than 285,000 singleton pregnancies. Although not as magnified as in the obese cohort, almost all complications are significantly increased in overweight women compared with those whose BMI is normal.

Obesity is detrimental to the accuracy of obstetrical ultrasound examination (Weichert, 2011). Other morbidity includes a higher incidence of failed trial of labor with a prior cesarean delivery (Bujold, 2005; Goodall, 2005; Hibbard, 2006; Robinson, 2005). Obesity and hypertension are common cofactors in causing peripartum heart failure (Cunningham, 1986, 2012). And, obese women present anesthesia challenges that include difficult epidural and spinal analgesia placement and complications from failed or difficult intubations (Hood, 1993; Mace, 2011). Second-trimester dilatation and evacuation was reported to take longer and be more difficult in women whose BMI was 30 kg/m² or greater (Dark, 2002).

Obese women are less likely to breast feed than normal-weight women (Li, 2003). They also have greater weight retention 1 year after delivery (Catalano, 2007; National Research Council and Institute of Medicine, 2007; Rode, 2005). Finally, there is evidence that quality-of-life measures are negatively affected by obesity during pregnancy (Amador, 2008). LaCoursiere and Varner (2009) found that postpartum depression was significantly increased in obese women in relation to the degree of obesity—class 1, 23 percent; class 2, 32 percent; and class 3, 40 percent.

**Gestational Diabetes**

Obesity and gestational diabetes are inextricably linked. Their coexistence with and adverse effects on pregnancy outcomes are discussed in Chapter 57 (p. 1139).
triglycerides, very-low-density lipoprotein cholesterol, insulin, and leptin compared with normal-weight pregnant women.

**Contraception**
Most studies report that oral contraceptive failure is more likely in overweight women. This is discussed in detail in Chapter 38 (p. 695).

**Perinatal Mortality**
Stillbirths are more prevalent as the degree of obesity increases (see Table 48-3). Indeed, in a review of almost 100 population-based studies, Flenady and associates (2011) found that obesity was the highest ranking modifiable risk factor for stillbirth. Chronic hypertension with superimposed preeclampsia associated with obesity is one cause of excessive stillbirths. An increased incidence of otherwise inexplicable late-pregnancy stillbirths and early neonatal deaths is also associated with obesity (Cnattingius, 1998; Stephansson, 2001; Waldenström, 2014; Yao, 2014). In one metaanalysis, there was a 1.5-fold increased risk for stillbirth in overweight and a 2.1-fold risk in obese women (Chu, 2007). A Scottish study of more than 186,000 nulliparas described an almost fourfold increased stillbirth rate in women with a BMI ≥ 35 kg/m² compared with women of normal size (Denison, 2008). Increased prepregnancy weight was the factor most strongly associated with unexplained fetal deaths even after adjusting for maternal age and excluding women with diabetes and hypertensive disorders (Huang, 2000; Nohr, 2005; Ovesen, 2011).

**Perinatal Morbidity**
Both fetal and neonatal complications are increased in obese women. The Atlantic Birth Defects Risk Factor Surveillance Study found a two- to threefold increased incidence in various anomalies in obese women (Watkins, 2003). Rasmussen and coworkers (2008) performed a metaanalysis and found 1.2-, 1.7-, and 3.1-fold increased risks for neural-tube defects in overweight, obese, and severely obese women, respectively. Another metaanalysis found that maternal obesity was significantly associated with an increased risk of a wide range of anomalies (Stothard, 2009). The National Birth Defect Prevention Study reported a correlation between BMI and congenital heart defects (Gilboa, 2010). According to Biggio and colleagues (2010), however, this may be related to diabetes as a cofactor. Already mentioned is concern for unreliable fetal anatomy sonographic screening in obese women (Dashe, 2009; Thornburg, 2009; Weichert, 2011).

Two important and interrelated cofactors that contribute to excessive rates of perinatal morbidity are chronic hypertension and diabetes mellitus, both of which are associated with obesity. Affected women have increased rates of preterm delivery and fetal-growth restriction (McDonald, 2010; Waldenström, 2014; Wang, 2011). As discussed above, pregestational diabetes increases the birth defect rate, and gestational diabetes is complicated by excessive numbers of large-for-gestational age and macrosomic fetuses (Chap. 44, p. 884).

Even without diabetes, the prevalence of macrosomic newborns is increased in obese women (Cedergren, 2004; Ovesen, 2011). The group from MetroHealth Medical Center in Cleveland has conducted studies of prepregnancy obesity, gestational weight gain, and prepregnancy and gestational diabetes and their relationship to newborn weight and fat mass (Catalano, 2005, 2007; Ehrenberg, 2004; Sewell, 2006). Although each of these variables was found to be associated with
larger and more corpulent newborns, prepregnancy BMI had the strongest influence on the prevalence of macrosomic neonates. They attributed this increased prevalence of macrosomic infants to the marked frequency of overweight or obese women in pregnancy—47 percent—rather than the 4 percent of pregnant women with diabetes. More recently, Edlow and associates (2013) have shown that genes expressed in the adult metabolic syndrome may be initiated in the fetus.

**Morbidity in Children Born to Obese Women**

It appears that obese women beget obese children, who themselves become obese adults. Whitaker (2004) studied low-income children in the Special Supplemental Food Program for Women, Infants, and Children (WIC) and found a linear association between early pregnancy maternal BMI and prevalence of overweight children at 2, 3, and 4 years. Schack-Nielson and associates (2005) reported a direct association between maternal, newborn, and childhood BMI. This association strengthened as offspring progressed to adulthood. Catalano and coworkers (2005) studied offspring at a median age of 7 years and found a direct association with maternal prepregnancy obesity and childhood obesity. They also reported associations with central obesity, elevated systolic blood pressure, increased insulin resistance, and decreased high-density lipoprotein (HDL) cholesterol levels—all elements of the metabolic syndrome. In their analysis of 28,540 women, Reynolds and associates (2013) found increased rates of cardiovascular disease and all-cause mortality in offspring of overweight and obese mothers. Boney and colleagues (2005) studied offspring of women with or without gestational diabetes. They observed that children who were large for gestational age at birth and whose mothers were either obese or had gestational diabetes had significantly increased risks for developing metabolic syndrome.

It also appears that excessive maternal weight gain in pregnancy may predict adulthood obesity in their offspring. Schack-Nielsen and associates (2005) found a linear association of maternal weight gain with the subsequent BMI in their children. Analyzing data from Project Viva, Oken (2006) confirmed this. However, not all studies concur. In their analysis of children in the WIC program cited above, Whitaker and associates (2004) found no obvious linear association between gestational weight gain and childhood obesity. This is also discussed in some detail in Chapter 44 (p. 876).

**Fetal Programming and Childhood Morbidity**

Epidemiological studies have addressed the association of childhood, adolescent, and even adult adverse health outcomes in relation to the fetal environment. Adverse outcomes include obesity, diabetes, hypertension, and the metabolic syndrome. Variables studied have included maternal prepregnancy BMI, obesity, gestational weight gain, and pregestational or gestational diabetes. The most robust evidence suggests a direct association between children born to women who had prepregnancy obesity or gestational diabetes and being overweight in childhood and adulthood.

The potential biological causes and mechanisms of these associations are not clear. Elucidation is limited by insufficient data on potential maternal and genetic predisposing factors and on the environment of the infant and child in relation to diet and activity. The science of epigenetics has provided some support for the possibility that perturbations of the maternal-fetal environment can adversely alter postdelivery events (Aagard-Tillery, 2006). Perhaps more likely are contributions of the maternal-child environment subsequent to birth (Gluck, 2009). These and other factors regarding fetal programming are discussed in Chapter 44 (p. 876).
Dietary Intervention in Pregnancy

Weight reduction is not advisable during pregnancy (Catalano, 2013). As noted, recommended weight gain in obese women is 11 to 20 pounds, and several dietary interventions to limit weight gain to these targets have been reported. These include lifestyle interventions and physical activity (Petrella, 2013). Reviews by Quinlivan (2011) and Tanentsapf (2011) found that randomized trials generally reported successful results with intervention. On the other hand, in many other studies, either these have been unsuccessful or the results were insufficient to permit a conclusion (Campbell, 2011; Dodd, 2010; Guelinckx, 2010; Nascimento, 2011; Ronnberg, 2010). Special attention to psychological aspects of pregnancy has been recommended by some (Skouteris, 2010).

Prenatal Care

Close prenatal surveillance detects most early signs of diabetes or hypertension. Standard screening tests for fetal anomalies are sufficient, while being mindful of sonographic limitations for detection of fetal anomalies. Accurate assessment of fetal growth usually requires serial sonography. Antepartum and intrapartum external fetal heart rate monitoring are likewise more difficult, and sometimes these are even impossible.

Surgical and Anesthetic Concerns

Evaluation by the anesthesia team is performed at a prenatal visit or on arrival at the labor unit (American College of Obstetricians and Gynecologists, 2013b). Anesthetic risks and complications faced by obese women are discussed in Chapter 25 (p. 505). Special attention is given to complications that might arise during labor and delivery. Vricella and coworkers (2010) reported the following frequencies of anesthetic complications in 142 morbidly obese women at cesarean delivery. These included technical problems with regional analgesia—up to 6 percent; use of general anesthesia—6 percent; hypotension—3 percent; and overall anesthetic complications of 8.4 percent.

For cesarean delivery, forethought is given to optimal placement and type of abdominal incision to allow access to the fetus and to effect the best wound closure with the least intervening tissue (Alexander, 2006). One technique is shown in Figure 48-7. Others prefer a transverse abdominal incision (Alanis, 2010). Individual differences in maternal body habitus preclude naming any one approach as superior (Gilstrap, 2002; McLean, 2012). Although some have reported similar wound complications with either incision, others reported a fourfold wound complication rate when a vertical abdominal incision was compared with a transverse incision—31 versus 8 percent (Houston, 2000; Thornburg, 2012; Wall, 2003). Finally, a mid-abdomen transverse incision has been advocated by some (Tixier, 2009).
FIGURE 48-7 Abdominal incision for the obese woman. A. Frontal view. The dotted line indicates an appropriate skin incision for abdominal entry relative to the panniculus. As shown by the uterus in the background, selection of this periumbilical site permits access to the lower uterine segment. B. Sagittal view.

Attention to closure of the subcutaneous layer is important. Chelmow and associates (2004) performed a metaanalysis of subcutaneous closure in 887 women undergoing cesarean delivery whose wound thickness was greater than 2 centimeters. Subcutaneous closure resulted in a modest but significant 6-percent decrease in wound disruption. The frequency of abdominal wound infections is directly related to BMI (Norman, 2013). Comorbid diabetes apparently increases this risk (Leth, 2011). Several reports describe a wound complication rate of 15 to 45 percent. Alanis and colleagues (2010) reported a 30-percent rate in 194 women whose BMI was > 50 kg/m². Of these, 90-percent were wound disruptions to the fascia, but there was only one evisceration. As indicated above, the transverse abdominal incision had fewer complications. Walsh and coworkers (2009) have reviewed the prevention and management of surgical site infections in morbidly obese women.

To lower thromboembolic complications, graduated compression stockings, hydration, and early mobilization after cesarean delivery in obese women are recommended by the American College of Obstetricians and Gynecologists (2013a). Some also recommend “mini-dose” heparin prophylaxis, but we do not routinely use this (Chap. 52, p. 1044).

Bariatric Surgery

Several surgical procedures have been designed to treat morbid obesity either by decreasing gastric volume—restrictive, or by bypassing gastrointestinal absorption—restrictive malabsorptive (Adams, 2007; Kushner, 2012). In nonpregnant patients, these procedures have been shown to improve or resolve diabetes, hyperlipidemia, hypertension, and obstructive sleep apnea (Buchwald, 2007; Mingrone, 2012; Schauer, 2012).

Pregnancy

Because of these successes, bariatric surgery currently has become popular, and many women are becoming pregnant following weight-reduction surgery (Abodeely, 2008). Several observational studies have reported improved fertility rates and reduced risks of obstetrical complications in women following bariatric surgery and compared with morbidly obese controls (Alatishe, 2013; Guelinckx, 2009; Kjaer, 2013a; Lesko, 2012; Tan, 2012). The largest of these studies is from the Swedish Birth Register, which included 681 women with a pregnancy following bariatric surgery (Josefsson, 2011). Despite surgical treatments, half of these women were still obese by the time of their first pregnancy following bypass, however, the proportion with morbid obesity was smaller. The frequency of large-for-gestational age infants decreased from 9.1 to 3.2 percent and that of small-for-gestational age neonates increased from 2.1 to 5.6 percent. In a recent systematic review, Kjaer and Nilas (2013b) reported a decreased risk after bariatric surgery for diabetes, preeclampsia, and large-for-gestational age infants. Most studies confirmed a higher risk for small-for-gestational age fetuses.

Restrictive Procedures

The prototypical vertical banded gastroplasty has been largely replaced by the laparoscopic adjustable silicone gastric banding (LASGB) operation. With the two approved LASGB
procedures—*LAPBAND* and *REALIZE*, an adjustable band is placed 2 cm below the gastroesophageal junction to create a small pouch. The pouch size is controlled by a saline reservoir in the band. Salutary effects on pregnancy outcomes involve before-and-after cohorts as well as pregnancies in postsurgical women compared with obese, nonsurgical controls (Vrebosch, 2012). In a report by Dixon and colleagues (2005), pregnancy outcomes were compared with their preprocedural outcomes and with a matched cohort of obese women. Following banding, the incidences of gestational hypertension—10 versus 45 percent—and gestational diabetes—6 versus 15 percent—were significantly lower compared with their preprocedural pregnancies. Incidences in banded patients were also significantly lower than those in the obese cohort, whose rates for hypertension were 38 percent, and for diabetes, 19 percent. The results from these and other studies are shown in Table 48-4.

Reported complications have been few and include excessive nausea and vomiting that abated with band adjustment (Martin, 2000). Rarely, women may have band slippage associated with hyperemesis or with advancing gestation (Pilone, 2012; Suffee, 2012). One newborn died after fetal cerebral hemorrhage developed from vitamin K deficiency associated with band slippage (Van Mieghem, 2008).

### Restrictive Malabsorptive Procedures

There are three procedures to accomplish gastric restriction and selective malabsorption. The most commonly used is the laparoscopically performed *Roux-en-Y gastric bypass* and *biliopancreatic diversion with duodenal switch*. With the Roux-en-Y procedure, the proximal stomach is completely transected to leave a 30-mL pouch. A gastroenterotomy is then created by connecting the proximal end of the distal jejunum to the pouch. A Roux-en-Y enteroenterostomy is also completed 60 cm distal to this gastrojejunostomy to allow drainage of the unused stomach and
proximal small intestine.

As with other bariatric procedures, pregnancy outcomes are changed remarkably following Roux-en-Y bypass (Wittgrove, 1998). As shown in Table 48-4, rates of hypertension, gestational diabetes, and fetal macrosomia are reduced. Serious complications are uncommon. Intussusception and small bowel obstruction develop from internal herniation, and maternal deaths from herniation and obstruction have been reported (Kakarla, 2005; Moore, 2004; Renault, 2012; Wax, 2007). Bowel obstruction is notoriously difficult to diagnose, and Wax and associates (2013) caution for a high index of suspicion.

**Recommendations**

The American College of Obstetricians and Gynecologists (2013a) recommends that women who have undergone bariatric surgery be assessed for vitamin and nutritional sufficiency. When indicated, vitamin B<sub>12</sub> and D, folic acid, and calcium supplementation are given. Vitamin A deficiency has also been reported (Chagas, 2013). Women with a gastric band should be monitored by their bariatric team during pregnancy because adjustments of the band may be necessary. Finally, special vigilance is appropriate for signs of intestinal obstruction.

Heart disease complicates more than 1 percent of all pregnancies and is now the leading cause of indirect maternal deaths—accounting for 20 percent of all cases (Simpson, 2012). In an analysis of maternal mortality in the United States between 1987 and 2005, the causes previously responsible for most maternal deaths—hemorrhage and hypertensive disorders—had progressively decreased rates, whereas deaths attributable to cardiovascular diseases had the greatest percentage increase (Berg, 2010). Similarly, in the United Kingdom, the rate of maternal mortality due to cardiac disease increased from 1.65 to 2.31 per 100,000 births between 1997–1999 and 2006–2008 (Centre for Maternal and Child Enquiries, 2011). Cardiovascular diseases also account for significant maternal morbidity and are a leading cause of obstetrical intensive care unit admissions (Small, 2012).

The increasing prevalence of cardiovascular diseases complicating pregnancy is likely due to a
number of causes, including higher rates of obesity, hypertension, and diabetes. Indeed, according to the United States National Center for Health Statistics, almost half of adults aged 20 and older have at least one risk factor for cardiovascular disease (Fryar, 2012). And as shown in Figure 49-1, the prevalence of these risk factors among reproductive-aged women is dramatic. Other related factors include delayed childbearing. From 1970 to 2006 the proportion of first births to women aged 35 years or older increased nearly eightfold (Mathews, 2009). Finally, as discussed subsequently, an increasing number of patients with congenital heart disease are now becoming pregnant.

**FIGURE 49-1** Prevalence of risk factors for cardiovascular disease among reproductive-aged women. DM = diabetes mellitus. (From Centers for Disease Control and Prevention, 2011.)

| PHYSIOLOGICAL CONSIDERATIONS IN PREGNANCY |

### Cardiovascular Physiology

The marked pregnancy-induced anatomical and functional changes in cardiac physiology can have a profound effect on underlying heart disease (Chap. 4, p. 58). Some of these changes are listed in Table 49-1. Importantly, cardiac output increases approximately 40 percent during pregnancy. Almost half of this total increase takes place by 8 weeks and is maximal by midpregnancy (Capeless, 1989). The early increase stems from augmented stroke volume that results from decreased vascular resistance. Later in pregnancy, resting pulse and stroke volume increase even more because of increased end-diastolic ventricular volume that results from pregnancy hypervolemia. This along with an increase in heart rate translates to increased cardiac output that continues to rise across pregnancy to average 40 percent higher at term. These changes are even more profound in multifetal pregnancy (Kametas, 2003; Kuleva, 2011).

**TABLE 49-1.** Hemodynamic Changes in 10 Normal Pregnant Women at Term Compared with Repeat Values Obtained 12 Weeks Postpartum
An important study by Clark and colleagues (1989) contributed greatly to the understanding of cardiovascular physiology during pregnancy. Using right-sided heart catheterization, hemodynamic function was measured in 10 healthy primigravid volunteers, and pregnancy values were compared with those measured again at 12 weeks postpartum. As shown in Table 49-1, the cardiac output near term in the lateral recumbent position increased 43 percent. Systemic and pulmonary vascular resistances were concomitantly decreased. Importantly, intrinsic left ventricular contractility did not change. Thus, normal left ventricular function is maintained during pregnancy, that is, pregnancy is not characterized by hyperdynamic function or a high cardiac-output state.

Women with underlying cardiac disease may not always accommodate these changes, and ventricular dysfunction leads to cardiogenic heart failure. A few women with severe cardiac dysfunction may experience evidence of heart failure before midpregnancy. In others, heart failure may develop after 28 weeks when pregnancy-induced hypervolemia and cardiac output reach their maximum. In most, however, heart failure develops peripartum when labor, delivery, and a number of common obstetrical conditions add undue cardiac burdens. Some of these include preeclampsia, hemorrhage and anemia, and sepsis syndrome. In a report of 542 women with heart disease, eight of 10 maternal deaths were during the puerperium (Etheridge, 1977).

### Ventricular Function in Pregnancy

Ventricular volumes increase to accommodate pregnancy-induced hypervolemia. This is reflected by increasing end-systolic as well as end-diastolic dimensions. At the same time, however, there is no change in septal thickness or in ejection fraction. This is because these changes are accompanied by substantive ventricular remodeling—plasticity—which is characterized by eccentric expansion of left-ventricular mass that averages 30 to 35 percent near term. All of these adaptations return to prepregnancy values within a few months postpartum.

Certainly for clinical purposes, ventricular function during pregnancy is normal as estimated by the Braunwald ventricular function graph depicted in Figure 4-9 (p. 59). For given filling pressures, there is appropriate cardiac output so that cardiac function during pregnancy is eudynamic. Despite these findings, it remains controversial whether myocardial function per se is normal, enhanced, or depressed. Myocardial performance is measured by preload, afterload, contractility, and heart rate. Because these depend on ventricular geometry, they can only be measured indirectly (Savu, 2012). In nonpregnant subjects with a normal heart who sustain a high-
output state, the left ventricle undergoes *longitudinal remodeling*, and echocardiographic functional indices of its deformation provide normal values. In pregnancy, there instead appears to be *spherical remodeling*, and these calculated indices that measure longitudinal deformation are depressed. Thus, these normal indices are likely inaccurate when used to assess function in pregnant women because they do not take into account the spherical eccentric hypertrophy characteristic of normal pregnancy.

**DIAGNOSIS OF HEART DISEASE**

The physiological adaptations of normal pregnancy can induce symptoms and alter clinical findings that may confound the diagnosis of heart disease. For example, in normal pregnancy, functional systolic heart murmurs are common; respiratory effort is accentuated and at times suggests dyspnea; edema in the lower extremities after midpregnancy is common; and fatigue and exercise intolerance develop in most women. Some systolic flow murmurs may be loud, and normal changes in the various heart sounds depicted in Figure 49-2 may suggest cardiac disease.
FIGURE 49-2 Normal cardiac examination findings in the pregnant woman. $S_1 =$ first sound; $M_1 =$ mitral first sound; $S_2 =$ second sound; $P_2 =$ pulmonary second sound. (From Gei, 2001; Hytten, 1991.)

Clinical findings that may suggest heart disease are listed in Table 49-2. Pregnant women with none of these rarely have serious heart disease. As an interesting aside, Melchiorre and associates (2011) found that the prevalence of previously undiagnosed maternal cardiac structural abnormalities is significantly increased in women with high midtrimester uterine artery Doppler
resistance indices (Chap. 17, p. 345).

Criteria for pulmonary hypertension

---

**Diagnostic Studies**

In most women, noninvasive cardiovascular studies such as electrocardiography, chest radiography, and echocardiography will provide data necessary for evaluation. In some situations, such as complex congenital heart disease, transesophageal echocardiography may be useful. Albumin or red cells tagged with technicium-99m are rarely needed during pregnancy to evaluate ventricular function. That said, the estimated fetal radiation exposure from nuclear medicine studies of myocardial perfusion are calculated to range between 5 and 17 mGy depending on the technique employed (Colletti, 2013). If indicated, cardiac catheterization can be performed with limited fluoroscopy time. During coronary angiography, the mean radiation exposure to the unshielded abdomen is 1.5 mGy, and less than 20 percent of this reaches the fetus because of tissue attenuation (European Society of Cardiology, 2011). Shielding the fetus from direct radiation and shortening the fluoroscopic time help to minimize radiation exposure. In women with clear indications, any minimal theoretical fetal risk is outweighed by maternal benefits (Chap. 46, p. 932).

**Electrocardiography**

As the diaphragm is elevated in advancing pregnancy, there is an average 15-degree left-axis deviation in the electrocardiogram (ECG), and mild ST changes may be seen in the inferior leads. Atrial and ventricular premature contractions are relatively frequent (Carruth, 1981). Pregnancy does not alter voltage findings.
Chest Radiography

Anteroposterior (AP) and lateral chest radiographs are useful, and when a lead apron shield is used, fetal radiation exposure is minimal (Chap. 46, p. 931). Gross cardiomegaly can usually be excluded, but slight heart enlargement cannot be detected accurately because the heart silhouette normally is larger in pregnancy. This is accentuated further with a portable AP chest radiograph.

Echocardiography

Widespread use of echocardiography has allowed accurate diagnosis of most heart diseases during pregnancy. It allows noninvasive evaluation of structural and functional cardiac factors. Some normal pregnancy-induced changes include slightly but significantly increased tricuspid regurgitation, left atrial end-diastolic dimension, and left ventricular mass. Savu (2012) and Vitarelli (2011) and their coworkers have provided normal morphological and functional echocardiographic parameters for pregnancy, which are listed in the Appendix (p. 1293).

Classification of Functional Heart Disease

There is no clinically applicable test for accurately measuring functional cardiac capacity. The clinical classification of the New York Heart Association (NYHA) was first published in 1928, and it was revised for the eighth time in 1979. This classification is based on past and present disability and is uninfluenced by physical signs:

- **Class I. Uncompromised—no limitation of physical activity:** These women do not have symptoms of cardiac insufficiency or experience anginal pain.
- **Class II. Slight limitation of physical activity:** These women are comfortable at rest, but if ordinary physical activity is undertaken, discomfort in the form of excessive fatigue, palpitation, dyspnea, or anginal pain results.
- **Class III. Marked limitation of physical activity:** These women are comfortable at rest, but less than ordinary activity causes excessive fatigue, palpitation, dyspnea, or anginal pain.
- **Class IV. Severely compromised—inability to perform any physical activity without discomfort:** Symptoms of cardiac insufficiency or angina may develop even at rest. If any physical activity is undertaken, discomfort is increased.

Siu and associates (2001b) expanded the NYHA classification and developed a scoring system for predicting cardiac complications during pregnancy. The system is based on a prospective analysis of 562 consecutive pregnant women with heart disease during 617 pregnancies in 13 Canadian teaching hospitals. Predictors of cardiac complications included the following: (1) prior heart failure, transient ischemic attack, arrhythmia, or stroke; (2) baseline NYHA class III or IV or cyanosis; (3) left-sided obstruction defined as mitral valve area < 2 cm², aortic valve area < 1.5 cm², or peak left ventricular outflow tract gradient > 30 mm Hg by echocardiography; (4) ejection fraction less than 40 percent. The risk of pulmonary edema, sustained arrhythmia, stroke, cardiac arrest, or cardiac death was substantially increased with one of these factors and even more so with two or more.

At least two studies have been conducted using these latter risk criteria. Khairy and colleagues (2006) reviewed 90 pregnancies in 53 women with congenital heart disease at Brigham and Women’s Hospital. There were no maternal deaths, and heart failure and symptomatic arrhythmias developed in 16.7 and 2.8 percent of the women, respectively. Similar to the Canadian study cited
above, the most important predictors of complications were prior congestive heart failure, depressed ejection fraction, and smoking. In a German study that also used these predefined risk predictors, they were found to be accurate in assessing most cardiac outcomes (Stangl, 2008).

---

### Preconceptional Counseling

Women with severe heart disease will benefit immensely from counseling before undertaking pregnancy, and they usually are referred for maternal-fetal medicine or cardiology consultation (Clark, 2012; Seshadri, 2012).

Maternal mortality rates generally vary directly with functional classification, and this relationship may change as pregnancy progresses. In the Canadian study, Siu and colleagues (2001b) observed significant worsening of NYHA class in 4.4 percent of 579 pregnancies if the baseline class was I or II. Their experiences, however, as well as those of McFaul and coworkers (1988), were that there were no maternal deaths in 1041 women with class I or II disease. As described later, some women have life-threatening cardiac abnormalities that can be reversed by corrective surgery, and subsequent pregnancy becomes less dangerous. In other cases, such as women with mechanical valves taking warfarin, fetal considerations predominate.

The World Health Organization Risk Classification of Cardiovascular Disease and Pregnancy is useful for assessing maternal risk associated with various cardiovascular conditions and for preconceptional counseling and planning (Thorne, 2006). Maternal risk is divided among four progressively worsening classes as shown in Table 49-3. Its use has been recommended by the European Society of Cardiology (2011).

---

**TABLE 49-3. World Health Organization (WHO) Risk Classification of Cardiovascular Disease and Pregnancy**
Congenital Heart Disease in Offspring

Many congenital heart lesions appear to be inherited as polygenic characteristics, which are discussed in Chapter 13 (p. 274). Because of this, some women with congenital heart lesions give birth to similarly affected infants, the risk of which varies widely as shown in Table 49-4. Environmental factors are also important. One example is a study from Tibet in which the prevalence of fetal heart disease was increased among women living at higher altitudes (> 3600 meters) and was presumably due to lower oxygen concentrations (Chen, 2008).

Modified from Thorne, 2006.
PERIPARTUM MANAGEMENT CONSIDERATIONS

In most instances, management involves a team approach with an obstetrician, cardiologist, anesthesiologist, and other specialists as needed. With complex lesions or with women who are especially at risk, evaluation by a multidisciplinary team is recommended early in pregnancy. During consultation, cardiovascular changes likely to be poorly tolerated by an individual woman are identified, and plans are formulated to minimize these. In some, pregnancy termination may be advisable. Maxwell (2010) has provided an in-depth checklist that considers detailed management options. The four changes that affect management that are emphasized by the American College of Obstetricians and Gynecologists (1992) include decreased vascular resistance, increased blood volume and cardiac output and their fluctuations peripartum, and hypercoagulability. Within this framework, both prognosis and management are influenced by the type and severity of the specific lesion and by the patient’s functional classification.

With rare exceptions, women in NYHA class I and most in class II negotiate pregnancy without morbidity. Special attention should be directed toward both prevention and early recognition of heart failure as discussed on page 990. Infection with sepsis syndrome is an important factor in precipitating cardiac failure. Moreover, bacterial endocarditis is a deadly complication of valvular heart disease (p. 990). Each woman should receive instructions to avoid contact with persons who have respiratory infections, including the common cold, and to report at once any evidence for infection. Pneumococcal and influenza vaccines are recommended.

Cigarette smoking is prohibited, because of both its cardiac effects and its propensity to cause upper respiratory infections. Illicit drug use may be particularly harmful, an example being the cardiovascular effects of cocaine or amphetamines. In addition, intravenous drug use increases the risk of infective endocarditis.

NS = not stated.
Data from Lupton, 2002.
Fortunately, cases of NYHA class III and IV are uncommon today. In the Canadian study, only 3 percent of approximately 600 pregnancies were complicated by NYHA class III heart disease, and no women had class IV when first seen (Siu, 2001b). In a Turkish study, 8 percent of pregnancies in women with cardiac diseases were NYHA class III or IV (Madazli, 2010). An important question in these women is whether pregnancy should be undertaken. If women make that choice, they must understand the risks, and they are encouraged to be compliant with planned care. In some, prolonged hospitalization or bed rest is often necessary with continued pregnancy.

Labor and Delivery

In general, vaginal delivery is preferred, and labor induction is usually safe (Oron, 2004). Cesarean delivery is limited to obstetrical indications, and considerations are given for the specific cardiac lesion, overall maternal condition, and availability of experienced anesthesia personnel and general support facilities. Some of these women tolerate major surgical procedures poorly and are best delivered in a unit experienced with management of complicated cardiac disease. In some women, pulmonary artery catheterization may be indicated for hemodynamic monitoring (Chap. 47, p. 941). In our experiences, however, invasive monitoring is rarely indicated.

Based on her review, Simpson (2012) recommends cesarean delivery for women with the following: (1) dilated aortic root > 4 cm or aortic aneurysm; (2) acute severe congestive heart failure; (3) recent myocardial infarction; (4) severe symptomatic aortic stenosis; (5) warfarin administration within 2 weeks of delivery; and (6) need for emergency valve replacement immediately after delivery. Although we agree with most of these, we have some caveats. For example, we prefer aggressive medical stabilization of pulmonary edema followed by vaginal delivery if possible. Also, warfarin anticoagulation can be reversed with vitamin K, plasma, or prothrombin concentrates.

During labor, the mother with significant heart disease should be kept in a semirecumbent position with lateral tilt. Vital signs are taken frequently between contractions. Increases in pulse rate much above 100 bpm or respiratory rate above 24 per minute, particularly when associated with dyspnea, may suggest impending ventricular failure. If there is any evidence of cardiac decompensation, intensive medical management must be instituted immediately. It is essential to remember that delivery itself does not necessarily improve the maternal condition and in fact, may worsen it. Moreover, emergency operative delivery may be particularly hazardous. Clearly, both maternal and fetal status must be considered in the decision to hasten delivery under these circumstances.

Analgesia and Anesthesia

Relief from pain and apprehension is important. Although intravenous analgesics provide satisfactory pain relief for some women, continuous epidural analgesia is recommended for most. The major problem with conduction analgesia is maternal hypotension (Chap. 25, p. 514). This is especially dangerous in women with intracardiac shunts in whom flow may be reversed. Blood passes from right to left within the heart or aorta and thereby bypasses the lungs. Hypotension can also be life-threatening if there is pulmonary arterial hypertension or aortic stenosis because ventricular output is dependent on adequate preload. In women with these conditions, narcotic conduction analgesia or general anesthesia may be preferable.

For vaginal delivery in women with only mild cardiovascular compromise, epidural analgesia given with intravenous sedation often suffices. This has been shown to minimize intrapartum
cardiac output fluctuations and allows forceps or vacuum-assisted delivery. Subarachnoid blockade is not generally recommended in women with significant heart disease. For cesarean delivery, epidural analgesia is preferred by most clinicians with caveats for its use with pulmonary arterial hypertension (p. 987). Finally, general endotracheal anesthesia with thiopental, succinylcholine, nitrous oxide, and at least 30-percent oxygen has also proved satisfactory.

Intrapartum Heart Failure
Cardiovascular decompensation during labor may manifest as pulmonary edema with hypoxia or as hypotension, or both. The proper therapeutic approach depends on the specific hemodynamic status and the underlying cardiac lesion. For example, decompensated mitral stenosis with pulmonary edema due to fluid overload is often best approached with aggressive diuresis. If precipitated by tachycardia, heart rate control with $\beta$-blocking agents is preferred. Conversely, the same treatment in a woman suffering decompensation and hypotension due to aortic stenosis could prove fatal. Unless the underlying pathophysiology is understood and the cause of the decompensation is clear, empirical therapy may be hazardous. Heart failure is discussed in more detail on page 990.

Puerperium
Women who have shown little or no evidence of cardiac compromise during pregnancy, labor, or delivery may still decompensate postpartum when fluid mobilization into the intravascular compartment and reduction of peripheral vascular resistance place higher demands on myocardial performance. Therefore, it is important that meticulous care be continued into the puerperium (Keizer, 2006; Zeeman, 2006). Postpartum hemorrhage, anemia, infection, and thromboembolism are much more serious complications with heart disease. Indeed, these factors often act in concert to precipitate postpartum heart failure (Cunningham, 1986). In addition to increased cardiac work, many of these—for example, sepsis and severe preeclampsia—cause or worsen pulmonary edema because of endothelial activation and capillary-alveolar leakage (Chap. 47, p. 947).

Sterilization and Contraception
If indicated, tubal sterilization is performed at cesarean delivery. If it is to be performed after vaginal delivery, the procedure can be delayed up to several days to ensure that the mother has become hemodynamically near normal and that she is afebrile, not anemic, and ambulating normally. Other women are given detailed contraceptive advice. Special considerations for contraception in women with various cardiac disorders are discussed in some of the following sections and in Table 38-3 (p. 698).

SURGICALLY CORRECTED HEART DISEASE
Most clinically significant congenital heart lesions are repaired during childhood. Examples of those frequently not diagnosed until adulthood include atrial septal defects, pulmonic stenosis, bicuspid aortic valve, and aortic coarctation (Brickner, 2000). In some cases, the defect is mild and surgery is not required. In others, a significant structural anomaly is amenable to surgical correction. With successful repair, many women attempt pregnancy. In some instances, surgical
Valve Replacement before Pregnancy

Numerous reports describe subsequent pregnancy outcomes in women who have a prosthetic mitral or aortic valve. The type of valve is paramount, and pregnancy is undertaken only after serious consideration in women with a prosthetic mechanical valve. This is because anticoagulation is requisite, and at least when not pregnant, warfarin is necessary. As shown in Table 49-5, a number of serious complications can develop with mechanical valves. Both thromboembolisms involving the prosthesis and hemorrhage from anticoagulation are of extreme concern. This is in addition to deterioration in cardiac function. Overall, the maternal mortality rate is 3 to 4 percent with mechanical valves, and fetal loss is common.

</tr>
</tbody>
</table>

Numbers estimated in some because definitions are not consistent.

Porcine tissue valves are much safer during pregnancy, primarily because thrombosis is rare and anticoagulation is not required (see Table 49-5). Despite this, valvular dysfunction with cardiac deterioration or failure is common and develops in 5 to 25 percent of involved pregnancies. Another drawback is that bioprostheses are not as durable as mechanical ones, and valve replacement longevity averages 10 to 15 years. Based on their longitudinal study of 100 reproductive-aged women with a biological heart valve prosthesis, Cleuziou and colleagues (2010) concluded that pregnancy does not accelerate the risk for replacement.

Anticoagulation

This is critical for women with mechanical prosthetic valves. Unfortunately, warfarin is the most...
effective anticoagulant for preventing maternal thromboembolic complications but causes significant fetal morbidity and mortality. Anticoagulation with heparin is less hazardous for the fetus, however, the risk of maternal thromboembolic complications is much higher (McLintock, 2011).

As noted, warfarin, despite its effective anticoagulation, is teratogenic and causes miscarriage, stillbirths, and fetal malformations (Chap. 12, p. 252). In one study of 71 pregnancies in women given warfarin throughout pregnancy, the rates of miscarriage were 32 percent; stillbirth, 7 percent; and embryopathy, 6 percent (Cotrufo, 2002). The risk was highest when the mean daily dose of warfarin exceeded 5 mg. From a systematic review, Chan and coworkers (2000) concluded that the best maternal outcomes were achieved with warfarin anticoagulation but with a 6.4-percent embryopathy rate. And although heparin substituted before 12 weeks’ gestation eliminated embryopathy, thromboembolic complications during that time were increased significantly.

In examining heparin, anticoagulation for mechanical valves using low-dose unfractionated heparin is definitely inadequate and has a high associated maternal mortality rate (Chan, 2000; Iturbe-Alessio, 1986). Evenfull anticoagulation with either unfractionated heparin (UFH) or one of the low-molecular-weight heparins (LMWH) is associated with valvular thrombosis (Leyh 2002, 2003; Rowan, 2001). Thus, many authorities recommend warfarin. However, the American College of Chest Physicians has recommended use of any of several regimens that include adjusted-dose UFH or LMWH heparin given throughout pregnancy as subsequently discussed (Bates, 2012).

**Recommendations for Anticoagulation.** A number of different treatment options—none of which are completely ideal—have been proposed and are principally based on consensus opinion. For this reason, they differ and allow more than one scheme. For example, and as shown in Table 49-6, the most recent guidelines of the American College of Chest Physicians for the management of pregnant women with mechanical prosthetic valves offer several different treatment options.

<table>
<thead>
<tr>
<th>TABLE 49-6. American College of Chest Physicians Guidelines for Anticoagulation of Pregnant Women with Mechanical Prosthetic Valves</th>
</tr>
</thead>
<tbody>
<tr>
<td>Any one of the following anticoagulant regimens is recommended:</td>
</tr>
<tr>
<td>Adjusted-dose LMWH twice daily throughout pregnancy. The doses should be adjusted to achieve the manufacturer’s peak anti-Xa level 4 hours after subcutaneous injection</td>
</tr>
<tr>
<td>Adjusted-dose UFH administered every 12 hours throughout pregnancy. The doses should be adjusted to keep the midinterval aPTT at least twice control or attain an anti-Xa level of 0.35 to 0.70 U/mL</td>
</tr>
<tr>
<td>LMWH or UFH as above until 13 weeks’ gestation, then warfarin substitution until close to delivery when LMWH or UFH is resumed</td>
</tr>
<tr>
<td>In women judged to be at very high risk of thromboembolism and in whom concerns exist about the efficacy and safety of LMWH or UFH as dosed above—some examples include older-generation prosthesis in the mitral position or history of thromboembolism—warfarin treatment is suggested throughout pregnancy with replacement by UFH or LMWH (as above) close to delivery. In addition, low-dose aspirin—75 to 100 mg daily—should be orally administered</td>
</tr>
</tbody>
</table>

aPTT = activated partial thromboplastin time; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin.
Heparin is discontinued just before delivery. If delivery supervenes while the anticoagulant is still effective, and extensive bleeding is encountered, then protamine sulfate is given intravenously. Anticoagulant therapy with warfarin or heparin may be restarted 6 hours following vaginal delivery, usually with no problems. Following cesarean delivery, full anticoagulation is withheld, but the duration is not exactly known. The American College of Obstetricians and Gynecologists (2011b) advises resuming unfractionated or low-molecular-weight heparin 6 to 12 hours after cesarean delivery. It is our practice, however, to wait at least 24 hours, and preferably 48 hours, following a major surgical procedure.

Because warfarin, low-molecular-weight heparin, and unfractionated heparin do not accumulate in breast milk, they do not induce an anticoagulant effect in the infant. Therefore, these anticoagulants are compatible with breast feeding (American College of Obstetricians and Gynecologists, 2011b).

Contraception

Because of their possible thrombogenic action, estrogen-progestin oral contraceptives are relatively contraindicated in women with prosthetic valves. Because these women are generally fully anticoagulated, however, any increased risk is speculative. Contraceptive options are discussed in Chapters 38 and 39. Sterilization should be considered because of the serious pregnancy risks faced by women with significant heart disease.

Cardiac Surgery During Pregnancy

Although usually postponed until after delivery, valve replacement or other cardiac surgery during pregnancy may be lifesaving. Several reviews confirm that such surgery is associated with major maternal and fetal morbidity and mortality. Sutton and associates (2005) found that maternal mortality rates with cardiopulmonary bypass are between 1.5 and 5 percent. Although these are similar to those for nonpregnant women, the fetal mortality rate approaches 20 percent. In a longitudinal study from the Mayo Clinic, John and coworkers (2011) reported the outcomes of 21 pregnant women who underwent cardiothoracic surgery requiring cardiopulmonary bypass between 1976 and 2009. The procedures included eight aortic valve replacements, six mitral valve repairs or replacements, two myxoma excisions, two aortic aneurysm repairs, one patent foramen ovale closure, one prosthetic aortic valve thrombectomy, and one septal myectomy. Median cardiopulmonary bypass time was 53 minutes, with a range of 16 to 185 minutes. One woman died two days after surgery, and three other deaths occurred 2, 10, and 19 years postoperatively. Three fetuses died, and 52 percent delivered before 36 weeks. To optimize outcomes, Chandrasekhar and coworkers (2009) recommend the following: surgery done electively when possible, pump flow rate maintained > 2.5 L/min/m², normothermic perfusion pressure > 70 mm Hg, pulsatile flow used, and hematocrit kept > 28 percent.

Mitral Valvotomy During Pregnancy

Tight mitral stenosis that requires intervention during pregnancy was previously treated by closed mitral valvotomy (Pavankumar, 1988). More recently, however, percutaneous transcatheter balloon dilatation of the mitral valve has largely replaced surgical valvotomy during pregnancy (Fawzy, 2007). Rahimtoola (2006) summarized outcomes of 36 women—25 of whom were
NYHA class III or IV—who underwent balloon commissurotomy at an average gestational age of 26 weeks. Surgery was successful in 35 women, and left atrial and pulmonary artery pressures were reduced as the mitral valve area was increased from 0.74 to 1.59 cm². Esteves and associates (2006) described similarly good outcomes in 71 pregnant women with tight mitral stenosis and heart failure who underwent percutaneous valvuloplasty. At delivery, 98 percent were either NYHA class I or II. At a mean of 44 months, the total event-free maternal survival rate was 54 percent, however, eight women required another surgical intervention. The 66 infants who were delivered at term all had normal growth and development.

**Pregnancy after Heart Transplantation**

The first successful pregnancy in a heart-transplant recipient was reported 25 years ago by Löwenstein and associates (1988). Since that time, more than 50 pregnancies in heart-transplant recipients have been described. Key (1989) and Kim (1996) and their colleagues provide detailed data to show that the transplanted heart responds normally to pregnancy-induced changes. Despite this, complications are common during pregnancy (Dashe, 1998).

Armenti (2002) from the National Transplantation Pregnancy Registry and Miniero (2004) each with their coworkers, described outcomes of 53 pregnancies in 37 heart recipients. Almost half developed hypertension, and 22 percent suffered at least one rejection episode during pregnancy. They were delivered—usually by cesarean—at a mean of 37 to 38 weeks. Three fourths of infants were liveborn. At follow-up, at least five women had died more than 2 years postpartum. From Scandinavia, Estensen and associates (2011) detailed the outcomes of 19 women who had received a heart transplant and six who received both a heart and lung transplant. These 25 women had 42 pregnancies, and there were no maternal deaths. Major complications included two rejections during the early puerperium, two cases of renal failure, and 11 spontaneous abortions. Five women died 2 to 12 years after delivery. Ethical considerations of counseling and caring for such women related to pregnancy were summarized by Ross (2006).

**VALVULAR HEART DISEASE**

Rheumatic fever is uncommon in the United States because of less crowded living conditions, availability of penicillin, and evolution of nonrheumatogenic streptococcal strains. Still, it remains the chief cause of serious mitral valvular disease (Roeder, 2011).

**Mitral Stenosis**

Rheumatic endocarditis causes most mitral stenosis lesions. The normal mitral valve surface area is 4.0 cm², and when stenosis narrows this to < 2.5 cm², symptoms usually develop (Desai, 2000). The contracted valve impedes blood flow from the left atrium to the ventricle. The most prominent complaint is dyspnea due to pulmonary venous hypertension and edema. Fatigue, palpitations, cough, and hemoptysis are also common.

With more severe stenosis, the left atrium dilates, left atrial pressure is chronically elevated, and significant passive pulmonary hypertension develops (Table 49-7). These women have a relatively fixed cardiac output, and thus the increased preload of normal pregnancy, as well as...
other factors that increase cardiac output, may cause ventricular failure and pulmonary edema. Indeed, a fourth of women with mitral stenosis have cardiac failure for the first time during pregnancy (Caulin-Glaser, 1999). Because the murmur may not be heard in some women, this clinical picture at term may be confused with idiopathic peripartum cardiomyopathy (Cunningham, 1986, 2012).

LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

Also with significant stenosis, tachycardia shortens ventricular diastolic filling time and increases the mitral gradient. This raises left atrial as well as pulmonary venous and capillary pressures and may result in pulmonary edema. Thus, sinus tachycardia is often treated prophylactically with β-blocking agents. Atrial tachyarrhythmias, including fibrillation, are common in mitral stenosis and are treated aggressively. Atrial fibrillation also predisposes to mural thrombus formation and cerebrovascular embolization that can cause stroke (Chap. 60, p. 1192). Atrial thrombosis can develop despite a sinus rhythm, and Hameed (2005) reported three such women. One suffered an embolic stroke, and another had pulmonary edema causing maternal hypoxemia leading to fetal encephalopathy.

**Pregnancy Outcomes**

In general, complications are directly associated with the degree of valvular stenosis. Recall that
investigators from the large Canadian study found that women with a mitral-valve area < 2 cm\(^2\) were at greatest risk. In another study, Hameed (2001) described 46 pregnant women with mitral stenosis—43 percent developed heart failure and 20 percent developed arrhythmias. Fetal-growth restriction was more common in those women with a mitral valve area < 1.0 cm\(^2\).

Prognosis is also related to maternal functional capacity. Among 486 pregnancies complicated by rheumatic heart disease—predominantly mitral stenosis—Sawhney (2003) reported that eight of 10 maternal deaths were in women in NYHA classes III or IV.

**Management**

Limited physical activity is generally recommended in women with mitral stenosis. If symptoms of pulmonary congestion develop, activity is further reduced, dietary sodium is restricted, and diuretics are given (Siva, 2005). A β-blocker drug is usually given to slow the ventricular response to activity (Maxwell, 2010). If new-onset atrial fibrillation develops, intravenous verapamil, 5 to 10 mg, is given, or electrocardioversion is performed. For chronic fibrillation, digoxin, a β-blocker, or a calcium-channel blocker is given to slow ventricular response. Therapeutic anticoagulation with heparin is indicated with persistent fibrillation. Some recommend heparin anticoagulation for those with severe stenosis even if there is a sinus rhythm (Hameed, 2005).

Labor and delivery are particularly stressful for women with symptomatic mitral stenosis. Uterine contractions increase cardiac output by increasing circulating blood volume. Pain, exertion, and anxiety cause tachycardia with possible rate-related heart failure. Epidural analgesia for labor is ideal, but with strict attention to avoid fluid overload. Abrupt increases in preload may increase pulmonary capillary wedge pressure and cause pulmonary edema. The effects of labor on pulmonary pressures in women with mitral stenosis are shown in Figure 49-3. Wedge pressures increase most immediately postpartum. Clark and colleagues (1985) hypothesize that this is likely due to loss of the low-resistance placental circulation along with the venous “autotransfusion” from a now-empty uterus and from the lower extremities and pelvis.
Most consider vaginal delivery to be preferable in women with mitral stenosis. Elective induction is reasonable so that labor and delivery are attended by a scheduled, experienced team. With severe stenosis and chronic heart failure, insertion of a pulmonary artery catheter may help guide management.

**Mitrail Insufficiency**

A trivial degree of mitral insufficiency is found in most normal patients (Maxwell, 2010). But if there is improper coaptation of mitral valve leaflets during systole, abnormal degrees of mitral regurgitation may develop. This is eventually followed by left ventricular dilatation and eccentric hypertrophy (see Table 49-7). Chronic mitral regurgitation has a number of causes, including rheumatic fever, mitral valve prolapse, or left ventricular dilatation of any etiology—for example, dilated cardiomyopathy. Less common causes include a calcified mitral annulus, possibly some appetite suppressants, and in older women, ischemic heart disease. Mitral valve vegetations—*Libman-Sacks endocarditis*—are relatively common in women with antiphospholipid antibodies (Roldan, 1996; Shroff, 2012). These sometimes coexist with systemic lupus erythematosus (Chap. 59, p. 1170). In contrast, acute mitral insufficiency is caused by chordae tendineae rupture, papillary muscle infarction, or leaflet perforation from infective endocarditis.

In nonpregnant patients, symptoms from mitral valve incompetence are rare, and valve replacement is seldom indicated unless infective endocarditis develops. Likewise, mitral regurgitation is well tolerated during pregnancy, probably because decreased systemic vascular resistance results in less regurgitation. Heart failure only rarely develops during pregnancy, and occasionally tachyarrhythmias require treatment.

**Mitrail Valve Prolapse**

This diagnosis implies the presence of a pathological connective tissue disorder—often termed *myxomatous degeneration*—which may involve the valve leaflets themselves, the annulus, or the chordae tendineae. Mitral insufficiency may develop. Most women with mitral valve prolapse are asymptomatic and are diagnosed by routine examination or while undergoing echocardiography. The small percentage of women with symptoms have anxiety, palpitations, atypical chest pain, dyspnea with exertion, and syncope (Guy, 2012).

Pregnant women with mitral valve prolapse rarely have cardiac complications. Hypervolemia may even improve alignment of the mitral valve, and women without pathological myxomatous change generally have excellent pregnancy outcomes (Leśniak-Sobelga, 2004; Rayburn, 1987). In a study of 3100 women in the Taiwanese Birth Registry with mitral valve prolapse, however, the preterm birth rate was 1.2 times higher than among controls (Chen, 2011).

For women who are symptomatic, β-blocking drugs are given to decrease sympathetic tone, relieve chest pain and palpitations, and reduce the risk of life-threatening arrhythmias. According to the American College of Obstetricians and Gynecologists (2011a), mitral valve prolapse is not considered an indication for infective endocarditis prophylaxis.
Aortic Stenosis

Usually a disease of aging, aortic stenosis in women younger than 30 years is most likely due to a congenital lesion. This stenosis is less common since the decline in incidences of rheumatic diseases, and the most frequent cause in this country is a bicuspid valve (Friedman, 2008). A normal aortic valve has an area of 3 to 4 cm$^2$, with a pressure gradient of less than 5 mm Hg. If the valve area is < 1 cm$^2$, there is severe obstruction to flow and a progressive pressure overload on the left ventricle (Carabello, 2002; Roeder, 2011). Concentric left ventricular hypertrophy follows, and if severe, end-diastolic pressures become elevated, ejection fraction declines, and cardiac output is reduced (see Table 49-7). Characteristic clinical manifestations develop late and include chest pain, syncope, heart failure, and sudden death from arrhythmias. Life expectancy averages only 5 years after exertional chest pain develops, and valve replacement is indicated for symptomatic patients.

Pregnancy

Clinically significant aortic stenosis is infrequent during pregnancy. Mild to moderate degrees of stenosis are well tolerated, however, severe disease is life threatening. The principal underlying hemodynamic problem is the fixed cardiac output associated with severe stenosis. During pregnancy, a number of events acutely decrease preload further and thus aggravate the fixed cardiac output. These include vena caval occlusion, regional analgesia, and hemorrhage. Importantly, these also decrease cardiac, cerebral, and uterine perfusion. It follows that severe aortic stenosis may be extremely dangerous during pregnancy. From the large Canadian multicenter study cited above, there were increased complications if the aortic valve area was < 1.5 cm$^2$ (Siu, 2001b). And in the report by Hameed and associates (2001) described earlier, the maternal mortality rate with aortic stenosis was 8 percent. Women with valve gradients exceeding 100 mm Hg appear to be at greatest risk.

Management

For the asymptomatic woman with aortic stenosis, no treatment except close observation is required. Management of the symptomatic woman includes strict limitation of activity and prompt treatment of infections. If symptoms persist despite bed rest, valve replacement or valvotomy using cardiopulmonary bypass must be considered. In general, balloon valvotomy for aortic valve disease is avoided because of serious complications, which exceed 10 percent. These include stroke, aortic rupture, aortic valve insufficiency, and death (Reich, 2004). In rare cases, it may be preferable to perform valve replacement during pregnancy (Datt, 2010).

For women with critical aortic stenosis, intensive monitoring during labor is important. Pulmonary artery catheterization may be helpful because of the narrow margin separating fluid overload from hypovolemia. Women with aortic stenosis are dependent on adequate end-diastolic ventricular filling pressures to maintain cardiac output and systemic perfusion. Abrupt decreases in end-diastolic volume may result in hypotension, syncope, myocardial infarction, and sudden death. Thus, the management key is avoidance of decreased ventricular preload and the maintenance of cardiac output. During labor and delivery, such women should be managed on the “wet” side, maintaining a margin of safety in intravascular volume in anticipation of possible hemorrhage. In women with a competent mitral valve, pulmonary edema is rare, even with moderate volume overload.

During labor, narcotic epidural analgesia seems ideal, thus avoiding potentially hazardous hypotension, which may be encountered with standard conduction analgesia techniques. Easterling
and coworkers (1988) studied the effects of epidural analgesia in five women with severe stenosis and demonstrated immediate and profound effects of decreased filling pressures. Xia and associates (2006) emphasize slow administration of dilute local anesthetic agents into the epidural space. Forceps or vacuum delivery is used for standard obstetrical indications in hemodynamically stable women. Late cardiac events include pulmonary edema, arrhythmias, cardiac interventions, and death, which were identified within 1 year of delivery in 70 pregnancies (Tzemos, 2009).

### Aortic Insufficiency

Aortic valve regurgitation or insufficiency allows diastolic flow of blood from the aorta back into the left ventricle. Frequent causes of abnormal insufficiency are rheumatic fever, connective-tissue abnormalities, and congenital lesions. With Marfan syndrome, the aortic root may dilate, resulting in regurgitation. Acute insufficiency may develop with bacterial endocarditis or aortic dissection. Aortic and mitral valve insufficiency have been linked to the appetite suppressants fenfluramine and dexfenfluramine and to the ergot-derived dopamine agonists cabergoline and pergolide (Gardin, 2000; Schade, 2007; Zanettini, 2007). With chronic insufficiency, left ventricular hypertrophy and dilatation develop and are followed by slow-onset fatigue, dyspnea, and edema, although rapid deterioration usually follows (see Table 49-7).

Aortic insufficiency is generally well tolerated during pregnancy. Like mitral valve incompetence, diminished vascular resistance is thought to improve hemodynamic function. If symptoms of heart failure develop, diuretics are given and bed rest is encouraged.

### Pulmonic Stenosis

The pulmonary valve is affected by rheumatic fever far less often than the other valves. Instead, pulmonic stenosis is usually congenital and also may be associated with Fallot tetralogy or Noonan syndrome. The clinical diagnosis is typically identified by auscultating a systolic ejection murmur over the pulmonary area that is louder during inspiration.

Increased hemodynamic burdens of pregnancy can precipitate right-sided heart failure or atrial arrhythmias in women with severe stenosis. Surgical correction ideally is done before pregnancy, but if symptoms progress, a balloon angioplasty may be necessary antepartum (Maxwell, 2010; Siu, 2001a). In a study of 81 pregnancies in 51 Dutch women with pulmonic stenosis, cardiac complications were infrequent (Drenthen, 2006). NYHA classification worsened in two women, and nine experienced palpitations or arrhythmias. No changes in pulmonary valvular function or other adverse cardiac events were reported. However, noncardiac complications were increased—17 percent had preterm delivery; 15 percent had hypertension; and 4 percent developed thromboembolism. Interestingly, two of the offspring were diagnosed with pulmonic stenosis, and another had complete transposition and anencephaly.

### CONGENITAL HEART DISEASE

The incidence of congenital heart disease in the United States is approximately 8 per 1000 liveborn infants. Approximately a third of these have critical disease that requires cardiac catheterization or surgery during the first year of life. Others require surgery in childhood, and it is
Currently estimated that there are nearly 1 million adults in this country with congenital heart disease (Bashore, 2007).

According to an analysis from the Nationwide Inpatient Sample discharge database, more than 30,000 women admitted for delivery between 1998 and 2007 had congenital heart disease—a rate of 71.6 per 100,000 deliveries (Opotowsky, 2012). After statistical adjustments, women with congenital heart disease were found to be eight times more likely to sustain an adverse cardiovascular event that included death, heart failure, arrhythmia, and cerebrovascular or embolic event. Of these, arrhythmia was the most common, and the rate of maternal death was approximately 1.5 per 1000. Thompson and coworkers (2014) found similar risks.

### Septal Defects

#### Atrial Septal Defects

After bicuspid aortic valve, these are the most frequently encountered adult congenital cardiac lesions. Indeed, a fourth of all adults have a patent foramen ovale (Kizer, 2005). Most are asymptomatic until the third or fourth decade. The secundum-type defect accounts for 70 percent, and associated mitral valve myxomatous abnormalities with prolapse are common. Most recommend repair if discovered in adulthood. Pregnancy is well tolerated unless pulmonary hypertension has developed, but this is uncommon (Maxwell, 2010; Zuber, 1999). Treatment is indicated for congestive heart failure or an arrhythmia. Based on their review, Aliaga and associates (2003) concluded that the risk of endocarditis with an atrial septal defect is negligible.

With the potential to shunt blood from right to left, a paradoxical embolism, that is, entry of a venous thrombus through the septal defect and into the systemic arterial circulation, is possible and may cause an embolic stroke (Chap. 60, p. 1192). Erkut and associates (2006) described a woman who developed an entrapped thrombus in a patent foramen ovale postpartum. In asymptomatic women, thromboembolism prophylaxis is problematic, and recommendations include either observation or antiplatelet therapy such as low-dose aspirin (Kizer, 2005; Maxwell, 2010). Compression stockings and prophylactic heparin for a pregnant woman with a septal defect and concurrent immobility or other risk factors for thromboembolism have also been recommended (Head, 2005).

#### Ventricular Septal Defects

These lesions close spontaneously during childhood in 90 percent of cases. Most defects are paramembranous, and physiological derangements are related to lesion size. In general, if the defect is less than 1.25 cm², pulmonary hypertension and heart failure do not develop. If the effective defect size exceeds that of the aortic valve orifice, symptoms rapidly develop. For these reasons, most children undergo surgical repair before pulmonary hypertension develops. Adults with unrepaired large defects develop left ventricular failure and pulmonary hypertension and have a high incidence of bacterial endocarditis (Brickner, 2000; Maxwell, 2010).

Pregnancy is well tolerated with small to moderate left-to-right shunts. If pulmonary arterial pressures reach systemic levels, however, there is reversal or bidirectional flow—Eisenmenger syndrome (p. 985). When this develops, the maternal mortality rate is significantly increased, and thus, pregnancy is not generally advisable. Bacterial endocarditis is more common with unrepaired defects, and antimicrobial prophylaxis is often required (p. 991). As shown in Table 49-4, up to 15 percent of offspring born to these women also have a ventricular septal defect.
Atrioventricular Septal Defects

These account for approximately 3 percent of all congenital cardiac malformations and are distinct from isolated atrial or ventricular septal defects. An atrioventricular (AV) septal defect is characterized by a common, ovoid AV junction. This defect is associated with aneuploidy, Eisenmenger syndrome, and other malformations, but still, some of these women become pregnant. Compared with simple septal defects, complications are more frequent during pregnancy. In a review of 48 pregnancies in 29 such women, complications included persistent deterioration of NYHA class in 23 percent, significant arrhythmias in 19 percent, and heart failure in 2 percent (Drenthen, 2005b). Congenital heart disease was identified in 15 percent of the offspring.

Persistent (Patent) Ductus Arteriosus

The ductus connects the proximal left pulmonary artery to the descending aorta just distal to the left subclavian artery. Functional closure of the ductus from vasoconstriction occurs shortly after term birth (Akintunde, 2011). The physiological consequences of persistence of this structure are related to its size. Most significant lesions are repaired in childhood, but for individuals who do not undergo repair, the mortality rate is high after the fifth decade (Brickner, 2000). In some younger women with an unrepaired ductus during pregnancy, however, pulmonary hypertension, heart failure, or cyanosis will develop if systemic blood pressure falls and leads to shunt reversal of blood from the pulmonary artery into the aorta (Maxwell, 2010). A sudden blood pressure decline at delivery—such as with conduction analgesia or hemorrhage—may lead to fatal collapse. Therefore, hypotension should be avoided whenever possible and treated vigorously if it develops. Prophylaxis for bacterial endocarditis may be indicated at delivery for unrepaired defects (p. 991). As shown in Table 49-4, the incidence of inheritance is approximately 4 percent.

Cyanotic Heart Disease

When congenital heart lesions are associated with right-to-left shunting of blood past the pulmonary capillary bed, cyanosis develops. The classic and most commonly encountered lesion in adults and during pregnancy is the Fallot tetralogy (Maxwell, 2010). It is characterized by a large ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta that receives blood from both the right and left ventricles. The magnitude of the shunt varies inversely with systemic vascular resistance. Hence, during pregnancy, when peripheral resistance decreases, the shunt increases and cyanosis worsens. Women who have undergone repair and who do not have a recurrence of cyanosis do well in pregnancy.

Some women with Ebstein anomaly with a malpositioned, malformed tricuspid valve may reach reproductive age. Right ventricular failure from volume overload and appearance or worsening of cyanosis are common during pregnancy. In the absence of cyanosis, these women usually tolerate pregnancy well.

Women with cyanotic heart disease generally do poorly during pregnancy. With uncorrected Fallot tetralogy, for example, maternal mortality rates approach 10 percent. Moreover, any disease complicated by severe maternal hypoxemia is likely to lead to miscarriage, preterm delivery, or fetal death. There is a relationship between chronic hypoxemia, polycythemia, and pregnancy outcome. When hypoxemia is intense enough to stimulate a rise in hematocrit above 65 percent, pregnancy wastage is virtually 100 percent.

Pregnancy after Surgical Repair
Some of the more complex lesions cannot be successfully repaired. But with satisfactory surgical correction of cyanotic lesions before pregnancy, maternal and fetal outcomes are much improved (Maxwell, 2010).

**Fallot Tetralogy.** Balci (2011) and Kamiya (2012) and their associates described a total of 197 pregnancies in 99 women with surgically corrected Fallot tetralogy. Pregnancy was usually well tolerated, and there were no maternal deaths. Still, almost 9 percent of pregnancies were complicated by adverse cardiac events including new onset or worsening of arrhythmias and heart failure. For women with a pulmonary valve replacement, Oosterhof and coworkers (2006) reported that pregnancy did not adversely affect graft function.

**Transposition of the Great Vessels.** Pregnancy following surgical correction of transposition also has risks. Canobbio (2006) and Drenthen (2005a), each with their colleagues, described outcomes of 119 pregnancies in 68 women—90 percent had a Mustard procedure and 10 percent a Senning procedure. During pregnancy, a fourth had arrhythmias. Twelve percent developed heart failure, and one of these patients subsequently required cardiac transplantation. One woman died suddenly a month after delivery, and another died 4 years later. A third of the newborns were delivered preterm, but no infant had heart disease. In a more recent study, Metz and associates (2011) reported that five of 14 pregnancies resulting in live births were complicated by symptomatic intracardiac baffle obstruction, which required postpartum stenting. In review, baffles are surgically constructed conduits that redirect anomalous cardiac blood flow and are integral to initial transposition correction.

Successful—although eventful—pregnancies in women with previously repaired *truncus arteriosus* and *double-outlet right ventricle* have also been described (Drenthen, 2008; Hoendermis, 2008).

**Single Functional Ventricle.** Feinstein and associates (2012) recently reviewed the remarkably improved treatments for patients with *hypoplastic left heart syndrome*. Almost 70 percent of these women are now expected to survive into adulthood and frequently become pregnant. Those who have undergone a *Fontan repair* are at particularly high risk for complications, which include atrial arrhythmias and peripartum heart failure (Nitsche, 2009). In a report of four pregnancies post-Fontan repair, there were no maternal deaths, but complications were frequent (Hoare, 2001). All were delivered preterm, two had supraventricular arrhythmias, and two developed ventricular failure. Similarly high complication rates were described by Jain and coworkers (2011) in 15 women with a systemic right ventricle, that is, one in which the right ventricle rather than the left pumps blood to the support systemic circulation.

**Eisenmenger Syndrome**

This describes secondary pulmonary hypertension that develops from any cardiac lesion. The syndrome develops when pulmonary vascular resistance exceeds systemic resistance and leads to concomitant right-to-left shunting. The most common underlying defects are atrial or ventricular septal defects and persistent ductus arteriosus (*Fig. 49-4*). Patients are asymptomatic for years, but eventually pulmonary hypertension becomes severe enough to cause right-to-left shunting, and few persons survive into the fifth decade (Makaryus, 2006; Maxwell, 2010).
FIGURE 49-4 Eisenmenger syndrome due to a ventricular septal defect (VSD). **A.** Substantial left-to-right shunting through the VSD leads to morphological changes in the smaller pulmonary arteries and arterioles. Specifically, medial hypertrophy, intimal cellular proliferations, and fibrosis lead to narrowing or closure of the vessel lumen. These vascular changes create pulmonary hypertension and a resultant reversal of the intracardiac shunt (**B**). With sustained pulmonary hypertension, extensive atherosclerosis and calcification often develop in the large pulmonary arteries. Although a VSD is shown here, Eisenmenger syndrome may also develop in association with a large atrial septal defect or patent ductus arteriosus.

The prognosis for pregnancy depends on the severity of pulmonary hypertension but survival has improved during the past 50 years. Women with Eisenmenger syndrome tolerate hypotension poorly, and the cause of death usually is right ventricular failure with cardiogenic shock. Management is discussed subsequently. In a review of 44 cases through 1978, maternal and perinatal mortality rates approximated 50 percent (Gleicher, 1979). In a later review of 73 pregnancies, Weiss and coworkers (1998) cited a 36-percent maternal death rate. Three of 26 deaths were antepartum, and the remainder died intrapartum or within a month of delivery. In a more recent study of 13 pregnant women, there was one maternal death 17 days after delivery, and
there were five perinatal deaths (Wang, 2011).

PULMONARY HYPERTENSION

Normal resting mean pulmonary artery pressure is 12 to 16 mm Hg. In the study by Clark and colleagues (1989), pulmonary vascular resistance in late pregnancy was approximately 80 dyn/sec/cm$^{-5}$, which was 34-percent less than the nonpregnant value of 120 dyne/sec/cm$^{-5}$. *Pulmonary hypertension* is a hemodynamic observation and not a diagnosis and is defined in nonpregnant individuals as a mean pulmonary pressure $>$ 25 mm Hg.

The World Health Organization classification shown in Table 49-8 has been adopted by the American College of Cardiology and the American Heart Association (McLaughlin, 2009). There are important prognostic and therapeutic distinctions between group I pulmonary hypertension and the other groups. Group I indicates that a specific disease affects pulmonary arterioles. It includes idiopathic or primary pulmonary arterial hypertension as well as those cases secondary to a known cause such as connective-tissue disease. Approximately a third of women with scleroderma and 10 percent with systemic lupus erythematosus have pulmonary hypertension (Rich, 2005). Other causes in young women are sickle-cell disease and thyrotoxicosis (Sheffield, 2004). Another is plexogenic pulmonary arteriopathy associated with cirrhosis and portal hypertension, and this has been reported to cause a maternal death (Sigel, 2007).

Adapted from Simmoneau, 2004.
Group II disorders are the most commonly encountered in pregnant women. These are secondary to pulmonary venous hypertension caused by left-sided atrial, ventricular, or valvular disorders. A typical example is mitral stenosis discussed on page 981. In contrast, groups II through V are seen infrequently in young otherwise healthy women.

### Diagnosis

Symptoms may be vague, and dyspnea with exertion is the most common. With group II disorders, orthopnea and nocturnal dyspnea are also usually present. Angina and syncope occur when right ventricular output is fixed, and they suggest advanced disease. Chest radiography commonly shows enlarged pulmonary hilar arteries and attenuated peripheral markings. It also may disclose parenchymal causes of hypertension. Although cardiac catheterization remains the standard criterion for the measurement of pulmonary artery pressures, noninvasive echocardiography is often used to provide an estimate. In 33 pregnant women who underwent both echocardiography and cardiac catheterization, pulmonary artery pressures were significantly overestimated by echocardiography in a third of cases (Penning, 2001).

### Prognosis

Longevity depends on the severity and cause of pulmonary hypertension at discovery. For example, although invariably fatal, idiopathic pulmonary hypertension has a 3-year survival rate of 60 percent, whereas that due to collagen-vascular diseases has only a 35-percent rate (McLaughlin, 2004). Some disorders respond to pulmonary vasodilators, calcium-channel blockers, prostacyclin analogues, or endothelin-receptor blockers, all which may improve quality of life. The prostacyclin analogues epoprostenol and treprostinil significantly lower pulmonary vascular resistance but must be given parenterally (Humbert, 2004; Roeleveld, 2004). Preconceptional counseling is imperative as emphasized by Easterling and associates (1999).

### Pulmonary Hypertension and Pregnancy

The maternal mortality rate is appreciable, but this is especially so with idiopathic pulmonary hypertension. In the past, there were frequently poor distinctions in identifying both causes and severity of hypertension. Thus, although most severe cases of idiopathic pulmonary arterial hypertension had the worst prognosis, it was erroneously assumed that all types of pulmonary hypertension were equally dangerous. With widespread use of echocardiography, less-severe lesions with a better prognosis are now separable. Curry (2012) and Weiss (1998) and their colleagues reviewed 36 cases of pulmonary hypertension in pregnancy and found an approximate 30-percent mortality rate. Bédard and coworkers (2009) reported that mortality statistics improved during the decade ending in 2007 compared with those for the decade ending in 1996. Mortality rates were 25 and 38 percent, respectively. Importantly, almost 80 percent of the deaths were during the first month postpartum.

Pregnancy is contraindicated with severe disease, especially those with pulmonary arterial changes—most cases in group I. With milder disease from other causes—group II being the most common—the prognosis is much better. With the more frequent use of echocardiography and
pulmonary artery catheterization in young women with heart disease, we have identified women with mild to moderate pulmonary hypertension who tolerate pregnancy, labor, and delivery well. One example described by Sheffield and Cunningham (2004) is that of pulmonary hypertension that develops with thyrotoxicosis but is reversible with treatment (Chap. 58, p. 1151). Similarly, Bogess and colleagues (1995) described nine women with interstitial and restrictive lung disease with varying degrees of pulmonary hypertension, and all tolerated pregnancy reasonably well.

Management
Treatment of symptomatic pregnant women includes activity limitation and avoidance of the supine position in late pregnancy. Diuretics, supplemental oxygen, and vasodilator drugs are standard therapy for symptoms. Some recommend anticoagulation (Hsu, 2011; Larson, 2010). In addition, there are many reports describing the successful use of intravenous pulmonary artery vasodilators in both singleton and twin gestations (Badalian, 2000; Easterling, 1999; Garabedian, 2010). Prostacyclin analogues that can be administered parenterally include epoprostenol and treprostinil, whereas iloprost is inhaled. There are reports of successful use of each in pregnant women, but data are insufficient to prefer one over another. Inhaled nitric oxide is also an option that has been employed in cases of acute cardiopulmonary decompensation during pregnancy or the puerperium (Lane, 2011).

Labor and Delivery
These women are at greatest risk during labor and delivery when there is diminished venous return and decreased right ventricular filling—both associated with most maternal deaths. To avoid hypotension, assiduous attention is given to epidural analgesia induction and to blood loss prevention and treatment at delivery. Parneix and coworkers (2009) describe low-dose spinal-epidural analgesia for cesarean delivery. Women with group I severe hypertension have been delivered successfully while using either inhaled nitric oxide or iloprost (Lam, 2001; Weiss, 2000).

CARDIOMYOPATHIES

The American Heart Association defines cardiomyopathies as a heterogeneous group of myocardial diseases associated with mechanical and/or electrical dysfunction. Affected women usually—but not invariably—have inappropriate ventricular hypertrophy or dilatation. Cardiomyopathies are due to various causes that frequently are genetic (Maron, 2006). In general, and as shown in Table 49-9, cardiomyopathies may be divided into two major groups:

• Primary—cardiomyopathies solely or predominantly confined to heart muscle—examples include hypertrophic cardiomyopathy, dilated cardiomyopathies, and peripartum cardiomyopathy.
• Secondary—cardiomyopathies due to generalized systemic disorders that produce pathological myocardial involvement—examples are diabetes, lupus, and thyroid disorders.

- Peripartum cardiomyopathy

- **Secondary Causes**

- Diabetes
- Lupus
- Thyroid disorders

The American Heart Association defines cardiomyopathies as a heterogeneous group of myocardial diseases associated with mechanical and/or electrical dysfunction. Affected women usually—but not invariably—have inappropriate ventricular hypertrophy or dilatation. Cardiomyopathies are due to various causes that frequently are genetic (Maron, 2006). In general, and as shown in Table 49-9, cardiomyopathies may be divided into two major groups:

• Primary—cardiomyopathies solely or predominantly confined to heart muscle—examples include hypertrophic cardiomyopathy, dilated cardiomyopathies, and peripartum cardiomyopathy.
• Secondary—cardiomyopathies due to generalized systemic disorders that produce pathological myocardial involvement—examples are diabetes, lupus, and thyroid disorders.
Genetic—hypertrophic cardiomyopathy, arrhythmogenic right ventricular dysplasia, left ventricular noncompaction, glycogen storage diseases, conduction system disease, mitochondrial myopathies, ion-channelopathies

Mixed—predominantly nongenetic—dilated and restrictive cardiomyopathy

Acquired—myocarditis, stress (takotsubo), peripartum cardiomyopathy

**Secondary Causes**

- Infiltrative—amyloidosis, Gaucher disease, Hurler and Hunter diseases
- Storage—hemochromatosis
- Toxicity—drugs, heavy metals
- Endomyocardial—hypereosinophilic syndrome
- Granulomatous—sarcoidosis
- Endocrine—diabetes mellitus, thyroid dysfunction
- Cardiofacial—Noonan syndrome
- Neuromuscular/neurological—Friedrich ataxia, neurofibromatosis
- Autoimmune—systemic lupus erythematosus, scleroderma

---

**Hypertrophic Cardiomyopathy**

Epidemiological studies suggest that the disorder is common, affecting approximately 1 in 500 adults (Maron, 2004). The condition—characterized by cardiac hypertrophy, myocyte disarray, and interstitial fibrosis—is caused by mutations in any one of more than a dozen genes that encode cardiac sarcomere proteins. Inheritance is autosomal dominant, and genetic screening is complex and not currently clinically available (Osio, 2007; Spirito, 2006). The myocardial muscle abnormality is characterized by left ventricular myocardial hypertrophy with a pressure gradient to left ventricular outflow. Diagnosis is established by echocardiographic identification of a hypertrophied and nondilated left ventricle in the absence of other cardiovascular conditions.

Most affected women are asymptomatic, but dyspnea, anginal or atypical chest pain, syncope, and arrhythmias may develop. Complex arrhythmias may progress to sudden death, which is the most common form of death. Asymptomatic patients with runs of ventricular tachycardia are especially prone to sudden death. Symptoms are usually worsened by exercise.

**Pregnancy**

Although limited reports suggest that pregnancy is well tolerated, adverse cardiac events are common. Thaman and coworkers (2003) reviewed 271 pregnancies in 127 affected women. Although there were no maternal deaths, more than a fourth had at least one adverse cardiac symptom—including dyspnea, chest pain, or palpitations. Singla and associates (2011) described a pregnant patient with undiagnosed hypertrophic cardiomyopathy who presented with preeclampsia and an acute myocardial infarction.

Management is similar to that for aortic stenosis. Strenuous exercise is prohibited during pregnancy. Abrupt positional changes are avoided to prevent reflex vasodilation and decreased preload. Likewise, drugs that evoke diuresis or diminish vascular resistance are generally not used. If symptoms develop, especially angina, β-adrenergic or calcium-channel blocking drugs are
given. The delivery route is determined by obstetrical indications. Choice of anesthesia is controversial, and in the opinion of some authors, general anesthesia is considered safest (Pitton, 2007). Infants rarely demonstrate inherited lesions at birth.

### Dilated Cardiomyopathy

This is characterized by left and/or right ventricular enlargement and reduced systolic function in the absence of coronary, valvular, congenital, or systemic disease known to cause myocardial dysfunction. Although there are many known causes of dilated cardiomyopathy—both inherited and acquired, the etiology remains undefined in approximately half of cases (Stergiopoulos, 2011). Some cases are result from viral infections, including myocarditis and human immunodeficiency virus (Barbaro, 1998; Felker, 2000). Other causes, which are potentially reversible, include alcoholism, cocaine abuse, and thyroid disease. Watkins and colleagues (2011) reviewed the many complex genetic mutations associated with inherited forms of dilated cardiomyopathy.

### Peripartum Cardiomyopathy

This disorder is very similar to other forms of nonischemic dilated cardiomyopathy except for its unique relationship with pregnancy (Pyatt, 2011). Currently, it is a diagnosis of exclusion following a concurrent evaluation for peripartum heart failure. Although the term peripartum cardiomyopathy has been used widely, at least until recently, there was little evidence to support a unique pregnancy-induced cardiomyopathy. Pearson (2000) reported findings of a workshop of the National Heart, Lung, and Blood Institute and the Office of Rare Diseases that established the following diagnostic criteria:

1. Development of cardiac failure in the last month of pregnancy or within 5 months after delivery,
2. Absence of an identifiable cause for the cardiac failure,
3. Absence of recognizable heart disease prior to the last month of pregnancy, and
4. Left ventricular systolic dysfunction demonstrated by classic echocardiographic criteria, such as depressed ejection fraction or fractional shortening along with a dilated left ventricle (Fig. 49-5).
The etiology of peripartum cardiomyopathy remains unknown, and many potential causes—including viral myocarditis, abnormal immune response to pregnancy, abnormal response to the increased hemodynamic burden of pregnancy, hormonal interactions, malnutrition, inflammation, and apoptosis—have been proposed but not proven (Elkayam, 2011). Another theory suggests that oxidative stress during late pregnancy leads to the proteolytic cleavage of prolactin (Hilfiker-Kleiner, 2007). The resulting 16-kDa prolactin fragment has been found to be cardiotoxic and can impair the metabolism and contractility of cardiomyocytes. Based on this proposed mechanism, bromocriptine therapy has been suggested because it inhibits prolactin secretion (Chap. 36, p. 673). Indeed, there has been at least one preliminary study in which bromocriptine improved recovery of affected women (Sliwa, 2010).

Another intriguing mechanism to explain the etiology of peripartum cardiomyopathy was described by Patten (2012). It links peripartum cardiomyopathy to preeclampsia syndrome. This is biologically plausible given that hypertensive disorders frequently coexist with peripartum cardiomyopathy (Cunningham, 2012; Fong, 2014; Gunderson, 2011). These investigators showed that antiangiogenic factors—already known to be associated with preeclampsia—can induce peripartum cardiomyopathy in susceptible mice. Thus, they posit peripartum cardiomyopathy to be a vascular disease precipitated by antiangiogenic factors that act in a host made susceptible because of insufficient proangiogenic factors.

In the absence of a proven etiology, the diagnosis of peripartum cardiomyopathy currently requires that other causes of cardiac dysfunction be excluded. Bültmann and coworkers (2005) studied endomyocardial biopsy specimens from 26 women with peripartum cardiomyopathy and reported that more than half had histological evidence of “borderline myocarditis.” They noted viral genomic material for parvovirus B19, human herpesvirus 6, Epstein-Barr virus, and...
cytomegalovirus. They attributed these findings to reactivation of latent viral infection that triggered an autoimmune response. Another report described 28 women at Parkland Hospital who had peripartum heart failure of obscure etiology who were initially thought to have idiopathic peripartum cardiomyopathy (Cunningham, 1986). In 21 of these, heart failure was found to be caused by hypertensive heart disease, clinically silent mitral stenosis, obesity, or viral myocarditis. Particularly important were the silent cardiomyopathic effects that even intermediate-duration chronic hypertension may have on ventricular function.

After exclusion of an underlying cause for heart failure, the default diagnosis is idiopathic or peripartum cardiomyopathy. Thus, its incidence is highly dependent on the diligence of the search for a cause. Because of this, the cited incidence varies from approximately 1 in 2500 to 1 in 15,000 births. In a review of the National Hospital Discharge Survey database of 3.6 million births, a prevalence of 1 in 3200 births was computed (Mielenzuk, 2006). Two other large population-based studies cited a frequency of 1 in 2000 to 2800 (Gunderson, 2011; Harper, 2012). In an earlier study from Parkland Hospital, we identified idiopathic cardiomyopathy in only approximately 1 in 15,000 deliveries—an incidence similar to that of idiopathic cardiomyopathy in young nonpregnant women (Cunningham, 1986).

Prognosis. The distinction between heart failure from an identifiable cause and peripartum cardiomyopathy is of obstetrical importance. Women with a true cardiomyopathy do not fare well overall as a group, and their immediate and 1-year mortality rate is 2 to 15 percent (Harper, 2012; Mielenzuk, 2006). Approximately 50 percent of women suffering from peripartum cardiomyopathy recover baseline ventricular function within 6 months of delivery, but in those with persistent cardiac failure, the mortality rate approaches 85 percent over 5 years (Moioli, 2010).

A study from India described the outcomes of 36 women with peripartum cardiomyopathy (Mandal, 2011). Five women died either from heart failure or cerebrovascular accident. Of six women who had a subsequent pregnancy, one woman died and two developed heart failure. In a follow-up study from Haiti, Fett and coworkers (2009) performed echocardiography every 6 months in 116 women with peripartum cardiomyopathy. Only 28 percent of these women recovered a left ventricular ejection fraction > 0.51, and in three fourths of these, this level was not attained until after a year. With a mean follow-up of 39 months, de Souza and colleagues (2001) reported that 18 percent of 44 such women had died from end-stage heart failure. Similar long-term outcomes were assessed by a survey of members of the American College of Cardiology (Elkayam, 2001). Respondents reported that a return to normal ventricular function does not guarantee a problem-free pregnancy, and that if another pregnancy is undertaken in women with an ejection fraction persistently < 0.5, it should be with great trepidation.

Other Primary Causes of Cardiomyopathy

Arrhythmogenic Right Ventricular Dysplasia

This unique cardiomyopathy is defined histologically by progressive replacement of right ventricular myocardium with adipose and fibrous tissue. As described on page 992, this disorder predisposes to ventricular tachyarrhythmias. It has an estimated prevalence is 1 in 5000 and is a cause of sudden death, particularly in younger people (Elliott, 2008). The additional risk of pregnancy in women with arrhythmogenic right ventricular cardiomyopathy is unknown. However, based on a systematic review, Krul and associates (2011) advise against pregnancy.
Restrictive Cardiomyopathy

This inherited cardiomyopathy is probably the least common type. It is characterized by a ventricular filling pattern in which increased myocardial stiffness causes ventricular pressure to rise precipitously with only a small increase in volume (Elliott, 2008). Due to the severe clinical course in nonpregnant patients and the poor prognosis in general, pregnancy is not advised (Krul, 2011).

HEART FAILURE

Regardless of the underlying condition that causes cardiac dysfunction, women who develop peripartum heart failure almost always have obstetrical complications that either contribute to or precipitate heart failure. For example, preeclampsia is common and may precipitate afterload failure. High-output states caused by hemorrhage and acute anemia increase cardiac workload and magnify the physiological effects of compromised ventricular function. Similarly, infection and sepsis syndrome increase cardiac output and oxygen utilization tremendously, and sepsis can depress myocardial function (Chap. 47, p. 948).

As described in Chapter 50 (p. 1003), in many populations, chronic hypertension with superimposed preeclampsia is the most frequent cause of heart failure in pregnant women. Many of these women have concentric left ventricular hypertrophy. In some, mild antecedent undiagnosed hypertension causes covert cardiomyopathy, and when superimposed preeclampsia develops, together they may cause otherwise inexplicable peripartum heart failure. As discussed throughout Chapter 48 (p. 963), obesity is a common cofactor with chronic hypertension, and it leads to eccentric ventricular hypertrophy. In the Framingham Heart Study, obesity alone was associated with a doubling of the heart failure risk in nonpregnant individuals (Kenchaiah, 2002).

Diagnosis

Congestive heart failure can have a gradual onset or may present as acute “flash” pulmonary edema. The first warning sign is likely to be persistent basilar rales, frequently accompanied by a nocturnal cough (Jessup, 2003). A sudden decline in the ability to complete usual duties, increased dyspnea on exertion, and/or attacks of smothering with cough are symptoms of serious heart failure. Clinical findings may include hemoptysis, progressive edema, tachypnea, and tachycardia. Dyspnea is universal, and other symptoms include orthopnea, palpitations, and substernal chest pain (Sheffield, 1999). Hallmark findings usually include cardiomegaly and pulmonary edema (see Fig. 49-5). Acutely, there is usually systolic failure, and echocardiographic findings include an ejection fraction < 0.45 or a fractional shortening < 30 percent, or both, and an end-diastolic dimension > 2.7 cm/m$^2$ (Hibbard, 1999). Coincidental diastolic failure may also be found, depending on the underlying cause.

Management

Pulmonary edema from heart failure usually responds promptly with diuretic administration to reduce preload. Hypertension is common, and afterload reduction is accomplished with hydralazine or another vasodilator. Because of marked fetal effects, angiotensin-converting enzyme inhibitors are withheld until the woman is delivered (Chap. 12, p. 247). With chronic heart failure,
there is a high incidence of associated thromboembolism, and thus prophylactic heparin is often recommended.

Left ventricular assist devices (LVADs) are employed more frequently for acute and chronic heart failure treatment. However, there are only a few reports describing their use during pregnancy (LaRue, 2011; Sims, 2011). Extracorporeal membrane oxygenation (ECMO) was reported to be lifesaving in a woman with fulminating cardiomyopathy (Smith, 2009).

### INFECTIVE ENDOCARDITIS

Bacterial infection of a heart valve involves cardiac endothelium and usually results in valvular vegetations. In this country, those at greatest risk are women with congenital heart lesions, intravenous drug use, degenerative valve disease, and intracardiac devices (Karchmer, 2012). Subacute bacterial endocarditis usually is due to a low-virulence bacterial infection superimposed on an underlying structural lesion. These are usually native valve infections. Organisms that cause indolent endocarditis are most often viridans-group streptococci or *Staphylococcus* or *Enterococcus* species. Among intravenous drug abusers and those with catheter-related infections, *Staphylococcus aureus* is the predominant organism. *Staphylococcus epidermidis* frequently causes prosthetic valve infections. *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* may occasionally cause acute, fulminating disease. Antepartum endocarditis has also been described with *Neisseria sicca* and *Neisseria mucosa*, the latter causing maternal death (Cox, 1988; Deger, 1992). Only a few cases of group B streptococcal endocarditis have been described (Kangavari, 2000). Endocarditis due to *Escherichia coli* following cesarean delivery was described in an otherwise healthy young woman (Kulaš, 2006).

### Diagnosis

Endocarditis symptoms are variable and often develop insidiously. Fever, often with chills, is seen in 80 to 90 percent of cases, a murmur is heard in 80 to 85 percent, and anorexia, fatigue, and other constitutional symptoms are common. The illness is frequently described as “flulike” (Karchmer, 2012). Other findings are anemia, proteinuria, and manifestations of embolic lesions, including petechiae, focal neurological manifestations, chest or abdominal pain, and ischemia in an extremity. In some cases, heart failure develops. Symptoms may persist for several weeks before the diagnosis is found, and a high index of suspicion is necessary.

Diagnosis is made using the *Duke criteria*, which include positive blood cultures for typical organisms and evidence of endocardial involvement (Hoen, 2013; Pierce, 2012). Echocardiography may be diagnostic, but lesions < 2 mm in diameter or those on the tricuspid valve may be missed. If uncertain, transesophageal echocardiography (TEE) is accurate and informative. Importantly, a negative echocardiographic study does not exclude endocarditis.

### Management

Treatment is primarily medical with appropriate timing of surgical intervention if necessary. Knowledge of the infecting organism and its sensitivities is imperative for sensible antimicrobial selection. Guidelines for appropriate antibiotic treatment are published by professional societies and are updated regularly (Hoen, 2013). Most streptococci are sensitive to penicillin G.
ceftriaxone, or vancomycin given intravenously for 4 to 6 weeks, along with gentamicin for 2 to 4 weeks. Complicated infections are treated longer, and women allergic to penicillin are either desensitized or given intravenous ceftriaxone or vancomycin for 4 weeks. Staphylococci, enterococci, and other organisms are treated according to microbial sensitivity for 4 to 6 weeks (Darouiche, 2004; Karchmer, 2012). Prosthetic valve infections are usually treated for 6 weeks. Recalcitrant bacteremia and heart failure due to valvular dysfunction are but a few reasons that persistent valvular infection may require replacement.

## Endocarditis in Pregnancy

Infective endocarditis is uncommon during pregnancy and the puerperium. Treatment is the same as that described above. During a 7-year period, the incidence of endocarditis at Parkland Hospital was approximately 1 in 16,000 births, and two of seven women died (Cox, 1988). From their reviews, Seaworth (1986) and Cox (1989) cited a maternal mortality rate of 25 to 35 percent.

### Endocarditis Prophylaxis

For years, patients with real or imagined heart valve problems were given periprocedural antibiotic prophylaxis for endocarditis. This was despite the questioned efficacy of antimicrobial prophylaxis. Currently, however, recommendations are more stringent. The American Heart Association recommends prophylaxis for dental procedures in those with prosthetic valves; prior endocarditis; un repaired or incompletely repaired cyanotic heart defects or during the 6 months following complete repair; and valvulopathy after heart transplantation (Wilson, 2007). In agreement with this, the American College of Obstetricians and Gynecologists (2011a) does not recommend endocarditis prophylaxis for either vaginal or cesarean delivery in the absence of pelvic infection. Exceptions are the small subset of patients cited above. Women at highest risk for endocarditis are those with cyanotic cardiac disease, prosthetic valves, or both.

When indicated, and for women not already receiving intrapartum antimicrobial therapy for another indication that would also provide coverage against endocarditis, prophylactic regimens are shown in [Table 49-10](#). These are administered as close to 30 to 60 minutes before the anticipated delivery time as is feasible. Despite these new recommendations, prophylaxis is still overused, likely because of prior liberal recommendations. In a study from one institution, only six of 50 women who received antibiotics for endocarditis prophylaxis were judged to have an appropriate indication (Pocock, 2006).

ARRHYTHMIAS

Both preexisting and new-onset cardiac arrhythmias are often encountered during pregnancy, labor, delivery, and the puerperium (Gowda, 2003). In a study of 73 women with a history of supraventricular tachycardia, paroxysmal atrial flutter or fibrillation, or ventricular tachycardia, recurrence rates during pregnancy were 50, 52, and 27 percent, respectively (Silversides, 2006). The mechanism(s) responsible for the increased incidence of arrhythmias during pregnancy are not well elucidated. According to Eghbali and associates (2006), adaptive electric cardiac remodeling of potassium-channel genes may be important. Perhaps the normal but mild hypokalemia of pregnancy and/or the physiological increase in heart rate serves to induce arrhythmias (Chap. 4, p. 58). Alternatively, detection of arrhythmias may be increased because of the frequent visits typical of normal prenatal care.

Bradyarrhythmias

Slow heart rhythms, including complete heart block, are compatible with a successful pregnancy outcome. Some women with complete heart block have syncope during labor and delivery, and occasionally temporary cardiac pacing is necessary (Hidaka, 2006). In our experiences, as well as those of Hidaka (2011) and Jaffe (1987) and their associates, women with permanent artificial pacemakers usually tolerate pregnancy well. With fixed-rate devices, cardiac output apparently is increased by augmented stroke volume.

Supraventricular Tachycardias

The most common arrhythmia seen in reproductive-aged women is *paroxysmal supraventricular tachycardia* (Robins, 2004). If diagnosed when nonpregnant, approximately a third of women have an occurrence during pregnancy (Maxwell, 2010). Conversely, rarely do *atrial fibrillation* and *atrial flutter* present for the first time during pregnancy. Indeed, new-onset atrial fibrillation should prompt a search for underlying etiologies including cardiac anomalies, hyperthyroidism, pulmonary embolism, drug toxicity, and electrolyte disturbances (DiCarlo-Meacham, 2011). Major complications include embolic stroke, and when associated with mitral stenosis, pulmonary edema may develop in later pregnancy if the ventricular rate is increased.

Treatment of supraventricular tachycardias include vagal maneuvers—Valsalva, carotid sinus massage, bearing down, and immersion of the face in ice water—which serve to increase vagal tone and block the atrioventricular node (Link, 2012). Intravenous adenosine is a very short-acting endogenous nucleotide that also blocks atrioventricular nodal conduction. Our experiences are similar to those of others in that adenosine is safe and effective for cardioversion in hemodynamically stable pregnant women (Maxwell, 2010; Robins, 2004). Transient fetal bradycardia has been described with adenosine (Dunn, 2000).

Electrical cardioversion with standard energy settings is not contraindicated in pregnancy, but vigilance is important. Barnes and associates (2002) described a case in which direct current cardioversion led directly to a sustained uterine contraction and fetal bradycardia. If cardioversion
fails or is unsafe because of concurrent thrombus, then long-term anticoagulation and heart rate control with medication are necessary (DiCarlo-Meacham, 2011).

Pregnancy may predispose otherwise asymptomatic women with Wolff-Parkinson-White (WPW) syndrome to exhibit arrhythmias (Maxwell, 2010). In a study of 25 women who had supraventricular tachycardia diagnosed before pregnancy, three of 12 women with WPW syndrome and six of 13 without the condition developed supraventricular tachycardia during pregnancy. In some patients, accessory pathway ablation may be indicated (Pappone, 2003). For this, the typical fluoroscopic procedure-related fetal radiation dose is < 1 cGy (Damilakis, 2001).

**Ventricular Tachycardia**

This form of arrhythmia is uncommon in healthy young women without underlying heart disease. Brodsky and associates (1992) described seven pregnant women with new-onset ventricular tachycardia and reviewed 23 reports. Most of these women were not found to have structural heart disease. In 14 cases, tachycardia was precipitated by physical exercise or psychological stress. Abnormalities found included two cases of myocardial infarction, two of prolonged QT interval, and anesthesia-provoked tachycardia in another. They concluded that pregnancy events precipitated the tachycardia and recommended β-blocker therapy for control. As previously discussed, arrhythmogenic right ventricular dysplasia will result occasionally in ventricular tachyarrhythmias (Lee, 2006). If unstable, emergency cardioversion is indicated, and standard adult energy settings are adequate (Jeejeebhoy, 2011; Nanson, 2001).

**Prolonged QT-Interval**

This conduction anomaly may predispose individuals to a potentially fatal ventricular arrhythmia known as *torsades de pointes* (Roden, 2008). Two studies involving a combined total of 502 pregnant women with *long QT syndrome* both reported a significant increase in cardiac events postpartum but not during pregnancy (Rashba, 1998; Seth, 2007). It was hypothesized that the normal increase in heart rate during pregnancy may be partially protective. Paradoxically, β-blocker therapy has been shown to decrease the risk of *torsades de pointes* in patients with long QT syndrome and should be continued during pregnancy and postpartum (Gowda, 2003; Seth, 2007). Importantly, many medications, including some used during pregnancy such as azithromycin, erythromycin, and clarithromycin, may predispose to QT prolongation (Al-Khatib, 2003; Ray, 2012; Roden, 2004).

**DISEASES OF THE AORTA**

**Aortic Dissection**

Marfan syndrome and coarctation are two aortic diseases that place the pregnant woman at increased risk for aortic dissection. Indeed, half of cases in young women are related to pregnancy (O’Gara, 2004). Other risk factors are bicuspid aortic valve and Turner or Noonan syndrome. Pepin and colleagues (2000) also reported a high rate of aortic dissection or rupture in patients with Ehlers-Danlos syndrome (Chap. 59, p. 1181). Although the mechanism(s) involved are unclear, the initiating event is a tear in the aorta’s intima layer, followed by hemorrhage into the media layer, and finally rupture.
In most cases, aortic dissection presents with severe chest pain described as ripping, tearing, or stabbing. Diminution or loss of peripheral pulses in conjunction with a recently acquired aortic insufficiency murmur is an important physical finding. The differential diagnosis of aortic dissection includes myocardial infarction, pulmonary embolism, pneumothorax, and aortic valve rupture as well as obstetrical catastrophes, especially placental abruption and uterine rupture (Lang, 1991).

More than 90 percent of patients with aortic dissection have an abnormal chest radiograph. Aortic angiography is the most definitive method for confirming the diagnosis. However, noninvasive imaging—sonography, computed tomography, and magnetic resonance (MR) imaging—is used more frequently. The urgency of the clinical situation frequently dictates which procedure is best.

Initial medical treatment is given to lower blood pressure. Proximal dissections most often need to be resected, and the aortic valve replaced if necessary. Distal dissections are more complex, and many may be treated medically. Survival in nonpregnant patients is not improved by elective repair of abdominal aortic aneurysms smaller than 5.5 cm (Lederle, 2002).

Marfan Syndrome

This autosomal dominant disorder has a high degree of penetrance. The incidence is 2 to 3 per 10,000 individuals and is without racial or ethnic predilection (Ammash, 2008). Prenatal diagnosis is usually possible using linkage analysis (Chap. 13, p. 277). The syndrome is due to abnormal fibrillin—a constituent of elastin—caused by any of dozens of mutations in the FBN1 gene located on chromosome 15q21 (Biggin, 2004). Thus, Marfan syndrome is a connective-tissue disorder characterized by generalized tissue weakness that can result in dangerous cardiovascular complications. Because all tissues are involved, other defects are frequent and include joint laxity and scoliosis. Progressive aortic dilatation causes aortic valve insufficiency, and there may be infective endocarditis and mitral valve prolapse with insufficiency. Aortic dilatation and dissecting aneurysm are the most serious abnormalities. Early death is due either to valvular insufficiency and heart failure or to a dissecting aneurysm.

Effect of Pregnancy on Marfan Syndrome

In the past, case reports reflected biased outcomes, and the maternal mortality rate was inaccurately magnified (Elkayam, 1995). In a prospective evaluation of 21 women during 45 pregnancies cared for at the Johns Hopkins Hospital, only two had dissection, and one died postpartum from graft infection (Rossiter, 1995). Although there were no maternal deaths among 14 women followed by Rahman and coworkers (2003), two required surgical correction of an aortic aneurysm. These investigators concluded that aortic dilatation > 40 mm or mitral valve dysfunction are high-risk factors for life-threatening cardiovascular complications during pregnancy. Conversely, women with minimal or no dilatation, and those with normal cardiac function by echocardiography, are counseled regarding the small but serious potential risk of aortic dissection.

The aortic root usually measures approximately 2 cm, and during normal pregnancy, it increases slightly (Easterling, 1991). With Marfan syndrome, if aortic root dilatation reaches 4 cm, then dissection is more likely. If dilatation reaches 5 to 6 cm, then elective surgery should be considered before pregnancy (Gott, 1999; Williams, 2002). Prophylactic β-blocker therapy has become the standard medical approach for pregnant women with Marfan syndrome because it reduces hemodynamic stress on the ascending aorta and slows the rate of dilation (Simpson,
Vaginal delivery with regional analgesia and an assisted second stage seem safe for women with an aortic root diameter < 4 cm.

When the aortic root measures 4 to 5 cm or greater, elective cesarean delivery is recommended with consideration of postpartum replacement of the proximal aorta with a prosthetic graft (Simpson, 2012). Successful aortic root replacement during pregnancy has been described, but the surgery has also been associated with fetal hypoxic-ischemic cerebral damage (Mul, 1998; Seeburger, 2007). There are a number of case reports describing emergency cesarean deliveries in women with acute type A dissection that was repaired successfully at the time of delivery (Guo, 2011; Haas, 2011; Papatsonis, 2009).

### Perinatal Outcomes

Obstetrical outcomes of 63 women with Marfan syndrome with a total of 142 pregnancies were reviewed by Meijboom and coworkers (2006). Of 111 women delivered after 20 weeks, 15 percent had preterm delivery, and 5 percent had preterm prematurely ruptured membranes. There were eight perinatal deaths, and half of the neonate survivors were subsequently diagnosed with Marfan syndrome.

### Aortic Coarctation

This is a relatively rare lesion often accompanied by abnormalities of other large arteries. A fourth of affected patients have a bicuspid aortic valve, and another 10 percent have cerebral artery aneurysms. Other associated lesions are persistent ductus arteriosus, septal defects, and Turner syndrome. The collateral circulation arising above the coarctation remodels and expands, often to a striking extent, to cause localized erosion of rib margins by hypertrophied intercostal arteries. Typical findings include hypertension in the upper extremities but normal or reduced pressures in the lower extremities. Several authors have described diagnosis during pregnancy using MR imaging (Dizon-Townson, 1995; Sherer, 2002; Zwiers, 2006).

### Effect of Pregnancy on Coarctation

Major complications include congestive heart failure after longstanding severe hypertension, bacterial endocarditis of the bicuspid aortic valve, and aortic rupture. Because hypertension may worsen in pregnancy, antihypertensive therapy using β-blocking drugs is usually required. Aortic rupture is more likely late in pregnancy or early postpartum. Cerebral hemorrhage from circle of Willis aneurysms may also develop. Beauchesne and associates (2001) described the outcomes of 188 pregnancies from the Mayo Clinic. A third had hypertension that was related to significant coarctation gradients, and one woman died from dissection at 36 weeks. Using the United States Nationwide Inpatient Sample between 1998 and 2007, Krieger and colleagues (2011) studied nearly 700 deliveries among women with coarctation. Hypertensive complications of pregnancy were increased three- to fourfold in women with coarctation. Importantly, almost 5 percent of women with coarctation had an adverse cardiovascular outcome—maternal death, heart failure, arrhythmia, cerebrovascular or other embolic event—compared with 0.3 percent of controls. A total of 41 percent of women with coarctation underwent cesarean delivery compared with 26 percent of controls.

Congestive heart failure demands vigorous efforts to improve cardiac function and may warrant pregnancy interruption. Some authors have recommended that resection of the coarctation be undertaken during pregnancy to protect against the possibility of a dissecting aneurysm and aortic rupture. This poses significant risk, especially for the fetus, because all the collaterals must be
clamped for variable periods.

Some authors recommend cesarean delivery to prevent transient blood pressure elevations that might lead to rupture of the aorta or coexisting cerebral aneurysms. Available evidence, however, suggests that cesarean delivery should be limited to obstetrical indications.

**ISCHEMIC HEART DISEASE**

United States statistics indicate that the mortality rate from coronary heart disease among all women aged 35 to 44 years has been increasing by an average of 1.3 percent per year since 1997 (Ford, 2007). Still, coronary artery disease and myocardial infarction are rare complications of pregnancy. In a review of California hospital discharge records between 1991 and 2000, Ladner and associates (2005) reported myocardial infarction in 2.7 per 100,000 deliveries. James and coworkers (2006) used the Nationwide Inpatient Sample database and reported acute myocardial infarction in 6.2 per 100,000 deliveries. In Canadian hospitals between 1970 and 1998, MacArthur and colleagues (2006) reported the incidence of peripartum myocardial ischemia to be 1.1 per 100,000 deliveries.

Pregnant women with coronary artery disease commonly have classic risk factors such as diabetes, smoking, hypertension, hyperlipidemia, and obesity (James, 2006). As an aside, a large, prospective population-based study from Germany found that women who had experienced recurrent spontaneous abortions or stillbirths were also at a substantially higher risk of myocardial infarction later in life (Kharazmi, 2011). Although the reason(s) for this association were not specifically studied, there are a number of conditions—such as certain thrombophilias—which are associated with both (Chap. 59, p. 1173).

Bagg and colleagues (1999) reviewed the course of 22 diabetic pregnant women with White class H ischemic heart disease (Chap. 57, p. 1126). These and other authors documented unusually high mortality rates in those who suffered myocardial infarction (Pombar, 1995; Reece, 1986). Coronary artery occlusion in two pregnant smokers with hypercholesterolemia has been described following a routine intramuscular injection of 0.5-mg ergometrine (Mousa, 2000; Sutaria, 2000). Finally, Schulte-Sasse (2000) described myocardial ischemia associated with prostaglandin E₁ vaginal suppositories for labor induction.

Diagnosis during pregnancy is not different from the nonpregnant patient. Measurement of serum levels of the cardiac-specific contractile protein troponin I provides an accurate diagnosis (Shade, 2002). Troponin I was reported by Shivvers and colleagues (1999) to be undetectable near term (Appendix, p. 1291). Koscica and colleagues (2002) found that levels do not increase following either vaginal or cesarean delivery. Importantly, however, levels of troponin I are higher in preeclamptic women than in normotensive controls (Atalay, 2005; Yang, 2006).

**Pregnancy with Prior Ischemic Heart Disease**

The advisability of pregnancy after a myocardial infarction is unclear. Ischemic heart disease is characteristically progressive, and because it is usually associated with hypertension or diabetes, pregnancy in most of these women seems inadvisable. Vinatier and associates (1994) reviewed 30 pregnancies in women who had sustained an infarction remote from pregnancy. Although none of these women died, four had congestive heart failure and four had worsening angina during pregnancy. Pombar and coworkers (1995) reviewed outcomes of women with diabetes-associated
ischemic heart disease and infarction. Three had undergone coronary artery bypass grafting before pregnancy. Of 17 women, eight died during pregnancy. Certainly, pregnancy increases cardiac workload, and all of these investigators concluded that ventricular performance should be assessed using ventriculography, radionuclide studies, echocardiography, or coronary angiography before conception. If there is no significant ventricular dysfunction, pregnancy will likely be tolerated.

For the woman who becomes pregnant before these studies are performed, echocardiography should be done. Exercise tolerance testing may be indicated, and radionuclide ventriculography results in minimal radiation exposure for the fetus (Chap. 46, p. 932). Zaidi and associates (2008) described the use of serial T2-weighted cardiovascular MR imaging in a woman who suffered a myocardial infarction during the first trimester to better define the extent and severity of infarction.

Myocardial Infarction During Pregnancy

The mortality rate with myocardial infarction in pregnancy is increased compared with age-matched nonpregnant women. Hankins and coworkers (1985) reviewed 68 cases and reported an overall maternal mortality rate of approximately 35 percent. Hands and colleagues (1990) found an overall mortality rate of 30 percent, and this was highest in the third trimester. Later studies are more reassuring. In a Nationwide Inpatient Sample study totaling 859 pregnancies complicated by acute infarction during 2000 to 2002, there was a 5.1-percent death rate (James, 2006). Women who sustain an infarction less than 2 weeks before delivery are at especially high risk of death due to the increased myocardial demand during labor or delivery (Esplin, 1999).

Treatment is similar to that for nonpregnant patients (Maxwell, 2010; Roth, 2008). Acute management includes administration of oxygen, nitroglycerin, low-dose aspirin, heparin, and β-blocking drugs with close blood pressure monitoring. Lidocaine is used to suppress malignant arrhythmias and calcium-channel blockers or β-blockers are given if indicated. Tissue plasminogen activator has been used in pregnant women, but only those remote from delivery because of hemorrhage. In some women, invasive or surgical procedures may be indicated because of acute or unrelenting disease. A number of reports describe successful percutaneous transluminal coronary angioplasty and stent placement during pregnancy (Balmain, 2007; Duarte, 2011; Dwyer, 2005). Cardiopulmonary resuscitation may be required, and maternal and perinatal effects are discussed in Chapter 47 (p. 956).

If the infarct has healed sufficiently, cesarean delivery is reserved for obstetrical indications, and epidural analgesia is ideal for labor (Esplin, 1999).

Chronic hypertension is one of the most common serious complications encountered during pregnancy. This is not surprising because, according to the National Health and Nutrition Examination Survey (NHANES) from the Centers for Disease Control and Prevention (2011), the average prevalence of hypertension in women aged 18 to 39 years is approximately 7 percent. The incidence of chronic hypertension in pregnancy is variable depending on population vicissitudes. In a study of more than 56 million deliveries from the Nationwide Patient Sample, 1.8 percent of births in 2007 and 2008 were in women with chronic hypertension (Bateman, 2012). The incidence was 1.0 percent in more than 530,000 singleton pregnancies in California in 2006 (Yanit, 2012). And according to the American College of Obstetricians and Gynecologists (2012), the incidence may be up 5 percent. Despite this substantive prevalence, optimal management has not been well studied. It is known that chronic hypertension usually improves during early pregnancy. This is followed by variable behavior later in pregnancy and importantly, by its unpredictable development of superimposed preeclampsia, which carries increased risks for maternal and perinatal morbidity and mortality.
To define chronic hypertension, first, the range of normal blood pressure levels must be established. This is not a simple task because, like all polygenic-determined biological variants, blood pressure norms differ between populations. And, within these norms, there are wide variations between individuals. Moreover, these are also greatly influenced by numerous epigenetic factors. For example, blood pressure not only varies between races and gender, but the pressures—especially systolic—increase directly with increasing age and weight. Pragmatically then, normal adults have a wide range of blood pressures, but so do those with chronic hypertension.

After these variables are acknowledged, an important consideration for any population is the attendant risks of chronic hypertension. There is an increasing incremental rate of cardiovascular, cerebrovascular, and renal disease that follows increasing levels of both diastolic and systolic pressures (Kotchen, 2012).

**Definition and Classification**

For the foregoing reasons, it seems logical that chronic hypertension would be defined as some level of sustained blood pressure that is associated with an increase in acute or long-term adverse effects. For many years in the United States, these values were based primarily on actuarial tables constructed using data derived from white adult males and compiled by life insurance companies. These “norms” disregarded interrelated factors such as ethnicity and gender as well as other important covariants. The importance of race, for example, was emphasized by Kotchen (2012), who cites statistics derived from 65 million American adults. In this study, the incidence of hypertension—defined as blood pressure > 140/90 mm Hg—was 34 percent in blacks, 29 percent in whites, and 21 percent in Mexican Americans.

For many years, guidelines for diagnosis, classification, and management of chronic hypertension have been promulgated by the Joint National Committee. In 2008, the National Heart Lung and Blood Institute discontinued these guidelines, and the Joint National Committee 8 (JNC 8) was instead asked to provide an evidence-based review (James, 2013). Findings pertinent to caring for young women with chronic hypertension are summarized in Table 50-1.

General black population—primary antihypertensive therapy should include thiazide-type diuretic or calcium-channel blocker.

Assess monthly, and after 1 month, if goals not met, then increase primary drug dose or add second drug. If no response, increase either or add third drug; then if no response, refer to hypertension specialist.

Summarized from James, 2013.

**Treatment and Benefits for Nonpregnant Adults**

There are proven benefits that accrue with treatment of otherwise normal adults who have sustained hypertension. A myriad of studies evaluating many combinations of antihypertensive therapy have been conducted with salutary results. Some of these include the ACCORD, ASCOT ACCOMPLISH, ALLHAT, SPRINT, TOHMS, TROPHY, and VALUE studies. Importantly, these trials evaluated monotherapy versus combination therapeutic regimens as well as ethnospecific benefits. Most evaluated cardiovascular outcomes, but many also confirmed risk reduction in cerebrovascular accidents, renal insufficiency, and overall mortality rates. Because of these incontrovertible benefits, the JNC 8 recommends the treatment outlined in Table 50-1.

Thus, even for mildly elevated blood pressures cited in Table 50-1, interventions to reduce pressure are beneficial. Moreover, it is clear that antihypertensive therapy in nonpregnant reproductive-aged women with sustained diastolic pressures ≥ 90 mm Hg would be considered standard. Not clear from these observations, however, is what constitutes the best management for the woman being treated who contemplates pregnancy, or the best management of the woman undergoing treatment who becomes pregnant, or the woman who is first identified to have chronic hypertension during pregnancy (August, 2014). In these and similar women, the benefits and safety of instituting antihypertensive therapy are less clear, as subsequently discussed.

**Preconceptional Counseling**

Women with chronic hypertension should ideally be counseled before pregnancy. The duration of hypertension, degree of blood-pressure control, and current therapy are ascertained. Home measurement devices should be checked for accuracy. Those who require multiple medications for control or those who are poorly controlled are also at increased risk for adverse pregnancy outcomes. General health, daily activities, and dietary habits are also assessed as shown in Table 50-2.

Summarized from Eckel, 2013.

In those with hypertension for more than 5 years or in diabetic women, cardiovascular and renal function should be assessed (August, 2014; Gainer, 2005). Women with evidence for organ dysfunction or those with prior adverse events such as cerebrovascular accident, arrhythmias, ventricular failure, or myocardial infarction are at markedly increased risk for a recurrence or worsening during pregnancy. Renal function is assessed by serum creatinine measurement, and proteinuria is quantified if the urine spot protein/creatinine ratio is abnormally high (Hladunewich, 2011). The Working Group Report on High Blood Pressure in Pregnancy (2000) of the National Heart, Lung, and Blood Institute concluded that the risks of fetal loss and accelerated deterioration of renal disease are increased if serum creatinine level is above 1.4 mg/dL (Chap. 53, p. 1061).

Although pregnancy is considered by many to be contraindicated in women with severe, poorly controlled hypertension, there is not a consensus regarding this. Certainly, pregnancy is at least relatively contraindicated in women who maintain persistent diastolic pressures of ≥ 110 mm Hg despite therapy, who require multiple antihypertensives, or who have a serum creatinine > 2 mg/dL. Even stronger contraindications include prior cerebrovascular accident, myocardial infarction, or cardiac failure.

**DIAGNOSIS AND EVALUATION IN PREGNANCY**

Classification of the hypertensive disorders complicating pregnancy is discussed in Chapter 40 (p. 728). Women are diagnosed with chronic hypertension if it is documented to precede pregnancy or if hypertension is identified before 20 weeks’ gestation. In some women without overt chronic hypertension, there is a history of repeated pregnancies complicated by gestational hypertension with or without the preeclampsia syndrome. Each is a risk marker for latent chronic hypertension, and this is especially so for preeclampsia, especially early-onset preeclampsia. In many ways, gestational hypertension is analogous to gestational diabetes in that such women have a chronic hypertensive diathesis, in which heredity plays a major role (Chap. 40, p. 769).

Although uncommon, secondary causes of hypertension are always a possibility in these women. Thus, consideration is given to an underlying pheochromocytoma, connective-tissue disease, Cushing syndrome, chronic renal disease, and myriad other causes. That said, most pregnant women with antecedent hypertension will have uncomplicated disease. As discussed above, some women—especially those with long-term or untreated hypertension—have complications that increase the risk of adverse pregnancy events. Thus, if not already accomplished, assessment during pregnancy is done for the cardiovascular system, the kidneys, and the cerebrovascular circulation.

**Associated Risk Factors**

Several factors increase the likelihood that pregnant women will have chronic hypertension. Three of those most frequently cited are ethnicity, obesity, and diabetes. As previously discussed,
Chronic hypertension has a population incidence that is highest in black and lower in white and Mexican-American women (Kotchen, 2012). Related to this, hundreds of blood pressure-related phenotypes and genomic regions have been identified, including candidate genes for preeclampsia and chronic hypertension (Cowley, 2006; Lévesque, 2004).

The metabolic syndrome with superimposed preeclampsia is a risk marker for persistent hypertension postpartum (Spaan, 2012). This is not surprising because obesity may increase the prevalence of hypertension tenfold, and it is an important factor predisposing to chronic hypertension (Chap. 48, p. 963). In addition, obese women are more likely to develop superimposed preeclampsia. Diabetes is also prevalent in chronically hypertensive women, and its interplay with obesity and preeclampsia is overwhelming. In the study of more than 56 million births cited above, the most common comorbidities associated with chronic hypertension were pregestational diabetes—6.6 percent, thyroid disorders—4.1 percent, and collagen-vascular disease—0.6 percent (Bateman, 2012). Similar comorbidities were described by Cruz and associates (2011).

**Effects of Pregnancy on Chronic Hypertension**

Blood pressure falls in early pregnancy in most women with chronic hypertension. It rises again during the third trimester (Fig. 50-1). According to studies by Tihtonen and coworkers (2007), women with chronic hypertension have persistently elevated vascular resistance and possibly a reduced intravascular volume increase. There is no doubt that adverse outcomes in these women are dependent largely on whether superimposed preeclampsia develops. This may be related to observations reported by Hibbard and colleagues (2005, 2014) that arterial mechanical properties are most marked in women with superimposed preeclampsia.

![FIGURE 50-1 Mean systolic and diastolic blood pressures across pregnancy in 107 untreated chronically hypertensive women (yellow) compared with blood pressures across pregnancy in 4589 healthy nulliparous women (blue). (Data from August, 2014; Levine, 1997; Sibai, 1990a.)](image-url)
Chronic hypertension is associated with several adverse maternal and perinatal outcomes listed in Table 50-3. The recurring theme is that these are directly related to severity and duration of hypertension before pregnancy and whether superimposed preeclampsia develops, especially early in gestation. In women with mild chronic hypertension, outcomes are also related to blood pressure levels during pregnancy (Ankumah, 2013).

### Maternal Morbidity and Mortality

Most women whose hypertension is well controlled with monotherapy before pregnancy will do well. Even these women, however, are at increased risk for adverse outcomes. Complications are more likely with severe baseline hypertension and especially with documented end-organ damage (Czeizel, 2011; Odibo, 2013). In a study of pregnancy outcomes in nearly 30,000 chronically hypertensive women, Gilbert and associates (2007) reported markedly increased maternal morbidity including stroke, pulmonary edema, and renal failure. These observations were verified in the report from the Nationwide Patient Sample of more than 56 million deliveries by Bateman and colleagues (2012). Complications of hypertension included stroke—2.7 per 1000, acute renal failure—5.9 per 1000, pulmonary edema—1.5 per 1000, mechanical ventilation—3.8 per 1000, and in-house maternal mortality—0.4 per 1000. The contribution of hypertension to pregnancy-related strokes is discussed in Chapter 60 (p. 1191) and to hypertensive and idiopathic peripartum hypertensive cardiomyopathy in Chapter 49 (p. 988).

Pregnancy-aggravated hypertension may be due to gestational hypertension or to superimposed preeclampsia. In either instance, blood pressures can be dangerously elevated. As emphasized by Clark and Hankins (2012), systolic pressure $\geq 160$ mm Hg or diastolic pressure $\geq 110$ mm Hg will rapidly cause renal or cardiopulmonary dysfunction or cerebral hemorrhage. With superimposed...
severe preeclampsia or eclampsia, the maternal prognosis is poor unless the pregnancy is ended. Placental abruption is a common and serious complication (Chap. 41, p. 793). In addition to hypertensive heart failure mentioned above, aortic dissection has been described by Weissman-Brenner and coworkers (2004) and is discussed in Chapter 49 (p. 992).

Chronic hypertension has been associated with a fivefold risk for maternal death (Gilbert, 2007). This is emphasized by the report by Berg (2010) describing 4693 pregnancy-related deaths in the United States from 1998 through 2005. Hypertensive disorders, including chronic hypertension and preeclampsia syndrome, accounted for 12.3 percent of these deaths. Undoubtedly related were other causes of death such as cardiovascular conditions—12.4 percent, cerebrovascular conditions—6.3 percent, and cardiomyopathy—11.5 percent. Moodley (2007) reported similar findings with 3406 maternal deaths from South Africa. Interestingly, Sibai and associates (2011) reported that chronically hypertensive women with a history of preeclampsia were not at higher risk for complications compared with hypertensive women without such a history.

**Superimposed Preeclampsia**

Because there is no precise definition of superimposed preeclampsia in women with chronic hypertension, the reported incidence is variable. The risk is directly related to the severity of baseline hypertension. In a Maternal-Fetal Medicine Units Network trial, Caritis and coworker (1998) identified superimposed preeclampsia in 25 percent. It was 29 percent in the California database study cited above (Yanit, 2012). According to the American College of Obstetricians and Gynecologists (2012), mild chronic hypertension has a 20-percent incidence for superimposed preeclampsia, whereas with severe hypertension, it is 50 percent. August and colleagues (2014) posit that this predilection may be because of similarities of genetic, biochemical, and metabolic abnormalities. In the study cited above, a history of superimposed preeclampsia did not increase the risk for recurrence, however, it was a marker for increased preterm delivery (Sibai, 2011).

Thus far, prognostic and predictive tests for superimposed preeclampsia have been disappointing when used clinically (American College of Obstetricians and Gynecologists, 2012; Conde-Agudelo, 2014; Zeeman, 2003). For example, Di Lorenzo and colleagues (2012) studied serum markers for Down syndrome and reported a sensitivity of 60 percent with a 20-percent false-positive rate. Similar results were found using antiangiogenic factors to discriminate among chronic hypertension, gestational hypertension, and preeclampsia (Sibai, 2008; Woolcock, 2008). According to Elovitz and coworkers (2013), microRNA assays may prove valuable as predictors of pregnancy-associated hypertension. This subject is discussed further in Chapter 40 (p. 747).

**Prevention of Superimposed Preeclampsia**

Trials of various substances to prevent preeclampsia in women with chronic hypertension have generally been disappointing. Low-dose aspirin has been evaluated most frequently. In the Network study by Caritis and associates (1998) cited above, the incidence of superimposed preeclampsia, fetal-growth restriction, or both was similar in women given low-dose aspirin or placebo. That said, Duley (2007) and Meads (2008) and their colleagues performed Cochrane reviews and found that low-dose aspirin was beneficial in some high-risk women. Minimal benefits were also found from a metaanalysis (Askie, 2007). To the contrary, however, the PARIS Collaborative Group (2007) reviewed individual data from 33,897 pregnant women enrolled in 33 randomized trials of low-dose aspirin and reported that women with chronic hypertension derived no benefits.

Spinnato and coworkers (2007) randomly assigned 311 women with chronic hypertension to
antioxidant treatment with vitamins C and E or to a placebo. A similar number in both groups developed preeclampsia—17 versus 20 percent, respectively.

**Placental Abruption**

There seems to be no doubt that chronic hypertension increases the risk two- to threefold for premature placental separation (American College of Obstetricians and Gynecologists, 2012). As discussed in Chapter 41 (p. 793), the overall risk is one in 200 to 300 pregnancies, and this is increased to 1 in 60 to 120 pregnancies in women with chronic hypertension (Ananth, 2007; Cruz, 2011; Madi, 2012; Tuuli, 2011). This risk is increased further if the woman smokes or if she develops superimposed preeclampsia. The risk is highest with severe hypertension, and Vigil-De Gracia and colleagues (2004) reported it to be 8.4 percent. Most abruptions are in women with worsening gestational hypertension or superimposed preeclampsia. From the Norwegian Birth Registry, supplemental folic acid slightly decreased the abruption incidence in women with chronic hypertension (Nilsen, 2008).

**Perinatal Morbidity and Mortality**

From the foregoing, it is not surprising that almost all adverse perinatal outcomes are increased in women with chronic hypertension. Some of those from a Network study are shown in Figure 50-2. The increasing incremental adverse effects of rising blood pressure levels are apparent. Interestingly, Bánhidy and colleagues (2011) have provided data suggesting that severe hypertension may be associated with fetal esophageal atresia or stenosis. As expected, for the entire group of women, those who developed preeclampsia had substantially increased adverse outcome rates compared with those without preeclampsia.

**FIGURE 50-2** Perinatal outcomes in 759 women with midrange chronic hypertension enrolled in a Maternal-Fetal Medicine Units Network study (Ankumah, 2013).
The stillbirth frequency is substantively greater in most reports (Chap. 35, p. 663). In the Nationwide Patient Sample study, the stillbirth rate was 15.1 per 1000 births (Bateman, 2012). This is similar to the frequency of 18 per 1000 from a Norwegian study (Ahmad, 2012). The rate was increased two- to threefold in the California database study by Yanit and associates (2012).

Low-birthweight infants are common and due to preterm delivery, fetal-growth restriction, or both. In the California study, a fourth of fetuses were delivered preterm (Yanit, 2012). This and other studies attest to the increased risk for fetal-growth restriction, and the incidence averages 20 percent. Zetterström and coworkers (2006) reported a 2.4-fold risk for fetal-growth restriction in 2754 chronically hypertensive Swedish women compared with the risk in normotensive women. Broekhuijsen and associates (2012) found a 1.3-fold increased risk for 1609 Dutch nulliparas with chronic hypertension compared with that in normotensive controls. Fetal-growth dysfunction is more likely in the chronically hypertensive women who develop superimposed preeclampsia. In one study, Chappell and colleagues (2008) reported an almost 50-percent incidence of growth-restricted fetuses born to women with superimposed preeclampsia compared with only 21 percent in women without preeclampsia. Because worsening hypertension frequently mandates preterm delivery, neonates born to these women have a correspondingly high rate of intensive-care nursery admission.

All of these aforementioned adverse perinatal effects of chronic hypertension contribute to the increased perinatal mortality rate, which is three- to fourfold higher in pregnancies complicated by chronic hypertension compared with those of normotensive women (American College of Obstetricians and Gynecologists, 2012). In the Network study shown in Figure 50-2, the perinatal death rate was 31 per 1000 with mild hypertension, 72 per 1000 with moderate disease, and 100 per 1000 in women with severe chronic hypertension. Again as expected, the highest rates are in women who develop superimposed preeclampsia, for whom the risk doubled from 4 to 8 percent. And, if diabetes coexists with chronic hypertension, then preterm delivery, fetal-growth restriction, and perinatal mortality rates are increased even more (Gonzalez-Gonzalez, 2008; Yanit, 2012).

MANAGEMENT DURING PREGNANCY

The diagnosis of chronic hypertension in pregnancy should be confirmed. For example, Brown and associates (2005) reported “white-coat” hypertension in a third of 241 women diagnosed in early pregnancy. Within this third, pregnancy outcomes were good, and only 8 percent developed preeclampsia.

Management goals for chronic hypertension include reductions of adverse maternal or perinatal outcomes just discussed. Treatment is targeted to prevent moderate or severe hypertension and to delay or ameliorate pregnancy-aggravated hypertension. To some extent, these goals can be achieved pharmacologically. Blood-pressure self-monitoring is encouraged, but for accuracy, automated devices must be properly calibrated (Brown, 2004; Staessen, 2004). Personal health modification includes dietary counseling and reduction of behaviors such as tobacco, alcohol, cocaine, or other substance abuse (see Table 50-2).

Blood Pressure Control

Women with severe hypertension must be treated for maternal neuro-, cardio-, and renoprotection regardless of pregnancy status (American College of Obstetricians and Gynecologists, 2012). Thi
includes women with prior adverse outcomes such as cerebrovascular events, myocardial infarction, and cardiac or renal dysfunction. We agree with the philosophy of beginning antihypertensive treatment in otherwise healthy pregnant women with persistent systolic pressures > 150 mm Hg or diastolic pressures of 95 to 100 mm Hg or greater (August, 2014; Working Group Report, 2000). With end-organ dysfunction, treatment of diastolic pressures ≥ 90 mm Hg is reasonable to mitigate further organ damage.

There are only sparse data indicating salutary effects on pregnancy outcomes with simply lowering blood pressure. These studies are relatively small and have widely varying inclusion and outcome criteria. In a Cochrane review of 46 of these studies that included a total of 4282 women, Abalos and coworkers (2007) confirmed that the risk for severe hypertension was lowered with therapy. There were, however, no differences in the frequencies of superimposed preeclampsia, eclampsia, abruption, preterm birth, fetal-growth restriction, or perinatal or maternal mortality. These studies do attest to the apparent safety of antihypertensive therapy except for angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (Chap. 12, p. 247). As emphasized by the Working Group Report (2000), there is a need for further trials in chronically hypertensive women.

“Tight Control”

During the past decade, the concept of tight control of blood pressure has been espoused as a means of optimizing maternal and perinatal outcomes. Such control is compared with that of glycemic control for management of the pregnant diabetic. In one study, El Guindy and Nabhar (2008) randomly assigned 125 pregnant women with mild chronic hypertension or gestational hypertension to rigid versus less strict blood pressure control. More women in the latter group developed severe hypertension, they had more hospital admissions, and they were delivered of infants at a lower mean gestational age than the tight-control group. Other than these preliminary observations, there are limited data concerning this type of treatment.

Antihypertensive Drugs

As concluded by the American College of Obstetricians and Gynecologists (2012), treatment during pregnancy has included every drug class, but there still is limited information regarding safety and efficacy (Czeizel, 2011; Podymow, 2011). Although many studies indicate increased perinatal adverse effects in treated women, it is still not known whether this is due to cause or effect (Orbach, 2013). The following summary of antihypertensive drugs is abstracted from several sources, including the 2014 Physicians’ Desk Reference. Many of these drugs are also discussed throughout Chapter 12 (p. 247) and have been recently reviewed by Umans and associates (2014).

Diuretics

Thiazide diuretics are sulfonamides, and these were the first drug group used to successfully treat chronic hypertension (Beyer, 1982). These agents and loop-acting diuretics such as furosemide are commonly used in nonpregnant hypertensives. In the short term, they provide sodium and water diuresis with volume depletion. But with time, there is sodium escape, and volume depletion is corrected. Some aspect of lowered peripheral vascular resistance likely contributes to their effectiveness in reducing long-term morbidity (Umans, 2014; Williams, 2001).

Thiazide drugs may be mildly diabetogenic, and expected volume expansion may be curtailed in pregnant women. Sibai and colleagues (1984) showed that plasma volume expanded only about 20
percent over time in hypertensive pregnant women who continued diuretic therapy compared with a 50-percent expansion in women who discontinued treatment. Although perinatal outcomes were similar in these women, such concerns have led to practices of withholding diuretics as first-line therapy, particularly after 20 weeks (Working Group Report, 2000). Even so, in a Cochrane review, Churchill and associates (2007) reported no differences in perinatal outcomes in 1836 nonhypertensive women randomly assigned to a thiazide diuretic or placebo for primary preeclampsia prevention. Overall, thiazide diuretics are considered safe in pregnancy (Briggs, 2011; Umans, 2014).

Adrenergic-Blocking Agents
This was the second class of effective antihypertensives. Peripherally acting β-adrenergic receptor blockers cause a generalized decrease in sympathetic tone. Examples are propranolol, metoprolol, and atenolol. Labetalol is a commonly used α/β-adrenergic blocker. Some adrenergic-blocking drugs act centrally by reducing sympathetic outflow to effect a generalized decreased vascular tone. Some of these are clonidine and α-methyldopa. The drugs most frequently used in pregnancy to treat hypertension are methyldopa or a β- or α/β-receptor blocking agent.

Vasodilators
Hydralazine relaxes arterial smooth muscle and has been used parenterally for decades to safely treat severe peripartum hypertension (Chap. 40, p. 767). Oral hydralazine monotherapy for chronic hypertension is not generally used because of its weak antihypertensive effects and resultant tachycardia. It may be an effective adjunct for long-term use with other antihypertensives, especially if there is chronic renal insufficiency. In the study by Su and coworkers (2013), vasodilator treatment of chronically hypertensive women was associated with a twofold increase in low-birthweight and growth-restricted neonates.

Calcium-Channel Blocking Agents
These drugs are divided into three subclasses based on their modification of calcium entry into cells and interference with binding sites on voltage-dependent calcium channels. Common agents include nifedipine—a dihydropyridine, and verapamil—a phenylalkyl amine derivative. These agents have negative inotropic effects and thus can worsen ventricular dysfunction and congestive heart failure. Theoretically, they may potentiate the actions of magnesium sulfate that is given for eclampsia neuroprophylaxis. There is minimal published experience with these agents during pregnancy (Abalos, 2007). That said, calcium-channel blockers appear to be safe for therapy for chronic hypertension (Briggs, 2011; Podymow, 2011; Umans, 2014).

The safety of acute peripartum nifedipine treatment has been questioned. The drug is used by some for rapid control of severe peripartum hypertension, and it is also widely used for tocolysis in preterm labor (Chap. 42, p. 853). Nifedipine for tocolysis should not be combined with intravenous β-agonists (Oei, 2006). Adverse outcomes reported in women given nifedipine for tocolysis or severe gestational hypertension include myocardial infarction and pulmonary edema (Abbas, 2006; Bal, 2004; Oei, 1999; Verhaert, 2004). Severe maternal hypotension with resultant fetal compromise necessitating cesarean delivery and fetal death have also been reported (Johnson, 2005; Kandysamy, 2005; van Veen, 2005).

Angiotensin-Converting Enzyme Inhibitors
These drugs inhibit the conversion of angiotensin-I to the potent vasoconstrictor angiotensin-II
They can cause severe fetal malformations when given in the second and third trimesters. These include hypocalvaria and renal dysfunction (Chap. 12, p. 247). Some preliminary studies have also suggested teratogenic effects, and because of this, they are not recommended during pregnancy (Briggs, 2011; Podymow, 2011).

Angiotensin-receptor blockers act in a similar manner. But, instead of blocking the production of angiotensin-II, they inhibit binding to its receptor. They are presumed to have the same fetal effects as ACE inhibitors and thus are also contraindicated.

**Antihypertensive Treatment in Pregnancy**

As discussed, continuation of prepregnancy antihypertensive treatment when women become pregnant is debated. Although blood-pressure reduction is certainly beneficial to the mother long term, it at least theoretically can decrease uteroplacental perfusion. According to older observational reports, in general, most pregnancy outcomes in women with mild to moderate hypertension were good without treatment and unless superimposed preeclampsia developed (Chesley, 1978; Umans, 2014).

There are no large randomized trials to settle the questions surrounding empirical treatment. Abalos and associates (2007) performed a Cochrane database review of 46 small trials enrolling a total of 4282 women. These studies varied widely in definitions of hypertension severity, use of placebos, gestational age at entry, and the type of drug(s) used. The salient results are shown in Table 50-4. These led the investigators to conclude again that treatment reliably lowered risk for severe hypertension during pregnancy.

aPertains to those receiving treatment.
SGA = small-for-gestational age.
Includes only studies in which β-blocking drugs were given.
Data from a Cochrane database review by Abalos, 2007.

This Cochrane review does raise concern for fetal-growth restriction with β-blocking drugs. It is not resolved, however, because diminished placental perfusion secondary to lowered maternal blood pressure is confounded by the fact that worsening blood pressure itself is associated with abnormal fetal growth. Some also posit that the drugs have a direct fetal action (Umans, 2014). In two of the larger randomized trials, however, the incidence of growth restriction was not altered in
women randomly assigned to treatment (Gruppo di Studio Ipertensione in Gravidanza, 1998; Sibai, 1990a).

Severe Chronic Hypertension
Most data suggest that the prognosis for pregnancy outcome with chronic hypertension is dependent on the severity of disease antedating renal disease—as either cause or effect (Cunningham, 1990). One report by Sibai and coworkers (1986) described outcomes from 44 pregnancies in women whose blood pressure at 6 to 11 weeks was ≥ 170/110 mm Hg. All were given oral treatment with \( \alpha \)-methyldopa and hydralazine to maintain pressures < 160/110 mm Hg. If dangerous hypertension developed, then the woman was hospitalized and treated with parenteral hydralazine. Of the 44 pregnancies, superimposed preeclampsia developed in half, and all adverse perinatal outcomes were in this group. Moreover, all neonates of women in the latter group were delivered preterm, nearly 80 percent were also growth restricted, and they had a 48-percent perinatal mortality rate. Conversely, those women with severe chronic hypertension who did not develop superimposed preeclampsia had reasonably good outcomes. There were no perinatal deaths, and only 5 percent of fetuses were growth restricted.

Recommendations for Therapy in Pregnancy
The Working Group on High Blood Pressure in Pregnancy (2000) concluded that there were limited data from which to draw conclusions concerning any decision to treat mild chronic hypertension in pregnancy. As discussed on page 1005, the Group did recommend empirical therapy in women whose blood pressures exceed threshold levels of 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic or in women with target-organ damage such as left ventricular hypertrophy or renal insufficiency. They also concluded that early treatment of hypertension would probably reduce subsequent hospitalization rates during pregnancy.

Some women will have persistently worrisome hypertension despite usual therapy (Samuel, 2011; Sibai, 1990a). In these women, primary attention is given to the likelihood of pregnancy-aggravated hypertension, with or without superimposed preeclampsia. Other possibilities include inaccurate blood-pressure measurements, suboptimal treatment, and antagonizing substances (Moser, 2006). Causes reported in nonpregnant cohorts were nonsteroidal antiinflammatory drugs including cyclooxygenase-2 inhibitors and alcohol consumption (Sowers, 2005; Xin, 2001).

Pregnancy-Aggravated Hypertension or Superimposed Preeclampsia
As discussed, the incidence of superimposed preeclampsia for women with chronic hypertension varies depending on the study population and hypertension severity. A reasonable average is 20 to 30 percent. The incidence of superimposed preeclampsia may be underreported if the diagnosis is based solely on urine protein dipstick testing (Gangaram, 2005; Lai, 2006). Importantly, in approximately half of chronically hypertensive women, superimposed preeclampsia develops before 37 weeks (Chappell, 2008).

The diagnosis may be difficult to make, especially in women with hypertension who have underlying renal disease with chronic proteinuria (Cunningham, 1990). As discussed in Chapter 40 (p. 730), conditions that support the diagnosis of superimposed preeclampsia include worsening hypertension, new-onset proteinuria, neurological symptoms such as severe headaches and visual
disturbances, generalized edema, oliguria, and certainly, convulsions or pulmonary edema. Supporting laboratory abnormalities are increasing serum creatinine levels, thrombocytopenia, serum hepatic transaminase elevations, or the triad of HELLP—hemolysis, elevated liver enzyme levels, low platelet count—syndrome. For women with chronic hypertension and superimposed preeclampsia with severe features, magnesium sulfate for maternal neuroprophylaxis is recommended (American College of Obstetricians and Gynecologists, 2013).

Some pregnant women with chronic hypertension have worsening hypertension with no other findings of superimposed preeclampsia. This is most commonly encountered near the end of the second trimester. In the absence of other supporting criteria for superimposed preeclampsia, including fetal-growth restriction or decreased amnionic fluid volume, this likely represents the higher end of the normal blood-pressure curve shown in Figure 50-1. In such women, if preeclampsia can be reasonably excluded, then it is reasonable to begin or to increase the dose of antihypertensive therapy.

Fetal Assessment

Women with well-controlled chronic hypertension and who have no complicating factors can generally be expected to have a good pregnancy outcome. Because even those with mild hypertension have an increased risk of superimposed preeclampsia and fetal-growth restriction, serial antepartum assessment of fetal well-being is recommended by many. That said, according to the American College of Obstetricians and Gynecologists (2012), with the exception of sonographic fetal-growth monitoring, there are no conclusive data to address either benefit or harm associated with various antepartum surveillance strategies.

Expectant Management

Given that half of these women develop superimposed preeclampsia before term, considerations for expectant management may be reasonable in some cases. In a study from Magee-Women’s Hospital, 41 carefully selected women with a median gestational age of 31.6 weeks were expectantly managed (Samuel, 2011). Despite liberal criteria to mandate delivery, 17 percent developed either placental abruption or pulmonary edema. The latency period was extended by a mean of 9.7 days, and there were no perinatal deaths. These investigators recommended randomized trials to study expectant management.

Delivery

For chronically hypertensive women who have complications such as fetal-growth restriction or superimposed preeclampsia, the decision to deliver is made by clinical judgment. The route of delivery is dictated by obstetrical factors. Certainly, most women with superimposed severe preeclampsia are better delivered even when there is a markedly preterm pregnancy. These women are at increased risk for placental abruption, cerebral hemorrhage, and peripartum heart failure (Cunningham, 1986, 2005; Martin, 2005).

For women with mild to moderate chronic hypertension who continue to have an uncomplicated pregnancy, there are at least two options for timing of delivery (American College of Obstetricians and Gynecologists, 2012). The first is delivery at term, that is, ≥ 39 completed weeks. Another option is from consensus committee findings by Spong and associates (2011), which recommend consideration for delivery at 38 to 39 weeks, that is, ≥ 37 completed weeks. A trial of labor
induction is preferable, and many of these women respond favorably and will be delivered vaginally (Alexander, 1999; Atkinson, 1995).

### Intrapartum Consideration

For women with severe preeclampsia, peripartum management is the same as described in Chapter 40 (p. 761). Epidural analgesia for labor and delivery is optimal with the caveat that it is not given to treat hypertension (Lucas, 2001). That said, women with severe superimposed preeclampsia are more sensitive to the acute hypotensive effects of epidural analgesia (Vricella, 2012). Magnesium sulfate neuroprophylaxis is initiated for prevention of eclampsia (Alexander, 2006). Severe hypertension—diastolic blood pressure ≥ 110 mm Hg or systolic pressure ≥ 160 mm Hg—is treated with either intravenous hydralazine or labetalol. Some prefer to treat women with a diastolic pressure of 100 to 105 mm Hg. Vigil-De Gracia and colleagues (2006) randomized 200 women to intravenous hydralazine or labetalol to acutely lower severe high blood pressure in pregnancy. Outcomes were similar except for significantly more maternal palpitations and tachycardia with hydralazine and significantly more neonatal hypotension and bradycardia with labetalol.

### Postpartum Hypertension

In most respects, postpartum observation, prevention, and management of adverse complications are similar in women with severe chronic hypertension and in those with severe preeclampsia–eclampsia (Chap. 40, p. 767). For persistent severe hypertension, consideration is given for a cause such as pheochromocytoma or Cushing disease (Sibai, 2012). And because of chronic end-organ damage, certain complications are more common. These include cerebral or pulmonary edema, heart failure, renal dysfunction, or cerebral hemorrhage, especially within the first 48 hours after delivery (Martin, 2005; Sibai, 1990b). These frequently are preceded by sudden increases—“spikes”—of mean arterial blood pressure, especially the systolic component (Cunningham, 2000, 2005).

Following delivery, as maternal peripheral resistance increases, left ventricular workload also increases. This rise is further aggravated by appreciable and pathological amounts of interstitial fluid that are mobilized to be excreted as endothelial damage from preeclampsia resolves. In these women, sudden hypertension—either moderate or severe—exacerbates diastolic dysfunction, causes systolic dysfunction, and leads to pulmonary edema (Cunningham, 1986; Gandhi, 2001). Prompt hypertension control, along with furosemide-evoked diuresis, usually quickly resolves pulmonary edema. It is possible in many women to forestall this by the administration of intravenous furosemide to augment the normal postpartum diuresis. Daily weights are helpful in this regard. On average, a woman should weigh 15 pounds less immediately after delivery. Excessive extracellular fluid can be estimated by subtracting the postpartum weight from the predelivery weight—if not determined on hospital admission, the weight at the last prenatal visit provides a relatively accurate estimate. In one study, 20-mg oral furosemide given daily to postpartum women with severe preeclampsia aided blood-pressure control (Ascarelli, 2005).

### Contraception

Women with chronic hypertension have special considerations for contraceptive and sterilization choices. These are discussed in detail throughout Chapters 38 and 39. These women are also at
ultimate high risk for lifetime cardiovascular complications, especially when accompanied by diabetes, obesity, and the metabolic syndrome.

Acute and chronic pulmonary disorders are frequently encountered during pregnancy. Chronic asthma or an acute exacerbation is the most common and affects up to 4 percent of pregnant women. These disorders along with community-acquired pneumonia accounted for almost 10 percent of nonobstetrical hospitalizations in one managed care plan (Gazmararian, 2002). Pneumonia is also a frequent complication requiring readmission postpartum (Belfort, 2010). These and other pulmonary disorders are superimposed on several important pregnancy-induced changes of ventilatory physiology. For example, pregnant women, especially those in the last trimester, do not appear to tolerate severe acute pneumonitis as evidenced by the disparate number of maternal deaths during the 1918 and 1957 influenza pandemics.

The important and sometimes marked changes in the respiratory system induced by pregnancy are reviewed in Chapter 4 (p. 62), and values for associated tests can be found in the Appendix (p. 1292). Lung volumes and capacities that are measured directly to assess pulmonary pathophysiology may be significantly altered. In turn, these change gas concentrations and acid-base values in blood. Some of the physiological alterations induced by pregnancy were summarized by Wise and associates (2006):

1. **Vital capacity** and **inspiratory capacity** increase by approximately 20 percent by late pregnancy.
2. **Expiratory reserve volume** decreases from 1300 mL to approximately 1100 mL.

3. **Tidal volume** increases approximately 40 percent as a result of respiratory stimulation by progesterone.

4. **Minute ventilation** increases 30 to 40 percent due to increased tidal volume. As a result, arterial $P_{O_2}$ increases from 100 to 105 mm Hg.

5. Increasing metabolic demands cause a 30-percent increase in **carbon dioxide production**, but because of its concomitantly increased diffusion capacity along with hyperventilation, the arterial $P_{CO_2}$ decreases from 40 to 32 mm Hg.

6. **Residual volume** decreases approximately 20 percent from 1500 mL to approximately 1200 mL.

7. **Chest wall compliance** is reduced by a third by the expanding uterus and increased abdominal pressure, which causes a 10-to 25-percent decrease in **functional residual capacity**—the sum of expiratory reserve and residual volumes.

The end result of these pregnancy-induced changes is substantively increased ventilation due to deeper but not more frequent breathing. These are thought to be stimulated by basal oxygen consumption as it increases incrementally from 20 to 40 mL/min in the second half of pregnancy.

---

**ASTHMA**

Asthma is seen frequently in young women and therefore often complicates pregnancy. Asthma prevalence increased steadily in many countries beginning in the mid-1970s but may have plateaued in the United States, with a prevalence in adults of approximately 10 percent (Barnes, 2012; Centers for Disease Control and Prevention, 2010c). The estimated asthma prevalence during pregnancy ranges between 4 and 8 percent, and this appears to be increasing (Kwon, 2006; Namazy, 2005). Finally, evidence is accruing that fetal as well as neonatal environmental exposures may contribute to the origins of asthma in certain individuals (Harding, 2012; Henderson, 2012).

**Pathophysiology**

Asthma is a chronic inflammatory airway syndrome with a major hereditary component. Increased airway responsiveness and persistent subacute inflammation have been associated with genes on chromosomes 5q that include cytokine gene clusters, β-adrenergic and glucocorticoid receptor genes, and the T-cell antigen receptor gene (Barnes, 2012). Asthma is heterogeneous, and there inevitably is an **environmental allergic stimulant** such as influenza or cigarette smoke in susceptible individuals (Bel, 2013).

The hallmarks of asthma are reversible airway obstruction from bronchial smooth muscle contraction, vascular congestion, tenacious mucus, and mucosal edema. There is mucosal infiltration with eosinophils, mast cells, and T lymphocytes that causes airway inflammation and increased responsiveness to numerous stimuli including irritants, viral infections, aspirin, cold air, and exercise. Several inflammatory mediators produced by these and other cells include histamine, leukotrienes, prostaglandins, cytokines, and many others. IgE also plays a central role in pathophysiology (Strunk, 2006). **Because F-series prostaglandins and ergonovine exacerbate**
Clinical Course

Asthma findings range from mild wheezing to severe bronchoconstriction, which obstructs airways and decreases airflow. These reduce the forced expiratory volume in 1 second (FEV₁)/forced vital capacity (FVC) ratio and the peak expiratory flow (PEF). The work of breathing progressively increases, and patients note chest tightness, wheezing, or breathlessness. Subsequent alterations in oxygenation primarily reflect ventilation–perfusion mismatching, because the distribution of airway narrowing is uneven.

Varied manifestations of asthma have led to a simple classification that considers severity as well as onset and duration of symptoms (Table 51-1). With persistent or worsening bronchial obstruction, stages progress as shown in Figure 51-1. Hypoxia initially is well augmented by hyperventilation, which maintains arterial P_{O₂} within a normal range while causing the P_{CO₂} to decrease with resultant respiratory alkalosis. As airway narrowing worsens, ventilation–perfusion defects increase, and arterial hypoxemia ensues. With severe obstruction, ventilation becomes impaired as fatigue causes early CO₂ retention. Because of hyperventilation, this may only be seen initially as an arterial P_{CO₂} returning to the normal range. With continuing obstruction, respiratory failure follows from fatigue.

FEV = forced expiratory volume; FVC = forced vital capacity.
From National Heart, Lung, and Blood Institute, 2007.
Although these changes are generally reversible and well tolerated by the healthy nonpregnant individual, even early asthma stages may be dangerous for the pregnant woman and her fetus. This is because smaller functional residual capacity and increased pulmonary shunting render the woman more susceptible to hypoxia and hypoxemia.

**Effects of Pregnancy on Asthma**

There is no evidence that pregnancy has a predictable effect on underlying asthma. In their review of six prospective studies of more than 2000 pregnant women, Gluck and Gluck (2006) reported that approximately a third each improved, remained unchanged, or clearly worsened. Exacerbations are more common with severe disease (Ali, 2013). In a study by Schatz and associates (2003), baseline severity correlated with asthma morbidity during pregnancy. With mild disease, 13 percent of women had an exacerbation and 2.3 percent required admission; with moderate disease, these numbers were 26 and 7 percent; and for severe asthma, 52 and 27 percent. Others have reported similar observations (Charlton, 2013; Hendler, 2006; Murphy, 2005). Carroll and colleagues (2005) reported disparate morbidity in black compared with white women.

Some women have asthma exacerbations during labor and delivery. Up to 20 percent of women...
Pregnancy Outcome

Women with asthma have had improved pregnancy outcomes during the past 20 years. From his review, Dombrowski (2006) concluded that, unless disease is severe, pregnancy outcomes are generally excellent. The incidence of spontaneous abortion in women with asthma may be slightly increased (Blais, 2013). Maternal and perinatal outcomes for nearly 30,000 pregnancies in asthmatic women are shown in Table 51-2. Findings are not consistent among these studies. For example, in some, but not all, incidences of preeclampsia, preterm labor, growth-restricted infants, and perinatal mortality are slightly increased (Murphy, 2011). Another report cited a small rise in the incidence of placental abruption and in preterm rupture of membranes (Getahun, 2006, 2007). But, in a European report of 37,585 pregnancies of women with asthma, the risks for most obstetrical complications were not increased (Tata, 2007). In the Canadian study in which inhaled-corticosteroid dosage was quantified, Cossette and coworkers (2013) found a nonsignificant trend between perinatal complications and increasing dosage. They concluded that low to moderate doses were not associated with perinatal risks and noted that more data were needed regarding higher doses.

^aIncludes preeclampsia syndromes.
^bIncidence not significantly different compared with control group or general obstetrical population.
^cIncidence significantly greater than control group or general obstetrical population.
NS = not stated.

Thus, there appears to be significantly increased morbidity linked to severe disease, poor control, or both. In the study by the Maternal-Fetal Medicine Units (MFMU) Network, delivery before 37 weeks’ gestation was not increased among the 1687 pregnancies of asthmatics compared with normal pregnancies.
with those of 881 controls (Dombrowski, 2004a). But for women with severe asthma, the rate was increased approximately twofold. In a prospective evaluation of 656 asthmatic pregnant women and 1052 pregnant controls, Triche and coworkers (2004) found that women with moderate to severe asthma, regardless of treatment, are at increased risk of preeclampsia. Finally, the MFMU Network study suggests a direct relationship of baseline pregnancy forced expiratory volume at 1 second \( \text{FEV}_1 \) with birthweight and an inverse relationship with rates of gestational hypertension and preterm delivery (Schatz, 2006).

Life-threatening complications from status asthmaticus include muscle fatigue with respiratory arrest, pneumothorax, pneumomediastinum, acute cor pulmonale, and cardiac arrhythmias. Maternal and perinatal mortality rates are substantively increased when mechanical ventilation is required.

**Fetal Effects**

With reasonable asthma control, perinatal outcomes are generally good. For example, in the MFMU Network study cited above, there were no significant adverse neonatal sequelae from asthma (Dombrowski, 2004a). The caveat is that severe asthma was uncommon in this closely monitored group. When respiratory alkalosis develops, both animal and human studies suggest that fetal hypoxemia develops well before the alkalosis compromises maternal oxygenation (Rolston, 1974). It is hypothesized that the fetus is jeopardized by decreased uterine blood flow, decreased maternal venous return, and an alkaline-induced leftward shift of the oxyhemoglobin dissociation curve.

The fetal response to maternal hypoxemia is decreased umbilical blood flow, increased systemic and pulmonary vascular resistance, and decreased cardiac output. Observations by Bracken and colleagues (2003) confirm that the incidence of fetal-growth restriction increases with asthma severity. The realization that the fetus may be seriously compromised as asthma severity increases underscores the need for aggressive management. Monitoring the fetal response is, in effect, an indicator of maternal status.

Possible teratogenic or adverse fetal effects of drugs given to control asthma have been a concern. Fortunately, considerable data have accrued with no evidence that commonly used antiasthmatic drugs are harmful (Blais, 2007; Källén, 2007; Namazy, 2006). Thus, it is worrisome that Enriquez and coworkers (2006) reported a 13- to 54-percent patient-generated decrease in \( \beta \)-agonist and corticosteroid use between 5 and 13 weeks’ gestation.

**Clinical Evaluation**

The subjective severity of asthma frequently does not correlate with objective measures of airway function or ventilation. Although clinical examination can also be an inaccurate predictor, useful clinical signs include labored breathing, tachycardia, pulsus paradoxus, prolonged expiration, and use of accessory muscles. Signs of a potentially fatal attack include central cyanosis and altered consciousness.

Arterial blood gas analysis provides objective assessment of maternal oxygenation, ventilation, and acid-base status. With this information, the severity of an acute attack can be assessed (see Fig. 51-1). That said, in a prospective evaluation, Wendel and associates (1996) found that routine arterial blood gas analysis did not help to manage most pregnant women who required admission for asthma control. If used, the results must be interpreted in relation to normal values for pregnancy. For example, a \( \text{P}_{\text{CO}_2} \) > 35 mm Hg with a pH < 7.35 is consistent with
hyperventilation and CO₂ retention in a pregnant woman.

*Pulmonary function testing should be routine in the management of chronic and acute asthma.* Sequential measurement of the FEV₁ or the peak expiratory flow rate—PEFR—are the best measures of severity. An FEV₁ less than 1 L, or less than 20 percent of predicted value, correlates with severe disease defined by hypoxia, poor response to therapy, and a high relapse rate. The PEFR correlates well with the FEV₁, and it can be measured reliably with inexpensive portable meters. Each woman determines her own baseline when asymptomatic—*personal best*—to compare with values when symptomatic. The PEFR does not change during the course of normal pregnancy (Brancazio, 1997).

### Management of Chronic Asthma

The management guidelines of the Working Group on Asthma and Pregnancy include:

1. Patient education—general asthma management and its effect on pregnancy
2. Environmental precipitating factors—avoidance or control. Viral infections—including the common cold—are frequent triggering events (Murphy, 2013).
3. Objective assessment of pulmonary function and fetal well-being—monitor with PEFR or FEV₁
4. Pharmacological therapy—in appropriate combinations and doses to provide baseline control and treat exacerbations. Compliance may be a problem, and periodic medication reviews are helpful (Sawicki, 2012).

In general, women with moderate to severe asthma should measure and record either their FEV₁ or PEFR twice daily. The FEV₁ ideally is > 80 percent of predicted. For PEFR, predicted values range from 380 to 550 L/min. Each woman has her own baseline value, and therapeutic adjustments can be made using this (American College of Obstetricians and Gynecologists, 2012; Rey, 2007).

Treatment depends on disease severity. Although β-agonists help to abate bronchospasm, corticosteroids treat the inflammatory component. Regimens recommended for outpatient management are listed in *Figure 51-2*. For mild asthma, inhaled β-agonists as needed are usually sufficient. For persistent asthma, *inhaled corticosteroids* are administered every 3 to 4 hours. The goal is to reduce the use of β-agonists for symptomatic relief. A case-control study from Canada with a cohort of more than 15,600 nonpregnant women with asthma showed that inhaled corticosteroids reduced hospitalizations by 80 percent (Blais, 1998). And Wendel and colleagues (1996) achieved a 55-percent reduction in readmissions for severe exacerbations in pregnant asthmatics given maintenance inhaled corticosteroids along with β-agonist therapy.
Theophylline is a methylxanthine, and its various salts are bronchodilators and possibly antiinflammatory agents. They have been used less frequently since inhaled corticosteroids became available. Some theophylline derivatives are considered useful for oral maintenance therapy if the initial response to inhaled corticosteroids and β-agonists is not optimal. Dombrowski and associates (2004b) conducted a randomized trial with nearly 400 pregnant women with moderate asthma. Oral theophylline was compared with inhaled beclomethasone for maintenance. In both groups, approximately 20 percent had exacerbations. Women taking theophylline had a significantly higher discontinuation rate because of side effects. Pregnancy outcomes were similar in the two groups.

Antileukotrienes inhibit leukotriene synthesis and include zileuton, zafirlukast, and montelukast. These drugs are given orally or by inhalation for prevention, but they are not effective for acute disease. For maintenance, they are used in conjunction with inhaled corticosteroids to allow minimal dosing. Approximately half of asthmatics will improve with these drugs (McFadden, 2005). They are not as effective as inhaled corticosteroids (Fanta, 2009). Finally, there is little experience with their use in pregnancy (Bakhireva, 2007).

Cromones include cromolyn and nedocromil, which inhibit mast cell degranulation. They are ineffective for acute asthma and are taken chronically for prevention. They are not as effective as inhaled corticosteroids and are used primarily to treat childhood asthma.

Management of Acute Asthma

Treatment of acute asthma during pregnancy is similar to that for the nonpregnant asthmatic (Barnes, 2012). However, the threshold for hospitalization is significantly lowered. Intravenous hydration may help clear pulmonary secretions, and supplemental oxygen is given by mask. The therapeutic aim is to maintain the $P_{O_2} > 60 \text{ mm Hg}$, and preferably normal, along with 95-percent oxygen saturation. Baseline pulmonary function testing includes $FEV_1$ or PEFR. Continuous puls
oximetry and electronic fetal monitoring, depending on gestational age, may provide useful information.

First-line therapy for acute asthma includes a β-adrenergic agonist, such as terbutaline, albuterol, isoetharine, epinephrine, isoproterenol, or metaproterenol, which is given subcutaneously, taken orally, or inhaled. These drugs bind to specific cell-surface receptors and activate adenylyl cyclase to increase intracellular cyclic AMP and modulate bronchial smooth muscle relaxation. Long-acting preparations are used for outpatient therapy.

If not previously given for maintenance, inhaled corticosteroids are commenced along with intensive β-agonist therapy. For severe exacerbations, magnesium sulfate may prove efficacious. **Corticosteroids should be given early to all patients with severe acute asthma.** Unless there is a timely response to bronchodilator and inhaled corticosteroid therapy, oral or parenteral corticosteroids are given (Lazarus, 2010). Intravenous methylprednisolone, 40 to 60 mg, every 6 hours for four doses is commonly used. Equipotent doses of hydrocortisone by infusion or prednisone orally can be given instead. **Because their onset of action is several hours, corticosteroids are given initially along with β-agonists for acute asthma.**

Further management depends on the response to therapy. If initial therapy with β-agonists is associated with improvement of FEV$_1$ or PEFR to above 70 percent of baseline, then discharge can be considered. Some women may benefit from observation. Alternatively, for the woman with obvious respiratory distress, or if the FEV$_1$ or PEFR is < 70 percent of predicted after three doses of β-agonist, admission is likely advisable (Lazarus, 2010). Intensive therapy includes inhaled β-agonists, intravenous corticosteroids, and close observation for worsening respiratory distress or fatigue in breathing (Wendel, 1996). The woman is cared for in the delivery unit or an intermediate or intensive care unit (ICU) (Dombrowski, 2006; Zeeman, 2003).

**Status Asthmaticus and Respiratory Failure**

Severe asthma of any type not responding after 30 to 60 minutes of intensive therapy is termed status asthmaticus. Braman and Kaemmerlen (1990) have shown that management of nonpregnant patients with status asthmaticus in an intensive care setting results in a good outcome in most cases. Consideration should be given to early intubation when maternal respiratory status worsens despite aggressive treatment (see Fig. 51-1). Fatigue, carbon dioxide retention, and hypoxemia are indications for mechanical ventilation. Lo and colleagues (2013) have described a woman with status asthmaticus in whom cesarean delivery was necessary to effect ventilation. Andrews (2013) cautioned that such clinical situations are uncommon.

**Labor and Delivery**

For the laboring asthmatic, maintenance medications are continued through delivery. Stress-dose corticosteroids are administered to any woman given systemic corticosteroid therapy within the preceding 4 weeks. The usual dose is 100 mg of hydrocortisone given intravenously every 8 hours during labor and for 24 hours after delivery. The PEFR or FEV$_1$ should be determined on admission, and serial measurements are taken if symptoms develop.

Oxytocin or prostaglandins E$_1$ or E$_2$ are used for cervical ripening and induction. A nonhistamine-releasing narcotic such as fentanyl may be preferable to meperidine for labor, and epidural analgesia is ideal. For surgical delivery, conduction analgesia is preferred because tracheal intubation can trigger severe bronchospasm. Postpartum hemorrhage is treated with
oxytocin or prostaglandin $E_2$. Prostaglandin $F_2\alpha$ or ergotamine derivatives are contraindicated because they may cause significant bronchospasm.

**ACUTE BRONCHITIS**

Infection of the large airways is manifest by cough without pneumonitis. It is common in adults, especially in winter months. Infections are usually caused by viruses, and of these, influenza A and B, parainfluenza, respiratory syncytial, coronavirus, adenovirus, and rhinovirus are frequent isolates (Wenzel, 2006). Bacterial agents causing community-acquired pneumonia are rarely implicated. The cough of acute bronchitis persists for 10 to 20 days (mean 18 days) and occasionally lasts for a month or longer. According to the 2006 guidelines of the American College of Chest Physicians, routine antibiotic treatment is not justified (Braman, 2006). Influenza bronchitis is managed as discussed below.

**PNEUMONIA**

According to Anand and Kollef (2009), current classification includes several types of pneumonia. Community-acquired pneumonia (CAP) is typically encountered in otherwise healthy young women, including during pregnancy. Health-care-associated pneumonia (HCAP) develops in patients in outpatient care facilities and more closely resembles hospital-acquired pneumonia (HAP). Other types are nursing home-acquired pneumonia (NHAO) and ventilator-associated pneumonia (VAP).

Community-acquired pneumonia in pregnant women is relatively common and is caused by several bacterial or viral pathogens (Brito, 2011; Sheffield, 2009). Gazmararian and coworkers (2002) reported that pneumonia accounts for 4.2 percent of antepartum admissions for nonobstetrical complications. Pneumonia is also a frequent indication for postpartum readmission (Belfort, 2010). During influenza season, admission rates for respiratory illnesses double compared with rates in the remaining months (Cox, 2006). Mortality from pneumonia is infrequent in young women, but during pregnancy severe pneumonitis with appreciable loss of ventilatory capacity is not as well tolerated (Rogers, 2010). This generalization seems to hold true regardless of the pneumonia etiology. Hypoxemia and acidosis are also poorly tolerated by the fetus and frequently stimulate preterm labor after midpregnancy. Because many cases of pneumonia follow viral upper respiratory illnesses, worsening or persistence of symptoms may represent developing pneumonia. Any pregnant woman suspected of having pneumonia should undergo chest radiography.

**Bacterial Pneumonia**

Many bacteria that cause community-acquired pneumonia, such as *Streptococcus pneumoniae*, are part of the normal resident flora (Bogaert, 2004). Some factors that perturb the symbiotic relationship between colonizing bacteria and mucosal phagocytic defenses include acquisition of a virulent strain or bacterial infections following a viral infection. Cigarette smoking and chronic bronchitis favor colonization with *S pneumoniae, Haemophilus influenzae*, and *Legionella*...
species. Other risk factors include asthma, binge drinking, and human immunodeficiency virus (HIV) infection (Goodnight, 2005; Sheffield, 2009).

Incidence and Causes
Pregnancy itself does not predispose to pneumonia. Jin and colleagues (2003) reported the antepartum hospitalization rate for pneumonia in Alberta, Canada, to be 1.5 per 1000 deliveries—almost identical to the rate of 1.47 per 1000 for nonpregnant women. Likewise, Yost and associates (2000) reported an incidence of 1.5 per 1000 for pneumonia complicating 75,000 pregnancies cared for at Parkland Hospital. More than half of adult pneumonias are bacterial, and \( S\) pneumoniae is the most common cause. Lim and coworkers (2001) studied 267 nonpregnant inpatients with pneumonia and identified a causative agent in 75 percent—\( S\) pneumoniae in 37 percent; influenza A, 14 percent; Chlamydophila pneumoniae, 10 percent; \( H\) influenzae, 5 percent; and Mycoplasma pneumoniae and Legionella pneumophila, 2 percent each. More recently, community-acquired methicillin-resistant Staphylococcus aureus (CA-MRSA) has emerged as the second most common pathogen in nonpregnant adults (Moran, 2013). These staphylococci may cause necrotizing pneumonia (Mandell, 2012; Rotas, 2007).

Diagnosis
Typical symptoms include cough, dyspnea, sputum production, and pleuritic chest pain. Mild upper respiratory symptoms and malaise usually precede these symptoms, and mild leukocytosis is usually present. Chest radiography is essential for diagnosis but does not accurately predict the etiology (Fig. 51-3). The responsible pathogen is identified in fewer than half of cases. According to the Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS) tests to identify a specific agent are optional. Thus, sputum cultures, serological testing, cold agglutinin identification, and tests for bacterial antigens are not recommended. At Parkland Hospital, the one exception to this is rapid serological testing for influenza A and B (Sheffield, 2009).
FIGURE 51-3 Chest radiographs in a pregnant woman with right lower lobe pneumonia. A. Complete opacification of the right lower lobe (arrows) is consistent with the clinical suspicion of pneumonia. B. Opacification (arrows) is also seen on the lateral projection.

Management

Although many otherwise healthy young adults can be safely treated as outpatients, at Parkland Hospital we hospitalize all pregnant women with radiographically proven pneumonia. For some, outpatient therapy or 23-hour observation is reasonable with optimal follow-up. Risk factors shown in Table 51-3 should prompt hospitalization.

<sup>a</sup>Criteria of the Infectious Diseases Society of America/American Thoracic Society.

WBC = white blood cell.
Adapted from Mandell, 2007.

With severe disease, admission to an ICU or intermediate care unit is advisable. Approximately 20 percent of pregnant women admitted to Parkland Hospital for pneumonia require this level of care (Zeeman, 2003). Severe pneumonia is a relatively common cause of acute respiratory distress syndrome during pregnancy, and mechanical ventilation may become necessary. Indeed, of the 51 pregnant women who required mechanical ventilation in the review by Jenkins and coworkers (2003), 12 percent had pneumonia.

Antimicrobial treatment is empirical (Mandell, 2012). Because most adult pneumonias are caused by pneumococci, mycoplasma, or chlamydophila, monotherapy initially is with a macrolide—azithromycin, clarithromycin, or erythromycin. Yost and colleagues (2000) reported that erythromycin monotherapy, given intravenously and then orally, was effective in all but one of 99 pregnant women with uncomplicated pneumonia.

For women with severe disease according to criteria in Table 51-3, Mandell and associates (2007) summarized IDSA/ATS guidelines, which call for either: (1) a respiratory fluoroquinolone—levofoxacin, moxifloxacin, or gemifloxacin; or (2) a macrolide plus a β-lactam—high-dose amoxicillin or amoxicillin-clavulanate, which are preferred β-lactams. β-lactam alternatives include ceftriaxone, cefpodoxime, or cefuroxime. In areas in which there is “high-level” resistance of pneumococcal isolates to macrolides, these latter regimens are preferred. The teratogenicity risk of fluoroquinolones is low, and these should be given if indicated (Briggs, 2011). If
community-acquired methicillin-resistant *Staphylococcus aureus* is suspected, then vancomycin or linezolid are added (Mandell, 2012; Sheffield, 2009). At this time, such therapy is empirical, and there are no tested regimens against CA-MRSA (Moran, 2013).

Clinical improvement is usually evident in 48 to 72 hours with resolution of fever in 2 to 4 days. Radiographic abnormalities may take up to 6 weeks to completely resolve (Torres, 2008). Worsening disease is a poor prognostic feature, and follow-up radiography is recommended if fever persists. Even with improvement, however, approximately 20 percent of women develop a pleural effusion. Pneumonia treatment is recommended for a minimum of 5 days. Treatment failure may occur in up to 15 percent of cases, and a wider antimicrobial regimen and more extensive diagnostic testing are warranted in these cases.

**Pregnancy Outcome with Pneumonia**

During the preantimicrobial era, as many as a third of pregnant women with pneumonia died (Finland, 1939). Although much improved, maternal and perinatal mortality rates both remain formidable. In five studies published after 1990, the maternal mortality rate was 0.8 percent of 632 women. Importantly, almost 7 percent of the women required intubation and mechanical ventilation.

Prematurely ruptured membranes and preterm delivery are frequent complications and have been reported in up to a third of cases (Getahun, 2007; Shariatzadeh, 2006). Likely related are older studies reporting a twofold increase in low-birthweight infants (Sheffield, 2009). In a more recent population-based study from Taiwan of nearly 219,000 births, there were significantly increased incidences of preterm and growth-restricted infants as well as preeclampsia and cesarean delivery (Chen, 2012).

**Prevention**

Pneumococcal vaccine is 60- to 70-percent protective against its 23 included serotypes. Its use has been shown to decrease emergence of drug-resistant pneumococci (Kyaw, 2006). The vaccine is not recommended for otherwise healthy pregnant women (American College of Obstetricians and Gynecologists, 2013). It is recommended for those who are immunocompromised, including those with HIV infection; significant smoking history; diabetes; cardiac, pulmonary, or renal disease; and asplenia, such as with sickle-cell disease (Table 9-9, p. 185). Protection against pneumococcal infection in women with chronic diseases may be less efficacious than in healthy patients (Moherley, 2013).

**Influenza Pneumonia**

**Clinical Presentation**

Influenza A and B are RNA viruses that cause respiratory infection, including pneumonitis. Influenza pneumonia can be serious, and it is epidemic in the winter months. The virus is spread by aerosolized droplets and quickly infects ciliated columnar epithelium, alveolar cells, mucus gland cells, and macrophages. Disease onset is 1 to 4 days following exposure (Longman, 2007). In most healthy adults, infection is self-limited.

Pneumonia is the most frequent complication of influenza, and it is difficult to distinguish from bacterial pneumonia. According to the Centers for Disease Control and Prevention (2010a) infected pregnant women are more likely to be hospitalized as well as admitted to an ICU. At Parkland Hospital during the 2003 to 2004 influenza season, pneumonia developed in 12 percent
of pregnant women with influenza (Rogers, 2010). The 2009 influenza pandemic with the H1N1 strain was particularly severe. In a Maternal-Fetal Medicine Units Network study, 10 percent of pregnant or postpartum women admitted with H1N1 influenza were cared for in an ICU, and 11 percent of these ICU patients died (Varner, 2011). Risk factors included late pregnancy, smoking, and chronic hypertension. In California, 22 percent of H1N1-infected women required intensive care, and a third of these died.

Primary influenza pneumonitis is the most severe and is characterized by sparse sputum production and radiographic interstitial infiltrates. More commonly, secondary pneumonia develops from bacterial superinfection by streptococci or staphylococci after 2 to 3 days of initial clinical improvement. The Centers for Disease Control and Prevention (2007b) reported several cases in which CA-MRSA caused influenza-associated pneumonitis with a case-fatality rate of 2% percent. Other possible adverse effects of influenza A and B on pregnancy outcome are discussed in Chapter 64 (p. 1241).

Management

Supportive treatment with antipyretics and bed rest is recommended for uncomplicated influenza. Early antiviral treatment has been shown to be effective (Jamieson, 2011). As discussed, influenza hospitalizations for those with advanced pregnancy are increased compared with nonpregnant women (Dodds, 2007; Schanzer, 2007). Rapid resistance of influenza A (H3N2) strains to amantadine or rimantadine in 2005 prompted the Centers for Disease Control and Prevention (2006) to recommend against their use. Instead, neuraminidase inhibitors were given within 2 days of symptom onset for chemoprophylaxis and treatment of influenza A and B (Chap. 64, p. 1242). The drugs interfere with release of progeny virus from infected host cells and thus prevent infection of new host cells (Moscona, 2005). Oseltamivir is given orally, 75 mg twice daily, or zanamivir is given by inhalation, 10 mg twice daily. Recommended treatment duration with either is 5 days. The drugs shorten the course of illness by 1 to 2 days, and they may reduce the risk for pneumonitis (Jamieson, 2011). Our practice is to treat all pregnant women with influenza whether or not pneumonitis is identified. There are few data regarding use of these agents in pregnant women, but the drugs were not teratogenic in animal studies and are considered low risk (Briggs, 2011).

Other concerns for viral resistance are for avian H5N1 and H7N9 strains isolated in Southeast Asia. These are candidate viruses for an influenza pandemic with a projected mortality rate that exceeds 50 percent (Beigi, 2007; World Health Organization, 2008). Currently, international efforts are being made to produce a vaccine effective against both strains.

Preventively, vaccination for influenza A is recommended and is discussed in detail in Chapter 64 (p. 1242). Prenatal vaccination also affords protection for a third of infants for at least 6 months (Zaman, 2008). During the 2012–2013 flu season, the Centers for Disease Control and Prevention (2013b) reported that only half of pregnant women received the vaccine.

Varicella Pneumonia

Infection with varicella-zoster virus—chicken pox—results in pneumonitis in 5 percent of pregnant women (Harger, 2002). Diagnosis and management are considered in Chapter 64 (p. 1240).
Fungal and Parasitic Pneumonia

**Pneumocystis Pneumonia**

Fungal and parasitic pulmonary infections are usually of greatest consequence in immunocompromised hosts, especially in women with acquired immunodeficiency syndrome (AIDS). Of these, lung infection with *Pneumocystis jiroveci*, formerly called *Pneumocystis carinii*, is a common complication in women with AIDS. The opportunistic fungus causes interstitial pneumonia characterized by dry cough, tachypnea, dyspnea, and diffuse radiographic infiltrates. Although this organism can be identified by sputum culture, bronchoscopy with lavage or biopsy may be necessary.

In a report from the AIDS Clinical Trials Centers, Stratton and colleagues (1992) described pneumocystis pneumonia as the most frequent HIV-related disorder in pregnant women. Ahmad and coworkers (2001) reviewed 22 cases during pregnancy and cited a 50-percent mortality rate. Treatment is with trimethoprim-sulfamethoxazole or the more toxic pentamidine (Walzer, 2005). Experience with dapsone or atovaquone is limited. In some cases, tracheal intubation and mechanical ventilation may be required.

As prophylaxis, several international health agencies recommend one double-strength trimethoprim-sulfamethoxazole tablet orally daily for certain HIV-infected pregnant women. These include women with CD4+ T-lymphocyte counts < 200/μL, those whose CD4+ T lymphocytes constitute less than 14 percent, or if there is an AIDS-defining illness, particularly oropharyngeal candidiasis (Centers for Disease Control and Prevention, 2013a; Forna, 2006).

**Fungal Pneumonia**

Any of a number of fungi can cause pneumonia. In pregnancy, this is usually seen in women with HIV infection or who are otherwise immunocompromised. Infection is usually mild and self-limited. It is characterized initially by cough and fever, and dissemination is infrequent.

*Histoplasmosis* and *blastomycosis* do not appear to be more common or more severe during pregnancy. Data concerning *coccidioidomycosis* are conflicting (Bercovitch, 2011; Patel, 2013). In a case-control study from an endemic area, Rosenstein and coworkers (2001) reported that pregnancy was a significant risk factor for disseminated disease. In another study, however, Caldwell and coworkers (2000) identified 32 serologically confirmed cases during pregnancy and documented dissemination in only three cases. Arsura (1998) and Caldwell (2000) and their associates reported that pregnant women with symptomatic infection had a better overall prognosis if there was associated *erythema nodosum*. Crum and Ballon-Landa (2006) reviewed 80 cases of coccidioidomycosis complicating pregnancy. Almost all women diagnosed in the third trimester had disseminated disease. Although the overall maternal mortality rate was 40 percent, it was only 20 percent for 29 cases reported since 1973. Spinello (2007) and Bercovitch (2011), with their associates, have provided reviews of coccidioidomycosis in pregnancy.

Most cases of *cryptococcosis* reported during pregnancy have been reported to manifest as meningitis. Ely and colleagues (1998) described four otherwise healthy pregnant women with cryptococcal pneumonia. Diagnosis is difficult because clinical presentation is similar to that of other community-acquired pneumonias.

The 2007 IDSA/ATS guidelines recommend itraconazole as preferred therapy for disseminated fungal infections (Mandell, 2007). Pregnant women have also been given intravenous *amphotericin B or ketoconazole* (Hooper, 2007; Paranyuk, 2006). Amphotericin B has been used extensively in pregnancy with no embryo-fetal effects. Because of evidence that fluconazole,
itraconazole, and ketoconazole may be embryotoxic in large doses in early pregnancy, Briggs and associates (2011) recommend that first-trimester use should be avoided if possible.

Three echinocandin derivatives—caspofungin, micafungin, and anidulafungin—are effective for invasive candidiasis (Medical Letter, 2006; Reboli, 2007). They are embryotoxic and teratogenic in laboratory animals and use in human pregnancies has not been reported (Briggs, 2011).

Severe Acute Respiratory Syndrome (SARS)
This coronaviral respiratory infection was first identified in China in 2002, but no new cases have been reported since 2005. It caused atypical pneumonitis with a case-fatality rate of approximately 10 percent (Dolin, 2012). SARS in pregnancy had a case-fatality rate of up to 25 percent (Lam 2004; Longman, 2007; Wong, 2004). Ng and coworkers (2006) reported that the placentas from 7 of 19 cases showed abnormal intervillous or subchorionic fibrin deposition in three, and extensive fetal thrombotic vasculopathy in two.

TUBERCULOSIS

Although tuberculosis is still a major worldwide concern, it is uncommon in the United States. The incidence of active tuberculosis in this country has plateaued since 2000 (Raviglione, 2012). More than half of active cases are in immigrants (Centers for Disease Control and Prevention 2009b). Persons born in the United States have newly acquired infection, whereas foreign-born persons usually have reactivation of latent infection. In this country, tuberculosis is a disease of the elderly, the urban poor, minority groups—especially black Americans, and patients with HIV infection (Raviglione, 2012).

Infection is via inhalation of Mycobacterium tuberculosis, which incites a granulomatous pulmonary reaction. In more than 90 percent of patients, infection is contained and is dormant for long periods (Zumla, 2013). In some patients, especially those who are immunocompromised or who have other diseases, tuberculosis becomes reactivated to cause clinical disease. Manifestations usually include cough with minimal sputum production, low-grade fever, hemoptysis, and weight loss. Various infiltrative patterns are seen on chest radiograph, and there may be associated cavitation or mediastinal lymphadenopathy. Acid-fast bacilli are seen on stained smears of sputum in approximately two thirds of culture-positive patients. Forms of extrapulmonary tuberculosis include lymphadenitis, pleural, genitourinary, skeletal, meningeal, gastrointestinal, and miliary or disseminated (Raviglione, 2012).

Treatment
Cure rates with 6-month short-course directly observed therapy—DOT—approach 90 percent for new infections. Resistance to antituberculosis drugs was first manifest in the United States in the early 1990s following the epidemic from 1985 through 1992 (Centers for Disease Control and Prevention, 2007a). Strains of multidrug-resistant tuberculosis (MDR-TB) increased rapidly as tuberculosis incidence fell during the 1990s. Because of this, the Centers for Disease Control and Prevention (2003) now recommends a multidrug regimen for initial empirical treatment of patients with symptomatic tuberculosis. Isoniazid, rifampin, pyrazinamide, and ethambutol are given until
susceptibility studies are performed. Other second-line drugs may need to be added. Drug susceptibility is performed on all first isolates.

In 2005, there was a worldwide emergence of extensively drug-resistant tuberculosis—XDR-TB. This is defined as resistance in vitro to at least the first-line drugs isoniazid and rifampin as well as to three or more of the six main classes of second-line drugs—aminoglycosides, polypeptides, fluoroquinolones, thioamides, cycloserine, and para-aminosalicylic acid (Centers for Disease Control and Prevention, 2009a). Like their predecessor MDR-TB, these extensively resistant strains predominate in foreign-born persons (Tino, 2007).

### Tuberculosis and Pregnancy

The considerable influx of women into the United States from Asia, Africa, Mexico, and Central America has been accompanied by an increased frequency of tuberculosis in pregnant women. Sackoff and coworkers (2006) reported positive-tuberculin tests in half of 678 foreign-born women attending perinatal clinics in New York City. Almost 60 percent were newly diagnosed. Pillay and colleagues (2004) stress the prevalence of tuberculosis in HIV-positive pregnant women. Margono and coworkers (1994) reported that for two New York City hospitals, more than half of pregnant women with active tuberculosis were HIV positive. At Jackson Memorial Hospital in Miami, Schulte and associates (2002) reported that 21 percent of 207 HIV-infected pregnant women had a positive skin test result. Recall also that silent endometrial tuberculosis can cause tubal infertility (Levison, 2010).

Without antituberculosis therapy, active tuberculosis appears to have adverse effects on pregnancy (Anderson, 1997; Mnyani, 2011). Contemporaneous experiences are few, however, because antitubercular therapy has diminished the frequency of severe disease. Outcomes are dependent on the site of infection and timing of diagnosis in relation to delivery. Jana and colleagues (1994) from India and Figueroa-Damian and Arrendondo-Garcia (1998) from Mexico City reported that active pulmonary tuberculosis was associated with increased incidences of preterm delivery, low-birthweight and growth-restricted infants, and perinatal mortality. From her review, Efferen (2007) cited twofold increased rates of low-birthweight and preterm infants as well as preeclampsia. The perinatal mortality rate was increased almost tenfold. Adverse outcomes correlate with late diagnosis, incomplete or irregular treatment, and advanced pulmonary lesions. From Taiwan, 761 pregnant women diagnosed with tuberculosis had a higher incidence of low-birthweight and growth-restricted infants (Lin, 2010).

Extrapulmonary tuberculosis is less common. Jana and coworkers (1999) reported outcomes in 33 pregnant women with renal, intestinal, and skeletal tuberculosis, and a third had low-birthweight newborns. Llewelyn and associates (2000) reported that nine of 13 pregnant women with extrapulmonary disease had delayed diagnoses. Prevost and Fung Kee Fung (1999) reviewec 56 cases of tuberculous meningitis in which a third of mothers died. Spinal tuberculosis may cause paraplegia, but vertebral fusion may prevent it from becoming permanent (Badve, 2011; Nanda, 2002). Other presentations include widespread intraperitoneal tuberculosis simulating ovarian carcinomatosis and degenerating leiomyoma, and hyperemesis gravidarum from tubercular meningitis (Kutlu, 2007; Moore, 2008; Sherer, 2005).

### Diagnosis

There are two types of tests to detect latent or active tuberculosis. One is the time-honored tuberculin skin test (TST), and the others are interferon-gamma release assays (IGRAs), which are becoming preferred (Horsburgh, 2011). IGRAs are blood tests that measure interferon-gamma...
release in response to antigens present in *M tuberculosis*, but not bacille Calmette-Guérin (BCG) vaccine (Ernst, 2007; Levison, 2010). The Centers for Disease Control and Prevention (2005b, 2010b) recommend either skin testing or IGRA testing of pregnant women who are in any of the high-risk groups shown in Table 51-4. For those who received BCG vaccination, IGRA testing is used (Mazurek, 2010).

HIV = human immunodeficiency virus.
From the Centers for Disease Control and Prevention, 2005a.

For skin testing, the preferred antigen is purified protein derivative (PPD) of intermediate strength of 5 tuberculin units. If the intracutaneously applied test result is negative, no further evaluation is needed. A positive skin test result measures ≥ 5 mm in diameter and requires evaluation for active disease, including a chest radiograph (Centers for Disease Control and Prevention, 2005a, 2010b). It also may be interpreted according to risk factors proposed by the American Thoracic Society/Centers for Disease Control and Prevention (1990). For very high-risk patients—that is, those who are HIV-positive, those with abnormal chest radiography, or those who have a recent contact with an active case—5 mm or greater is considered a reason to treat. For those at high risk—foreign-born individuals, intravenous drug users who are HIV-negative, low-income populations, or those with medical conditions that increase the risk for tuberculosis—10 mm or greater is considered treatable. For persons with none of these risk factors, 15 mm or greater is defined as requiring treatment.

There are two IGRAAs available: *QuantiFERON-TB Gold* and *T-SPOT.TB* tests are recommended by the Centers for Disease Control and Prevention (2005a,b) for the same indications as skin testing. These tests have not been evaluated as extensively as tuberculin skin testing. Lalvani (2007) reviewed them and found them to be useful in identifying patients with latent tuberculosis and at risk for progression to active disease. Kowada (2014) concluded that these tests are cost effective.

Essential laboratory methods for detection or verification of infection—both active and latent—include microscopy, culture, nucleic acid amplification assay, and drug-susceptibility testing (Centers for Disease Control and Prevention, 2009a, 2010b).

### Treatment

**Latent Infection.** Different schemes are recommended for latent and active tuberculosis. In nonpregnant tuberculin-positive patients who are younger than 35 years and who have no evidence
of active disease, isoniazid, 300 mg orally daily, is given for 9 months. Isoniazid has been used for decades, and it is considered safe in pregnancy (Briggs, 2011; Taylor, 2013). Compliance is a major problem, and Sackoff (2006) and Cruz (2005) and their associates reported a disappointing 10-percent treatment completion. One obvious disconnect is that care for tuberculosis is given in health systems different from prenatal care (Zenner, 2012). These observations are important because most recommend that isoniazid therapy be delayed until after delivery. Because of possibly increased isoniazid-induced hepatitis risk in postpartum women, some recommend withholding treatment until 3 to 6 months after delivery. That said, neither method is as effective as antepartum treatment to prevent active infection. Boggess and colleagues (2000) reported that only 42 percent of 167 tuberculin-positive asymptomatic women delivered at San Francisco General Hospital completed 6-month therapy that was not given until the first postpartum visit.

There are exceptions to delayed treatment in pregnancy. Known recent skin-test convertors are treated antepartum because the incidence of active infection is 5 percent in the first year (Zumla, 2013). Skin-test-positive women exposed to active infection are treated because the incidence of infection is 0.5 percent per year.

HIV-positive women are treated because they have an approximate 10-percent annual risk of active disease. Treatment of these women is of special concern if there is antiretroviral naiveté. In these circumstances, beginning concomitant therapy with antituberculosis and antiretroviral therapy can cause the immune reconstitution inflammatory syndrome (IRIS) with toxic drug effects (Török, 2011). Recent studies, however, support earlier administration of highly active antiretroviral therapy (HAART)—within 2 to 4 weeks—after beginning antituberculosis therapy (Blanc, 2011; Havlir, 2011; Karim, 2011).

Active Infection. Recommended initial treatment for active tuberculosis in pregnant patients is a four-drug regimen with isoniazid, rifampin, ethambutol, and pyrazinamide, along with pyridoxine. In the first 2-month phase, all four drugs are given—bactericidal phase. This is followed by a 4-month phase of isoniazid and rifampin—continuation phase (Raviglione, 2012; Zumla, 2013). Reports of MDR-TB during pregnancy are few, and Lessnau and Qarah (2003) and Shin and coworkers (2003) have reviewed treatment options. Breast feeding is not prohibited during antituberculous therapy.

As discussed above, beginning concomitant antituberculosis and antiretroviral therapy may cause the immune reconstitution inflammatory syndrome, and risks versus benefits are assessed. Also, for HIV-infected women, rifampin or rifabutin use may be contraindicated if certain protease inhibitors or nonnucleoside reverse transcriptase inhibitors are being administered. If there is resistance to rifabutin or rifampin, then pyrazinamide therapy is given. Of the second-line regimens, the aminoglycosides—streptomycin, kanamycin, amikacin, and capreomycin—are ototoxic to the fetus and are contraindicated (Briggs, 2011).

Neonatal Tuberculosis. Tubercular bacillemia can infect the placenta, but it is uncommon that the fetus becomes infected—congenital tuberculosis. The term also applies to newborns who are infected by aspiration of infected secretions at delivery. Each route of infection constitutes approximately half of the cases. A rare case of congenital tuberculosis caused by in vitro fertilization (IVF) was reported (Doudier, 2008). Neonatal tuberculosis simulates other congenital infections and manifests with hepatosplenomegaly, respiratory distress, fever, and lymphadenopathy (Smith, 2002).

Cantwell and associates (1994) reviewed 29 cases of congenital tuberculosis reported since 1980. Only 12 of the mothers had active infection, and tuberculosis was frequently demonstrated
by postpartum endometrial biopsy. Adhikari and colleagues (1997) described 11 South African postpartum women whose endometrial biopsy was culture-positive. Six of their neonates had congenital tuberculosis.

Neonatal infection is unlikely if the mother with active disease has been treated before delivery or if her sputum culture is negative. Because the newborn is susceptible to tuberculosis, most authors recommend isolation from the mother suspected of having active disease. If untreated, the risk of disease in the infant born to a woman with active infection is 50 percent in the first year (Jacobs, 1988).

SARCOIDOSIS

Sarcoidosis is a chronic, multisystem disease of unknown etiology characterized by an accumulation of T lymphocytes and phagocytes within noncaseating granulomas (Baughman, 2012). Predisposition to the disease is genetically determined and characterized by an exaggerated response of helper T lymphocytes to environmental triggers (Moller, 2007; Spagnolo, 2007). Pulmonary involvement is most common, followed by skin, eyes, and lymph nodes. The prevalence of sarcoid in the United States is 20 to 60 per 100,000, with equal sex distribution, but it is 3 to 17 times more common for black compared with white persons (Baughman, 2012). Most patients are between 20 and 40 years. Clinical presentation varies, but more than half of patients have dyspnea and a dry cough without constitutional symptoms that develop insidiously over months. Disease onset is abrupt in about 25 percent of patients, and 10 to 20 percent are asymptomatic at discovery.

Pulmonary symptoms are dominant, and more than 90 percent of patients have an abnormal chest radiograph at some point (Lynch, 2007). Interstitial pneumonitis is the hallmark of pulmonary involvement. Approximately 50 percent of affected patients develop permanent radiological changes. Lymphadenopathy, especially of the mediastinum, is present in 75 to 90 percent of cases, and 25 percent have uveitis. A fourth have skin involvement, usually manifest as erythema nodosum. In women, sarcoid causes about 10 percent of cases of erythema nodosum (Acosta, 2013; Mert, 2007). Finally, any other organ system may be involved. Confirmation of the diagnosis is with biopsy, and because the lung may be the only obviously involved organ, tissue acquisition is often difficult.

The overall prognosis for sarcoidosis is good, and it resolves without treatment in 50 percent of patients. Still, there is diminished quality of life (de Vries, 2007). In the other 50 percent, permanent organ dysfunction, albeit mild and nonprogressive, persists. About 10 percent die because of their disease.

Glucocorticoids are the most widely used treatment, and methotrexate is second-line medication. Permanent organ derangement is seldom reversed by their use (Paramothayan, 2002). Thus, the decision to treat is based on symptoms, physical findings, chest radiograph, and pulmonary function tests. Unless respiratory symptoms are prominent, therapy is usually withheld for a several-month observation period. If inflammation does not subside, then prednisone, 1 mg/kg, is given daily for 4 to 6 weeks (Baughman, 2012). For those with an inadequate response, cytotoxic agents or cytokine modulators may be indicated.

Sarcoidosis and Pregnancy

Because sarcoidosis is uncommon and is frequently benign, it is not often seen in pregnancy. De
Regt (1987) described 14 cases in 20,000 pregnancies during a 12-year period—almost 1 in 1500. Although sarcoidosis seldom affects pregnancy adversely, serious complications such as meningitis, heart failure, and neurosarcoidosis have been described (Cardonick, 2000; Maisel, 1996; Seballos, 1994).

In general, perinatal outcomes are unaffected by sarcoidosis. Selroos (1990) reviewed 655 patients with sarcoidosis referred to the Mjölbolsta Hospital District in Finland. Of 252 women between 18 and 50 years, 15 percent had sarcoidosis during pregnancy or within 1 year postpartum. There was no evidence for disease progression in the 26 pregnancies in women with active disease. Three aborted spontaneously, and the other 23 women were delivered at term. In 18 pregnancies in 12 women with inactive disease, pregnancy outcomes were good. Agha and coworkers (1982) reported similar experiences with 35 pregnancies at the University of Michigan.

Active sarcoidosis is treated using the same guidelines as for the woman who is not pregnant. Severe disease warrants serial determination of pulmonary function. Symptomatic uveitis, constitutional symptoms, and pulmonary symptoms are treated with prednisone, 1 mg/kg orally per day.

### Cystic Fibrosis

One of the most common fatal genetic disorders in whites, cystic fibrosis is caused by one of more than 1500 mutations in a 230-kb gene on the long arm of chromosome 7 that encodes an amino acid polypeptide (Boucher, 2012). This peptide functions as a chloride channel and is termed the **cystic fibrosis transmembrane conductance regulator (CFTR)**. There is a wide phenotypic variation, even among homozygotes for the common ΔF508 mutation (Rowntree, 2003). This is discussed in greater detail in Chapter 14 (p. 295). Approximately 20 percent of affected individuals are diagnosed shortly after birth because of meconium peritonitis (Boucher, 2012). Currently, nearly 80 percent of females with cystic fibrosis now survive to adulthood, and their median survival is about 30 years (Gillet, 2002).

#### Pathophysiology

Mutations in the chloride channel cause altered epithelial cell membrane transport of electrolytes. This affects all organs that express CFTR—secretory cells, sinuses, lung, pancreas, liver, and reproductive tract. Disease severity depends on which two alleles are inherited, and homozygosity for ΔF508 is one of the most severe (McKone, 2003).

Exocrine gland ductal obstruction develops from thick, viscous secretions (Rowe, 2005). In the lung, submucosal glandular ducts are affected. Eccrine sweat gland abnormalities are the basis for the diagnostic sweat test, characterized by elevated sodium, potassium, and chloride levels in sweat.

Lung involvement is commonplace and is frequently the cause of death. Bronchial gland hypertrophy with mucous plugging and small-airway obstruction leads to subsequent infection that ultimately causes chronic bronchitis and bronchiectasis. For complex and not completely explicable reasons, chronic inflammation from *Pseudomonas aeruginosa* occurs in more than 90 percent of patients. *S aureus, H influenzae*, and *Burkholderia cepacia* are recovered in a minority (Rowe, 2005). Colonization with the last has been reported to signify a worse prognosis, especially in pregnancy (Gillet, 2002). Acute and chronic parenchymal inflammation ultimately
causes extensive fibrosis, and along with airway obstruction, there is a ventilation–perfusion mismatch. Pulmonary insufficiency is the end result. Lung or heart–lung transplantation has a 5-year survival rate of 33 percent (Aurora, 1999). A few women have successfully undergone pregnancy following lung transplantation (Kruszka, 2002; Shaner, 2012).

## Preconceptional Counseling

Women with cystic fibrosis are subfertile because of tenacious cervical mucus. Males have oligospermia or aspermia from vas deferens obstruction, and 98 percent are infertile (Ahmad, 2013). Despite this, the North American Cystic Fibrosis Foundation estimates that 4 percent of affected women become pregnant every year (Edenborough, 1995). The endometrium and tubes express some CFTR but are functionally normal, and the ovaries do not express the CFTR gene (Edenborough, 2001). Both intrauterine insemination and IVF have been used successfully in affected women (Rodgers, 2000). Several ethical considerations of undertaking pregnancy by these women were reviewed by Wexler and colleagues (2007). For male infertility, Sobczyńska-Tomaszewska and associates (2006) have emphasized the importance of molecular diagnosis.

## Screening

The American College of Obstetricians and Gynecologists (2011) recommends that carrier screening be offered to at-risk couples. This is discussed in detail in Chapter 14 (p. 295). The Centers for Disease Control and Prevention also added cystic fibrosis to newborn screening programs (Comeau, 2007). This is discussed also in Chapter 32 (p. 632) and was the subject of a Cochrane Database review (Southern, 2009).

## Pregnancy with Cystic Fibrosis

Pregnancy outcome is inversely related to severity of lung dysfunction. Severe chronic lung disease, hypoxia, and frequent infections may prove deleterious. At least in the past, cor pulmonale was common, but even that does not preclude successful pregnancy (Cameron, 2005). In some women, pancreatic dysfunction may cause poor maternal nutrition. Normal pregnancy-induced insulin resistance frequently results in gestational diabetes after midpregnancy (Hardin, 2005; McMullen, 2006). In one study of 48 pregnancies, half had pancreatic insufficiency and a third required insulin (Thorpe-Beeson, 2013). Diabetes is most frequent with the ΔF508 homozygous mutation (Giacobbe, 2012).

Cystic fibrosis per se is not affected by pregnancy (Schechter, 2013). Early reports of a deleterious effect on the course of cystic fibrosis were related to severe disease (Olson, 1997). An important factor to be considered in childbearing is the long-term prognosis for the mother. When matched with nonpregnant women by disease severity, recent reports indicate no deleterious effects on long-term survival (McMullen, 2006; Schechter, 2013).

## Management

Prepregnancy counseling is imperative. Women who choose to become pregnant should have close surveillance for development of superimposed infection, diabetes, and heart failure. They are followed closely with serial pulmonary function testing, for management as well as for prognosis. When the FEV₁ is at least 70 percent, women usually tolerate pregnancy well. Emphasis is placed on postural drainage, bronchodilator therapy, and infection control.
β-Adrenergic bronchodilators help control airway constriction. Inhaled recombinant human deoxyribonuclease I improves lung function by reducing sputum viscosity (Boucher, 2012). Inhaled 7-percent saline has been shown to produce short- and long-term benefits (Donaldson, 2006; Elkins, 2006). Nutritional status is assessed and appropriate dietary counseling given. Pancreatic insufficiency is treated with replacement of oral pancreatic enzyme.

Infection is heralded by increasing cough and mucus production. Oral semisynthetic penicillins or cephalosporins usually suffice to treat staphylococcal infections. Pseudomonas infection is most problematic in adults. Inhaled tobramycin and colistin have been used successfully to control this organism (Boucher, 2012; Ratjen, 2003).

Immediate hospitalization and aggressive therapy are warranted for serious pulmonary infections. The threshold for hospitalization with other complications is low. For labor and delivery, epidural analgesia is recommended.

**Pregnancy Outcome**

When Cohen and coworkers (1980) conducted the first major survey of cystic fibrosis centers, severity was assessed by the Schwachman-Kulezycki or Taussig scores based on radiological and clinical criteria. Although pregnancy outcomes were not disastrous, 18 percent of 129 women died within 2 years of giving birth. In a later review through 1991, Kent and Farquharson (1993) described similar outcomes in 215 pregnancies in 160 women.

More recent reports describe better outcomes, but there still are serious complications. Disease severity is now quantified by pulmonary function studies, which are the best predictor of pregnancy and long-term maternal outcome. Edenborough and colleagues (2000) reported 69 pregnancies from 11 cystic fibrosis centers in the United Kingdom. If prepregnancy FEV\textsubscript{1} was < 60 percent of predicted, there was substantive risk for preterm delivery, respiratory complications, and death of the mother within a few years of childbirth. Thorpe-Beeson and associates (2013) reported similar findings.

Fitzsimmons and coworkers (1996) performed a case-control study of 258 women with cystic fibrosis who had a live birth. The 889 matched controls were women with cystic fibrosis who had not been pregnant. Pregnancy had no effect on worsening of any serious complications, and 8 percent in both groups had died by 2 years. Gillet and colleagues (2002) reported 75 pregnancies from the French Cystic Fibrosis Registry. Almost 20 percent of infants were delivered preterm and 30 percent had growth restriction. The one maternal death was due to Pseudomonas sepsis in a woman whose prepregnancy FEV\textsubscript{1} was 60 percent. Long-term, however, 17 percent of women died and four infants had confirmed cystic fibrosis. Likewise, in the study by Thorpe-Beeson (2013) cited above, four of eight women whose FEV\textsubscript{1} was < 40 to 50 percent died from 2 to 8 years after delivery.

**Lung Transplantation**

Cystic fibrosis is a common antecedent disease leading to lung transplantation. Gyi and coworkers (2006) reviewed 10 pregnancies in such women and reported nine liveborn infants. Maternal outcomes were less favorable—three developed rejection during pregnancy, and all three had progressively declining pulmonary function and died of chronic rejection by 38 months after delivery.

---

**CARBON MONOXIDE POISONING**
Carbon monoxide is a ubiquitous gas, and most nonsmoking adults have a carbon monoxyhemoglobin saturation of 1 to 3 percent. In cigarette smokers, levels may be as high as 5 to 10 percent. Carbon monoxide is the most frequent cause of poisoning worldwide (Stoller, 2007). Toxic levels are often encountered in inadequately ventilated areas warmed by space heaters.

Carbon monoxide is particularly toxic because it is odorless and tasteless and has a high affinity for hemoglobin binding. Thus, it displaces oxygen and impedes its transfer with resultant hypoxia. Besides acute sequelae including death and anoxic encephalopathy, cognitive defects develop in as many as half of patients following loss of consciousness or in those with carbon monoxide levels > 25 percent (Weaver, 2002). Hypoxic brain damage has a predilection for the cerebral cortex and white matter and for the basal ganglia (Lo, 2007; Prockop, 2007).

### Pregnancy and Carbon Monoxide Poisoning

Through several physiological alterations, the rate of endogenous carbon monoxide production almost doubles in normal pregnancy (Longo, 1977). Although the pregnant woman is not more susceptible to carbon monoxide poisoning, the fetus does not tolerate excessive exposure. With chronic exposure, maternal symptoms usually appear when the carboxyhemoglobin concentration is 5 to 20 percent. Symptoms include headache, weakness, dizziness, physical and visual impairment, palpitations, and nausea and vomiting. With acute exposure, concentrations of 30 to 50 percent produce symptoms of impending cardiovascular collapse. Levels > 50 percent may be fatal for the mother.

Because hemoglobin F has an even higher affinity for carbon monoxide, fetal carboxyhemoglobin levels are 10 to 15 percent higher than those in the mother. This may be due to facilitated diffusion (Longo, 1977). Importantly, the half-life of carboxyhemoglobin is 2 hours in the mother but 7 hours in the fetus. Because carbon monoxide is bound so tightly to hemoglobin F, the fetus may be hypoxic even before maternal carbon monoxide levels are appreciably elevated. Several anomalies are associated with embryonic exposure, and anoxic encephalopathy is the primary sequela of later fetal exposure (Alehan, 2007; Aubard, 2000).

### Treatment

For all victims, treatment of carbon monoxide poisoning is supportive along with immediate administration of 100-percent inspired oxygen. Indications for hyperbaric oxygen treatment in nonpregnant individuals are unclear (Kao, 2005). Weaver and associates (2002) reported that hyperbaric oxygen treatment minimized the incidence of cognitive defects in adults at both 6 weeks and 1 year compared with that with normobaric oxygen. Hyperbaric oxygen is generally recommended in pregnancy if there has been “significant” carbon monoxide exposure (Aubard, 2000; Ernst, 1998). The problem is how to define significant exposure. Although maternal carbon monoxide levels are not accurately predictive of those in the fetus, some clinicians recommend hyperbaric therapy if maternal levels exceed 15 to 20 percent. With fetal heart rate pattern evaluation, Towers and Corcoran (2009) described affected fetuses to have an elevated baseline, diminished variability, and absent accelerations and decelerations. Treatment of the affected newborn with hyperbaric oxygen is also controversial (Bar, 2007).

Elkharrat and colleagues (1991) reported successful hyperbaric treatments in 44 pregnant women. Silverman and Montano (1997) reported successful management of a woman whose
abnormal neurological and cardiopulmonary findings abated in a parallel fashion with resolution of associated fetal heart rate variable decelerations. Greingor and coworkers (2001) used 2.5-atm hyperbaric 100-percent oxygen for 90 minutes in a 21-week pregnant woman who was delivered of a healthy infant at term. According to the Divers Alert Network—DAN (2013)—at Duke University, there are 700 chambers in North and Central America and the Caribbean. Consultation from DAN is available at 919-684-9111.

The risk of venous thrombosis and pulmonary embolism in otherwise healthy women is considered highest during pregnancy and the puerperium. Indeed, in a recent study from the United Kingdom of nearly 1 million reproductive-aged women, the risks of venous thromboembolism for those during the third trimester and the first 6 weeks postpartum were calculated to be six and 22 times higher, respectively, than for nonpregnant women (Sultan, 2011). The incidence of all thromboembolic events averages approximately 1 per 1000 pregnancies, and about an equal number are identified antepartum and in the puerperium. In a study from Norway of more than 600,000 pregnancies, Jacobsen and colleagues (2008) reported that deep-vein thrombosis alone was more frequent antepartum, whereas pulmonary embolism was more common in the first 6 weeks postpartum.

Venous thromboembolism frequency during the puerperium has decreased remarkably as early ambulation has become more widely practiced. Even so, the thromboembolism rate has increased significantly during the past two decades (Callaghan, 2012). Although this increase may reflect the higher sensitivities of newer diagnostic modalities, pulmonary embolism still remains a leading cause of maternal death in the United States (Table 1-3, p. 6) (O’Connor, 2011). Specifically, Berg and associates (2010) reported that approximately 10 percent of pregnancy-related maternal deaths in the United States between 1998 and 2005 were caused by thrombotic pulmonary embolism.
Rudolf Virchow (1856) postulated that stasis, local trauma to the vessel wall, and hypercoagulability predisposed to venous thrombosis development. The risk for each of these increases during normal pregnancy. For example, compression of the pelvic veins and inferior vena cava by the enlarging uterus renders the lower extremity venous system particularly vulnerable to stasis. From their review, Marik and Plante (2008) cite a 50-percent reduction in venous flow velocity in the legs that lasts from the early third trimester until 6 weeks postpartum. This stasis is the most constant predisposing risk factor for venous thrombosis. Venous stasis and delivery may also contribute to endothelial cell injury. Last, as listed in the Appendix (p. 1288), marked increases in the synthesis of most clotting factors during pregnancy favor coagulation.

Risk factors for developing thromboembolism during pregnancy are shown in Table 52-1. The most important of these is a personal history of thrombosis. Indeed, 15 to 25 percent of all venous thromboembolism cases during pregnancy are recurrent events (American College of Obstetricians and Gynecologists, 2011). The magnitude of other risk factors was estimated by James and coworkers (2006) using data from the Agency for Healthcare Research and Quality of all hospital discharges during 2000 and 2001. They identified the diagnosis of venous thromboembolism in 7177 women during pregnancy and 7158 during the postpartum period. Calculated risks for thromboembolism were approximately doubled in women with multifetal gestation, anemia, hyperemesis, hemorrhage, and cesarean delivery. The risk was even greater in pregnancies complicated by postpartum infection. In a more recent nested case-control study of nearly 100,000 women with 10-year follow-up, Waldman and colleagues (2013) found that the risk of venous thromboembolism was slightly higher in women with advanced maternal age and approximately doubled in women with great parity, a hypertensive disorder, cesarean delivery, or obesity. Risks were significantly greater among women who had a stillbirth or who underwent peripartum hysterectomy. At Parkland Hospital, the risk of postpartum thromboembolism most recently is approximately 1 in 5350 deliveries, with all of these risk factors confirmed.

<sup>a</sup> Risk factors include multifetal gestation, anemia, hyperemesis, hemorrhage, and cesarean delivery.
The likelihood of developing a thrombosis during pregnancy is especially increased in women with certain genetic risk factors. Indeed—and likely related—after personal history of thrombosis, the next most important individual risk factor is thrombophilia. An estimated 20 to 50 percent of women who develop a venous thrombosis during pregnancy or postpartum have an identifiable underlying genetic disorder (American College of Obstetricians and Gynecologists, 2011).

### THROMBOPHILIAS

Several important regulatory proteins act as inhibitors in the coagulation cascade. Normal values...
for many of these proteins during pregnancy are found in the Appendix (p. 1288). Inherited or acquired deficiencies of these inhibitory proteins are collectively referred to as *thrombophilias*. These can lead to hypercoagulability and recurrent venous thromboembolism. Although these disorders are collectively present in about 15 percent of white European populations, they are responsible for approximately 50 percent of all thromboembolic events during pregnancy (Lockwood, 2002; Pierangeli, 2011). Some aspects of the more common inherited thrombophilias are summarized in Table 52-2 and Figure 52-1.

FIGURE 52-1 Overview of the inherited thrombophilias and their effect(s) on the coagulation cascade. (Adapted from Seligsohn, 2001.)
Inherited Thrombophilias

Patients with inherited thrombophilic disorders often have a family history of thrombosis. Inherited thrombophilias are also found in up to half of all patients who present with venous thromboembolism before the age of 45 years, particularly in those whose event occurred in the absence of well-recognized risk factors, such as surgery or immobilization, or with minimal provocation such as after a long-distance flight or after taking estrogens. Of greatest significance is a family history of sudden death due to pulmonary embolism or a history of multiple family members requiring long-term anticoagulation therapy because of recurrent thrombosis (Anderson, 2011).

Antithrombin Deficiency

Antithrombin is synthesized in the liver and is one of the most important inhibitors of thrombin in clot formation. Antithrombin functions as a natural anticoagulant by binding and inactivating thrombin and the activated coagulation factors IXa, Xa, XIa, and XIIa (Franchini, 2006). Of note, the rate of antithrombin interaction with its target proteases is accelerated by heparin (Anderson, 2011). Antithrombin deficiency may result from hundreds of different mutations that are almost always autosomal dominant. Type I deficiency is the result of reduced synthesis of biologically normal antithrombin, and type II deficiency is characterized by normal levels of antithrombin with reduced functional activity (Anderson, 2011). Homozygous antithrombin deficiency is lethal (Katz, 2002).

Antithrombin deficiency is rare—it affects approximately 1 in 2000 to 5000 individuals, and it is the most thrombogenic of the heritable coagulopathies. Indeed, the thrombosis risk during pregnancy among antithrombin-deficient women without a personal or family history is 3 to 7 percent, and it is 11 to 40 percent with such a history (Lockwood, 2012). Specifically, those affected have approximately a 50-percent lifetime risk of venous thromboembolism.

Sabadell and associates (2010) studied the outcomes of 18 pregnancies complicated by antithrombin deficiency. Twelve of these were treated with low-molecular-weight heparin, and six were not treated because antithrombin deficiency had not yet been diagnosed. Three of the untreated patients suffered a thromboembolic episode compared with none in the treated group. Untreated women also had a 50-percent risk of stillbirth and fetal-growth restriction. By comparison, none of the treated women had a stillbirth, and approximately a fourth developed fetal-growth restriction. Seguin and coworkers (1994) reviewed the outcomes of 23 newborns with antithrombin deficiency and described 11 cases of thrombosis and 10 deaths.

Given such risk, affected women are treated during pregnancy with heparin regardless of whether they have had a prior thrombosis. When anticoagulation is necessarily withheld, such as during surgery or delivery, Paidas and colleagues (2013) found that treatment with recombinant human antithrombin protected against venous thromboembolism development in 21 patients with hereditary antithrombin deficiency. Sharpe and associates (2011) described successful use of antithrombin concentrate infusions plus therapeutic anticoagulation in a pregnant woman with antithrombin deficiency who developed a thrombosis during the third trimester despite therapeutic doses of low-molecular-weight heparin.

Protein C Deficiency

When thrombin is bound to thrombomodulin on endothelial cells of small vessels, its procoagulant activities are neutralized. This binding also activates protein C, a natural anticoagulant that in the presence of protein S controls thrombin generation, in part, by inactivating factors Va and VIIIa (see Fig. 52-1). Activated protein C also inhibits the synthesis of plasminogen-activator inhibitor 1
Protein C activity is largely unchanged in pregnancy (Appendix, p. 1288). Based on their study of 440 healthy women, however, Said and associates (2010b) found that protein C activity increases modestly but significantly throughout the first half of pregnancy. These investigators speculated that this increase may play a role in maintaining early pregnancy through both anticoagulant and inflammatory regulatory pathways.

More than 100 different autosomal dominant mutations for the protein C gene have been described. The prevalence of protein C deficiency is 2 to 3 per 1000, but many of these individuals do not have a thrombosis history because the phenotypic expression is highly variable (Anderson, 2011). These prevalence estimates correspond with functional activity threshold values of 50 to 60 percent, which are used by most laboratories and which are associated with a six- to 12-fold increased risk for venous thromboembolism (Lockwood, 2012).

Protein S Deficiency
This circulating anticoagulant is activated by protein C, which enhances its capacity to inactivate factors Va and VIIIa (see Fig. 52-1). Protein S deficiency may be caused by more than 100 different mutations, with an aggregate prevalence of approximately 2 per 1000 (Lockwood, 2012). Protein S deficiency may be measured by antigenically determined free, functional, and total S levels. All three decline substantively during normal gestation, thus the diagnosis in pregnant women—as well as in those taking certain oral contraceptives—is difficult (Archer, 1999). If screening during pregnancy is necessary, threshold values for free protein S antigen levels in the second and third trimesters have been identified at less than 30 percent and less than 24 percent, respectively. Among those with a positive family history, the venous thromboembolism risk in pregnancy has been reported to be 6 to 7 percent (American College of Obstetricians and Gynecologists, 2013).

Conard and coworkers (1990) described thrombosis in 5 of 29 pregnant women with protein S deficiency. One woman had a cerebral vein thrombosis. Similarly, Burneo and colleagues (2002) reported maternal cerebral vein thrombosis at 14 weeks’ gestation. Neonatal homozygous protein C or S deficiency is usually associated with a severe clinical phenotype known as purpura fulminans. This is characterized by extensive thromboses in the microcirculation soon after birth leading to skin necrosis (Salonvaara, 2004).

Activated Protein C Resistance—Factor V Leiden Mutation
The most prevalent of the known thrombophilia syndromes, this condition is characterized by resistance of plasma to the anticoagulant effects of activated protein C. A number of mutations have been described, but the most common is the factor V Leiden mutation, which was named after the city in which it was described. This missense mutation in the factor V gene results from a substitution of glutamine for arginine at position 506 in the factor V polypeptide, which gains resistance to degradation by activated protein C. The unimpeded abnormal factor V protein retains its procoagulant activity and predisposes to thrombosis (see Fig. 52-1).

Heterozygous inheritance for factor V Leiden is the most common heritable thrombophilia. It is found in 3 to 15 percent of select European populations and 3 percent of African Americans, but it is virtually absent in African blacks and Asians (Lockwood, 2012). As shown in Table 52-2, women who are heterozygous for factor V Leiden account for approximately 40 percent of venous thromboembolism cases during pregnancy. However, the actual risk among pregnant women who are heterozygous and who do not have a personal history or a first-degree relative with a
thrombotic episode before age 50 years is 5 to 12 per 1000. In contrast, this risk increases to at least 10 percent among women with a personal or family history. Pregnant women who are homozygous without a personal or family history have a 1- to 4-percent risk for venous thromboembolism, whereas those with such a history have an approximately 17-percent risk (American College of Obstetricians and Gynecologists, 2013).

As described later (p. 1034), diagnosis during pregnancy is performed by DNA analysis for the mutant factor V gene. This is because bioassay is confounded by the fact that resistance is normally increased after early pregnancy because of alterations in other coagulation proteins (Walker, 1997). Of note, activated protein C resistance can also be caused by antiphospholipid syndrome, which is described later (p. 1033) and also detailed in Chapter 59 (p. 1173) (Eldor, 2001; Saenz, 2011).

To assess the prognostic significance of maternal factor V Leiden mutation during pregnancy, Kjellberg and colleagues (2010) compared the outcomes of 491 carriers with 1055 controls. All three of the thromboembolic events occurred among the carriers. But, there were no differences in preterm birth, birthweight, or hypertensive complications between the two groups. Similarly, Hammerová and coworkers (2011) found that adverse pregnancy events were not increased among women with heterozygous mutations. In a meticulously executed prospective observational study of approximately 5000 women conducted by the Maternal-Fetal Medicine Units Network, Dizon-Townson and associates (2005) found that the heterozygous mutant gene incidence was 2.7 percent. Of three pulmonary emboli and one deep-vein thrombosis cases—a rate of 0.8 per 1000 pregnancies—none were among these carriers. There was no increased risk of preeclampsia, placental abruption, fetal-growth restriction, or pregnancy loss in heterozygous women. The investigators concluded that universal prenatal screening for the Leiden mutation and prophylaxis for carriers without a prior venous thromboembolism is not indicated. Finally, Clark and colleagues (2002) concluded that such routine prenatal screening was not cost effective.

**Prothrombin G20210A Mutation**

This missense mutation in the prothrombin gene leads to excessive accumulation of prothrombin, which then may be converted to thrombin. As with factor V Leiden, a personal history or a family history of venous thromboembolism in a first-degree relative before age 50 years increases the risk of venous thromboembolism during pregnancy (see Table 52-2). For a heterozygous carrier with such a history, the risk exceeds 10 percent. Without such a history, heterozygous carriers of the mutation have less than a 1-percent risk of venous thromboembolism during pregnancy (American College of Obstetricians and Gynecologists, 2013).

Homozygous patients or those who coinherit a G20210A mutation with a factor V Leiden mutation have an even greater thromboembolism risk. Stefano and associates (1999) performed a retrospective cohort study of 624 nonpregnant patients with one prior episode of deep-vein thrombosis. They found that those doubly heterozygous individuals had a 2.6-fold increased risk of recurrence relative to those with the heterozygous Leiden mutation alone. They concluded that carriers with both mutations are candidates for lifelong anticoagulation after a first thrombotic episode.

In a secondary analysis of the Maternal-Fetal Medicine Units Network study described earlier Silver and coworkers (2010) tested nearly 4200 women for the prothrombin G20210A mutation. A total of 157—or 3.8 percent—of the women carried the mutation, and only one of these was homozygous. Carriers had similar rates of pregnancy loss, preeclampsia, growth restriction, and placental abruption compared with noncarriers. The three thromboembolic events occurred in women who tested negative for the mutation.
Hyperhomocysteinemia

The most common cause of elevated homocysteine is the C667T thermolabile mutation of the enzyme 5, 10-methylene-tetrahydrofolate reductase (MTHFR). Inheritance is autosomal recessive. Elevated homocysteine levels may also result from deficiency of one of several enzymes involved in methionine metabolism and from correctible nutritional deficiencies of folie acid, vitamin B₆, or vitamin B₁₂ (Hague, 2003; McDonald, 2001). During normal pregnancy, mean homocysteine plasma concentrations are decreased (López-Quesada, 2003; McDonald, 2001). Thus, to make a diagnosis during pregnancy, Lockwood (2002) recommends a fasting threshold of > 12 μmol/L to define hyperhomocysteinemia.

Although hyperhomocysteinemia was previously reported to be a modest risk factor for venous thromboembolism, more recent data indicate that an elevated homocysteine level is actually a weak risk factor (American College of Obstetricians and Gynecologists, 2013). In an interesting metaanalysis, den Heijer and colleagues (2005) found that international studies of MTHFR polymorphisms were collectively associated with slightly increased significant risks for thrombosis—odds ratios 1.15 to 1.6. In contrast, studies conducted in North America collectively demonstrated no such association. The authors speculated that folic acid supplementation could explain the difference. Recall that folic acid serves as a cofactor in the remethylation reaction of homocysteine to methionine. Similarly, the American College of Chest Physicians concluded that the lack of an association with thromboembolism could reflect the physiological reductions in homocysteine levels associated with pregnancy and the effects of widespread prenatal folic acid supplementation (Bates, 2012).

In a follow-up study of 167 women who developed a venous thromboembolism during pregnancy and 128 controls, Kovac and associates (2010) found no difference in the prevalence of MTHFR C677T homozygosity between the two groups. The American College of Obstetrician and Gynecologists (2013) has concluded that there is insufficient evidence to support assessment of MTHFR polymorphisms or measurement of fasting homocysteine levels in the evaluation for venous thromboembolism.

Other Thrombophilia Mutations

A number of potentially thrombophilic polymorphisms are being discovered at an ever-increasing rate. Unfortunately, information regarding the prognostic significance of such newly discovered mutations is limited. For example, protein Z is a vitamin K-dependent protein that serves as a cofactor in factor Xa inactivation. Studies in nonpregnant patients have found that low protein Z levels are associated with an increased thromboembolism risk (Santacroce, 2006). Similarly, plasminogen activator inhibitor type 1 (PAI-1) is an important regulator of fibrinolysis. Certain polymorphisms in the gene promoter have been associated with small increased venous thromboembolism risks. These thrombophilias and others, including alternative mutations in the factor V gene and activity-enhancing mutations in various clotting factor genes, appear to exert little independent risk for venous thromboembolism. And although they may exacerbate risk among patients when coinherited with other thrombophilias, the American College of Obstetricians and Gynecologists (2013) has concluded that there is insufficient evidence to recommend screening.

As an interesting aside, Galanaud and coworkers (2010) hypothesized that a paternal thrombophilia could increase the risk of a maternal thromboembolism. Specifically, these investigators found that a paternal thrombophilia—the PROCR 6936G allele—affects the endothelial protein C receptor. This receptor is expressed by villous trophoblast and thus is exposed to maternal blood. Although this research is preliminary, it could help explain the
Acquired Thrombophilias

Some examples of acquired hypercoagulable states include antiphospholipid syndrome (Chap. 59, p. 1173), heparin-induced thrombocytopenia (p. 1040), and cancer (Chap. 63, p. 1219).

Antiphospholipid Antibodies

These autoantibodies are detected in approximately 2 percent of patients who have nontraumatic venous thrombosis. The antibodies are directed against cardiolipin(s) or against phospholipid-binding proteins such as β2-glycoprotein I. They are commonly—but not always—found in patients with systemic lupus erythematosus and are described in detail in Chapter 59 (p. 1169). Women with moderate-to-high levels of these antibodies may have antiphospholipid syndrome, which, as summarized by the American College of Obstetricians and Gynecologists (2012), is defined by a number of clinical features. In addition to vascular thromboses, these include: (1) at least one otherwise unexplained fetal death at or beyond 10 weeks; (2) at least one preterm birth before 34 weeks because of eclampsia, severe preeclampsia, or placental insufficiency; or (3) at least three unexplained consecutive spontaneous abortions before 10 weeks.

In these women, thromboembolism—either venous or arterial—most commonly involves the lower extremities. Importantly, the syndrome should also be considered in women with thromboses in unusual sites, such as the portal, mesenteric, splenic, subclavian, axillary, and cerebral veins. Antiphospholipid antibodies predispose to arterial thromboses, which may also occur in relatively unusual locations, such as the retinal, subclavian, brachial, or digital arteries. The thrombotic mechanisms associated with antiphospholipid syndrome have recently been reviewed by Giannakopoulos and Krilis (2013).

The thrombosis risk increases significantly during pregnancy in women with antiphospholipid syndrome. Indeed, up to 25 percent of thrombotic events in women with antiphospholipid syndrome occur during pregnancy or in the puerperium. Looking at this a different way, women with antiphospholipid syndrome have a 5- to 12-percent risk of thrombosis during pregnancy or the puerperium (American College of Obstetricians and Gynecologists, 2012).

Thrombophilias and Pregnancy Complications

Attention has been directed toward possible relationships between inherited thrombophilias and pregnancy complications other than thromboses. Summarized in Table 52-3 are the findings of 25 studies systematically reviewed by Robertson and associates (2005). These were incorporated into the most recent recommendations of the American College of Chest Physicians (Bates, 2012). Importantly, the considerable heterogeneity and wide confidence intervals illustrate the uncertainty of these associations.

More recent investigations continue to underscore the heterogeneity of results. For example, Kahn and coworkers (2009) found no increased risk for early-onset or severe preeclampsia in women with factor V Leiden mutation, prothrombin G20210A mutation, MTHFR C677T polymorphism, or hyperhomocysteinemia. Said and associates (2010a) prospectively screened more than 2000 healthy nulliparous women for factor V Leiden, prothrombin gene mutation, MTHFR C677T, MTHFR A1298C, and thrombomodulin polymorphism. Women who carried the prothrombin gene mutation had a 3.6-fold increased risk of adverse pregnancy outcome, including severe preeclampsia, fetal-growth restriction, placental abruption, or stillbirth. But, none of the other polymorphisms conferred an increased risk of these adverse outcomes. Moreover, this group of investigators found no association between the PAI-1 4G/5G polymorphism and adverse pregnancy outcome (Said, 2012). Similarly, based on their prospective study of 750 pregnancies complicated by stillbirth, Korteweg and colleagues (2010) concluded that routine thrombophilia testing after fetal death is inadvisable.

Because of uncertainties associated with the magnitude of risk as well as any benefits of prophylaxis given to prevent pregnancy complications in women with heritable thrombophilias, it remains unproven that screening is in the best interest of these women. The American College of Obstetricians and Gynecologists (2013) has concluded that a definitive causal link cannot be made between inherited thrombophilias and adverse pregnancy outcomes. Similarly, the American College of Chest Physicians recently concluded that it was unclear whether screening for inherited thrombophilias is prudent in women with pregnancy complications (Bates, 2012). In contrast, and as shown in Table 52-3 and detailed in Chapter 59 (p. 1174), the association between antiphospholipid syndrome and adverse pregnancy outcomes—including fetal loss, recurrent pregnancy loss, and preeclampsia—is much stronger.
Given the high incidence of thrombophilia in the population and the low incidence of venous thromboembolism, universal screening during pregnancy is not cost effective (Carbone, 2010). Thus, a selective screening strategy is required. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that thrombophilia screening be considered in the following clinical circumstances: (1) a personal history of venous thromboembolism that was associated with a nonrecurrent risk factor such as fractures, surgery, and/or prolonged immobilization; and (2) a first-degree relative (parent or sibling) with a history of high-risk thrombophilia or venous thromboembolism before age 50 years in the absence of other risk factors.

As described earlier, the American College of Obstetricians and Gynecologists (2013) has concluded that testing for inherited thrombophilias in women who have experienced recurrent fetal loss or placental abruption is not recommended because there is insufficient clinical evidence that antepartum heparin prophylaxis prevents recurrence. Similarly, testing is not recommended for women with a history of fetal-growth restriction or preeclampsia. The American College of Chest Physicians also recommends against screening women with prior pregnancy complications (Bates, 2012). As discussed in Chapter 59, however, screening for antiphospholipid antibodies may be appropriate in women who have experienced a fetal loss.

### Screening Tests

Methods of screening for the more common inherited thrombophilias are shown in Table 52-4. Whenever possible, laboratory testing should be performed at least 6 weeks after the thrombotic event, while the patient is not pregnant, and when she is not receiving anticoagulation or hormonal therapy. Because of the lack of association between methylenetetrahydrofolate reductase (MTHFR) gene mutations—the most common cause of hyperhomocysteinemia—and adverse pregnancy outcomes, screening with fasting homocysteine levels or MTHFR mutation analyses is not recommended (American College of Obstetricians and Gynecologists, 2013).

\(^a\)In nonpregnant patients, protein S deficiency should be assessed initially by performing a functional assay. A value < 55 percent should be followed with measurement of free protein S levels. A free protein S antigen value < 55 percent is consistent with protein S deficiency. If screening in pregnancy is necessary, threshold values for free protein S antigen levels in the second and third trimesters have been identified at < 30 percent and < 24 percent, respectively. Adapted from the American College of Obstetricians and Gynecologists, 2013.

### DEEP-VEIN THROMBOSIS

#### Clinical Presentation

During pregnancy, most venous thromboses are confined to the deep veins of the lower extremity. Approximately 70 percent of cases are located in the iliofemoral veins without involvement of the calf veins. Isolated iliac vein and calf vein thromboses occur in approximately 17 and 6 percent of cases, respectively (Chan, 2010).

The signs and symptoms vary greatly and depend on the degree of occlusion and the intensity of the inflammatory response. Most cases during pregnancy are left sided. Ginsberg and coworkers (1992) reported that 58 of 60 antepartum women—97 percent—had left leg thromboses. Blanco-Molina and coworkers (2007) reported left-leg involvement in 78 percent. Our experiences at Parkland Hospital are similar—approximately 90 percent of lower extremity thromboses involved the left leg. Greer (2003) hypothesizes that this results from compression of the left iliac vein by the right iliac and ovarian artery, both of which cross the vein only on the left side. Yet, as described in Chapter 53 (p. 1051), the ureter is compressed more on the right side!

Classic thrombosis involving the lower extremity is abrupt in onset, and there is pain and edema of the leg and thigh. The thrombus typically involves much of the deep-venous system to the iliofemoral region. Occasionally, reflex arterial spasm causes a pale, cool extremity with diminished pulsations. Conversely, there may be appreciable clot, yet little pain, heat, or swelling. Importantly, calf pain, either spontaneous or in response to squeezing or to Achilles tendon stretching—*Homans sign*—may be caused by a strained muscle or contusion. Between 30 and 60 percent of women with a confirmed lower-extremity acute deep-vein thrombosis have an asymptomatic pulmonary embolism (p. 1041).
Clinical diagnosis of deep-vein thrombosis is difficult, and thus other methods are imperative for confirmation. In one study of pregnant women, the clinical diagnosis was confirmed in only 10 percent (Hull, 1990). Shown in Figure 52-2 is one diagnostic algorithm recommended by the American College of Chest Physicians that can be used for evaluation of pregnant women (Guyatt 2012). With a few modifications, we follow a similar evaluation at Parkland Hospital.

**FIGURE 52-2** Algorithm for evaluation of suspected deep-vein thrombosis in pregnancy. CT = computed tomography; MR = magnetic resonance. (Adapted from the American College of Chest Physicians, Guyatt, 2012.) aSigns and symptoms include swelling of the entire leg, with or without flank, buttock, or back pain.

**Compression Ultrasonography**
In pregnant women with suspected deep-vein thrombosis, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend compression ultrasonography of the proximal veins as the initial diagnostic test. According to the American College of Chest Physicians, this noninvasive technique is currently the most-used first-line test to detect deep-vein thrombosis (Guyatt, 2012). The diagnosis is based on the noncompressibility and typical echoarchitecture of a thrombosed vein.

For nonpregnant patients with suspected thrombosis, the safety of withholding anticoagulation has been established for those who have normal serial compression examinations over a week (Birdwell, 1998; Heijboer, 1993). Specifically, isolated calf thromboses that extend into the proximal veins in about a fourth of patients will do so within 1 to 2 weeks of presentation. Moreover, these are usually detected by serial ultrasonographic compression.
