NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Faculty Associate, Department of Obstetrics and Gynecology
University of Texas Southwestern Medical Center at Dallas
These are trying times for academic medicine. They are especially vexing for departments of obstetrics and gynecology. Combined with draconian funding shortages, there is burdensome oversight with sometimes meaningless regulations as well as myriad forms and paperwork foisted upon us by an ever-increasing but already bloated bureaucracy. Despite these seemingly overwhelming challenges, the chairs of academic departments and the directors of residency training programs resiliently continue to emphasize the basics that are fundamental to academic training. It is to these stalwart individuals that we dedicate this 24th edition of Williams Obstetrics.
CONTENTS

Preface
Acknowledgments

SECTION 1

OVERVIEW

1. Overview of Obstetrics

SECTION 2

MATERNAL ANATOMY AND PHYSIOLOGY

2. Maternal Anatomy
3. Congenital Genitourinary Abnormalities
4. Maternal Physiology

SECTION 3

PLACENTATION, EMBRYOGENESIS, AND FETAL DEVELOPMENT

5. Implantation and Placental Development
6. Placental Abnormalities
7. Embryogenesis and Fetal Morphological Development
SECTION 4
PRECONCEPTIONAL AND PRENATAL CARE

8. Preconceptional Counseling
9. Prenatal Care

SECTION 5
THE FETAL PATIENT

10. Fetal Imaging
11. Amnionic Fluid
12. Teratology, Teratogens, and Fetotoxic Agents
13. Genetics
14. Prenatal Diagnosis
15. Fetal Disorders
16. Fetal Therapy
17. Fetal Assessment

SECTION 6
EARLY PREGNANCY COMPLICATIONS

18. Abortion
19. Ectopic Pregnancy
20. Gestational Trophoblastic Disease
SECTION 7

LABOR

21. Physiology of Labor
22. Normal Labor
23. Abnormal Labor
24. Intrapartum Assessment
25. Obstetrical Analgesia and Anesthesia
26. Induction and Augmentation of Labor

SECTION 8

DELIVERY

27. Vaginal Delivery
28. Breech Delivery
29. Operative Vaginal Delivery
30. Cesarean Delivery and Peripartum Hysterectomy
31. Prior Cesarean Delivery

SECTION 9

THE NEWBORN

32. The Newborn
33. Diseases and Injuries of the Term Newborn
34. The Preterm Newborn
SECTION 10
THE PUEPERIUM

36. The Puerperium
37. Puerperal Complications
38. Contraception
39. Sterilization

SECTION 11
OBSTETRICAL COMPLICATIONS

40. Hypertensive Disorders
41. Obstetrical Hemorrhage
42. Preterm Labor
43. Postterm Pregnancy
44. Fetal-Growth Disorders
45. Multifetal Pregnancy

SECTION 12
MEDICAL AND SURGICAL COMPLICATIONS

46. General Considerations and Maternal Evaluation
47. Critical Care and Trauma
48. Obesity
49. Cardiovascular Disorders
50. Chronic Hypertension
51. Pulmonary Disorders
52. Thromboembolic Disorders
53. Renal and Urinary Tract Disorders
54. Gastrointestinal Disorders
55. Hepatic, Biliary, and Pancreatic Disorders
56. Hematological Disorders
57. Diabetes Mellitus
58. Endocrine Disorders
59. Connective-Tissue Disorders
60. Neurological Disorders
61. Psychiatric Disorders
62. Dermatological Disorders
63. Neoplastic Disorders
64. Infectious Diseases
65. Sexually Transmitted Infections

APPENDIX

Serum and Blood Constituents
Maternal Echocardiographic Measurements
Fetal Sonographic Measurements
This 24th edition of *Williams Obstetrics* has been extensively and strategically reorganized. Primarily writing for the busy practitioner—those “in the trenches”—we continue to present the detailed staples of basic obstetrics such as maternal anatomy and physiology, preconceptional and prenatal care, labor, delivery, and the puerperium, along with detailed discussions of obstetrical complications exemplified by preterm labor, hemorrhage, hypertension, and many more. Once again, we emphasize the scientific-based underpinnings of clinical obstetrics with special emphasis on biochemical and physiological principles of female reproduction. And, as was the hallmark of previous editions, these dovetail with descriptions of evidence-based practices. The reorganized format allows a greater emphasis on the fetus as a patient along with expanded coverage of fetal diagnosis and therapy. These changes are complemented by more than 100 new sonographic and magnetic resonance images that display normal fetal anatomy and common fetal anomalies. Finally, to emphasize the “M” in maternal–fetal medicine, we continue to iterate the myriad medical and surgical disorders that can complicate pregnancy.

To accomplish these goals, the text has been updated with more than 3000 new literature citations through 2014. Moreover, there are nearly 900 figures that include sonograms, MR images, photographs, micrographs, and data graphs, most in vivid color. Much of the original artwork was rendered by our own medical illustrators.

In this edition, as before, we continue to incorporate contemporaneous guidelines from professional and academic organizations such as the American College of Obstetricians and Gynecologists, the Society for Maternal–Fetal Medicine, the National Institutes of Health, and the Centers for Disease Control and Prevention, among others. Many of these data are distilled into almost 100 newly constructed tables, in which information has been arranged in a format that is easy to read and use. In addition, several diagnostic and management algorithms have been added to guide practitioners. While we strive to cite numerous sources to provide multiple evidence-based options for such management schemes, we also include our own clinical experiences drawn from a large obstetrical service. As usual, while we are convinced that these are disciplined examples of evidence-based obstetrics, we quickly acknowledge that they do not constitute the sole method of management.

This 24th edition shows a notable absence of four colleagues who provided valuable editorial assistance for prior volumes of *Williams Obstetrics*. From the University of Alabama at Birmingham, Dr. John Hauth, who served as an editor for the 21st through 23rd editions, has now directed his efforts to research endeavors. Dr. Dwight Rouse, an associate editor of the 22nd and an editor of the 23rd edition, has assumed a clinical and research role at Brown University. We will certainly miss their insightful wisdom concerning the vicissitudes of randomized controlled trials and their true meanings! Colleagues leaving us from the University of Texas Southwestern Medical Center include Dr. George Wendel, Jr.—associate editor for the 22nd and 23rd editions—who has now assumed the important role of overseeing development of Maintenance of Certification for the American Board of Obstetrics and Gynecology. And leaving for practice in Montana is Dr. Jim Alexander, who served as a contributing editor for the 23rd edition. These talented clinicians provided valuable knowledge, both evidence-based and from the bedside.
To fill the shoes of these departing stalwart colleagues, we have enlisted four new editors—all from UT Southwestern Medical Center—each of whom has expertise in important areas of contemporaneous obstetrics and maternal–fetal medicine. Dr. Jodi Dashe—who contributed extensively to the 21st through 23rd editions—joins us as editor and brings her extensive experiences and incredible skills with obstetrical sonography, fetal diagnosis, and prenatal genetics. Dr. Barbara Hoffman brings widespread clinical knowledge regarding general obstetrics and contraception as well as embryology, anatomy, and placental pathology. Dr. Brian Casey adds his in-depth obstetrical and research experience, with special interests in diabetes, fetal-growth disorders, and thyroid physiology. Dr. Jeanne Sheffield joins us with her knowledge and clinical acumen and research interests in maternal medical disorders, critical care, and obstetrical and perinatal infections.

There are also two returning associate editors who continue to add considerable depth to this textbook. Dr. Diane Twickler uses her fantastic experiences and knowledge regarding clinical and technological advances related to fetal and maternal imaging with ultrasonography as well as with x-ray and magnetic resonance techniques. Dr. Mala Mahendroo is a talented basic scientist who continues to perform a magnificent job of providing a coherent translational version of basic science aspects of human reproduction. Finally, four new contributing editors round out the editorial team that make this book possible. Drs. Kevin Worley and Seth Hawkins bring additional strengths to the areas of clinical and academic maternal–fetal medicine. Dr. Don McIntire provided much of the data garnered from the extensive database that chronicles the large obstetrical service at Parkland Hospital and UT Southwestern Medical Center. Mr. Lewis Calver continues to do an impeccable job of supervising and rendering new artwork for this and prior editions. In toto, the strength of each contributor has added to create the sum total of our academic endeavor.

F. Gary Cunningham
Kenneth J. Leveno
Steven L. Bloom
During the creation and production of this textbook, we were fortunate to have the assistance and support of countless talented professionals both within and outside the Department of Obstetrics and Gynecology. To begin, we acknowledge that an undertaking of this magnitude would not be possible without the unwavering support provided by Dr. Barry Schwarz, whose financial and academic endorsement has been essential.

In constructing such an expansive academic compilation, the expertise of many colleagues was needed to add vital and contemporaneous information. It was indeed fortuitous for us to have access to a pantheon of contributors here as well as from other academic medical centers. From the University of Texas Southwestern Medical Center, Dr. April Bailey of the Departments of Radiology and Obstetrics and Gynecology added insights and provided illustrative maternal and fetal magnetic resonance images. These were further complimented by other visual contributions from Drs. Elysa Moschos, Michael Landay, Jeffrey Pruitt, and Douglas Sims. From the Department of Pathology, Drs. Kelley Carrick and Brian Levenson generously donated exemplary photomicrographs. From the Department of Dermatology, Dr. Amit Pandya provided a number of classic figures. From the Division of Urogynecology, our nationally known pelvic anatomist, Dr. Marlene Corton, prepared graphic masterpieces for the anatomy chapter. Drs. Claudia Werner and William Griffith lent valuable insight into the management of cervical dysplasia. Much of the Appendix of this textbook was originally compiled by Drs. Mina Abbassi-Ghanavati and Laura Greer. Finally, clinical photographs were contributed by many current and former faculty and fellows, including Drs. Patricia Santiago-Muñoz, Julie Lo, Lisa Halvorson, Kevin Doody, Michael Zaretsky, Judith Head, David Rogers, Sunil Balgobin, Manisha Sharma, Michael Hnat, Rigobert Santos-Ramos, Shayzreen Roshanravan, April Bleich, and Roxane Holt.

Several contributions were made by our national and international colleagues. Experts in placental pathology who shared their expertise and images include Drs. Kurt Benirschke, Ona Marie Faye-Petersen, Mandolin Ziadie, Michael Conner, Jaya George, and Erika Fong. Input for hypertensive disorders was provided by Drs. Marshall Lindheimer and Gerda Zeeman and for operative vaginal delivery by Dr. Edward Yeomans. Seminal images were contributed by Drs. Timothy Crombleholme, Togas Tulandi, Edward Lammer, Charles Read, and Frederick Elder.

In addition to these contributors, we relied heavily on numerous other colleagues and coworkers for their intellectual and clinical input. Specifically, we cite the entire Division of Maternal–Fetal Medicine, whose faculty, in addition to providing expert content, graciously assisted us to cover clinical duties when writing and editing were especially time consuming. These include Drs. Scott Roberts, Oscar Andujo, Vanessa Rogers, Morris Bryant, Stepha Shivvers, Stephanie Chang, Robyn Horsager, Patricia Santiago-Muñoz, Julie Lo, Ashley Zink, E Wells, and Mark Peters.

We also note that production of Williams Obstetrics would not be feasible without the help of our maternal–fetal medicine fellows and residents in obstetrics and gynecology. Their insatiable curiosity serves to energize us to find new and effective ways to convey age-old truths, new data, and cutting-edge concepts. Their logical and critical questions lead us to weaknesses in the text, and thereby, always help us to improve our work. In addition, we sincerely thank them for their
vigilance in capturing photographs of spectacular examples of both obstetrical pathology and normal findings. For example, included in this edition are photographs contributed by Drs. Elaine Duryea, Stacey Thomas, Jonathan Willms, Kara Ehlers, Nidhi Shah, Abel Moron, Kyler Elwel, Rebecca Stone, Angela Fields, Emily Adhikari, and Elizabeth Mosier.

Thanks to generous funding from the McGraw-Hill Companies, this 24th edition now contains more than 200 color illustrations. Most of these were crafted by several skilled medical illustrators, including Ms. Marie Sena, Ms. Erin Frederikson, Ms. Mollie Gove, Mr. Jordan Piet, Ms. SangEun Cha, and Ms. Jennifer Hulsey. All of these talented artists trained here at UT Southwestern under the tutelage of Mr. Lewis Calver. Additional artistic support came from Mr. Joseph Varghese, Ms. Dharmesh Thakur, and their team at Thomson Digital, who provided the full-color graphs and line art used to enhance this edition. They were aided by medical-content expert Dr. Shetoli Zhimomi, who precisely translated our academic vision to each image. Their team tirelessly coordinated efforts between author and artist and graciously accommodated our numerous changes and tweaks.

Production of the 5000-page manuscript would not have been possible without a dedicated team to bring these efforts together. Once again, we are deeply indebted to Ms. Connie Utterback for her untiring efforts as production coordinator. She received able assistance with manuscript production from the Dallas group that included Ms. Melinda Epstein, Ms. Dawn Wilson, Ms. Marsha Zint, Ms. Minnie Tregaskis, Ms. Dina Trujillano, and Ms. Ellen Watkins. Information technology support was provided by the very knowledgeable and responsive Mr. Charles Richards and Mr. Thomas Ames. For these and many more that go unnamed, we could not have done our job without their expertise.

It again has been a privilege and a pleasure to work with the dedicated professionals from McGraw-Hill Education. Ms. Alyssa Fried has brought her considerable intelligence, energetic work ethic, and creativity to this edition of *Williams Obstetrics*. Her dedication to creating the best textbook possible equaled our efforts, and we are in awe of her unflappable, productive, and gracious style. Mr. Peter Boyle shepherded our book through production. We greatly appreciate his calm and efficient efforts. Mr. Richard Ruzycka served as production supervisor for this edition of the textbook. He skillfully kept our project on track through an array of potential hurdles. Last, we have had the pleasure to work with Mr. Armen Ovsepyan in coordinating the artwork for many of our editions. His organization and efficiency are unrivaled.

Our text took its final shape under the watchful care of our compositors at Aptara, Inc. We thank Ms. Indu Jawwad for her talents in skillfully coordinating and overseeing composition. Her dedicated attention to detail and organization were vital to completion of our project. Also at Aptara, Mr. Mahender Singh served a crucial task of quality control and assisted in creating beautiful chapter layouts to highlight our content aesthetically and informatively.

Finally—but certainly not last—we acknowledge our significant debt to the women who have allowed us to participate in their care. The clinical expertise and many graphic illustrations presented in this text would not have been possible without their collaborative spirit to help us advance obstetrical knowledge. We also offer enthusiastic and heartfelt appreciation to our families and friends. Without their patience, generosity, and encouragement, this task would have been impossible.

The Editors
Obstetrics is concerned with human reproduction and as such is always a subject of considerable contemporary relevance. The specialty promotes health and well-being of the pregnant woman and her fetus through quality perinatal care. Such care entails appropriate recognition and treatment of complications, supervision of labor and delivery, ensuring care of the newborn, and management of the puerperium. Postpartum care promotes health and provides family planning options.

The importance of obstetrics is reflected by the use of maternal and neonatal outcomes as an index of the quality of health and life among nations. Intuitively, indices that reflect poor obstetrical and perinatal outcomes would lead to the assumption that medical care for the entire population is lacking. With those thoughts, we now provide a synopsis of the current state of maternal and newborn health in the United States as it relates to obstetrics.

The National Vital Statistics System of the United States is the oldest and most successful example of intergovernmental data sharing in public health. The National Center for Health Statistics collects and disseminates official statistics through contractual agreements with vital registration systems. These systems that operate in various jurisdictions are legally responsible for registration of births, fetal deaths, deaths, marriages, and divorces. Legal authority resides individually with the 50 states; two regions—the District of Columbia and New York City; and five territories—American Samoa, Guam, the Northern Mariana Islands, Puerto Rico, and the Virgin Islands.

Standard certificates for the registration of live births and deaths were first developed in 1900. An act of Congress in 1902 established the Bureau of the Census to develop a system for the annual collection of vital statistics. The Bureau retained authority until 1946, when the function was transferred to the United States Public Health Service. It is presently assigned to the Division of Vital Statistics of the National Center for Health Statistics, which is a division of the Center.
The standard birth certificate was revised in 1989 to include more information on medical and lifestyle risk factors and obstetrical practices. In 2003, an extensively revised *Standard Certificate of Live Birth* was implemented in the United States to enhance collection of obstetrical and newborn clinical information. The enhanced data categories and specific examples of each are summarized in Table 1-1. By 2011, 36 states had implemented this revised birth certificate representing 83 percent of all births (Hamilton, 2012).

**Definitions**

The uniform use of standard definitions is encouraged by the World Health Organization as well as the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012). Such uniformity allows data comparison not only between states or regions of the country but also between countries. Still, not all definitions are uniformly applied. For example, the American College of Obstetricians and Gynecologists recommends that reporting include all fetuses and neonates born weighing at minimum 500 g, whether alive or dead. But not all states follow this recommendation. Twenty-eight states stipulate that fetal deaths beginning at 20 weeks’ gestation should be recorded as such; eight states report all products of conception as fetal deaths; and still others use a minimum birthweight of 350 g, 400 g, or 500 g to define fetal death. To further the confusion, the National Vital Statistics Reports tabulates fetal deaths from gestations that are 20 weeks or older (Centers for Disease Control and Prevention, 2009). This is problematic because the 50th percentile for fetal weight at 20 weeks approximates 325 to 350 g—considerably less than the 500-g definition. Indeed, a birthweight of 500 g corresponds closely with the 50th percentile for 22 weeks.

Definitions recommended by the National Center for Health Statistics and the Center for Disease Control and Prevention are as follows:

**Perinatal period.** The interval between the birth of an infant born after 20 weeks’ gestation and the 28 completed days after that birth. When perinatal rates are based on birthweight, rather than gestational age, it is recommended that the perinatal period be defined as commencing at 500 g.

**Birth.** The complete expulsion or extraction from the mother of a fetus after 20 weeks’ gestation. As described above, in the absence of accurate dating criteria, fetuses weighing < 500 g are usually not considered as births but rather are termed *abortuses* for purposes of vital statistics.

**Birthweight.** The weight of a neonate determined immediately after delivery or as soon thereafter
Birth rate. The number of live births per 1000 population.

Fertility rate. The number of live births per 1000 females aged 15 through 44 years.

Live birth. The term used to record a birth whenever the newborn at or sometime after birth breathes spontaneously or shows any other sign of life such as a heartbeat or definite spontaneous movement of voluntary muscles. Heartbeats are distinguished from transient cardiac contractions, and respirations are differentiated from fleeting respiratory efforts or gasps.

Stillbirth or fetal death. The absence of signs of life at or after birth.

Early neonatal death. Death of a liveborn neonate during the first 7 days after birth.

Late neonatal death. Death after 7 days but before 29 days.

Stillbirth rate or fetal death rate. The number of stillborn neonates per 1000 neonates born, including live births and stillbirths.

Neonatal mortality rate. The number of neonatal deaths per 1000 live births.

Perinatal mortality rate. The number of stillbirths plus neonatal deaths per 1000 total births.

Infant death. All deaths of liveborn infants from birth through 12 months of age.

Infant mortality rate. The number of infant deaths per 1000 live births.

Low birthweight. A newborn whose weight is < 2500 g.

Very low birthweight. A newborn whose weight is < 1500 g.

Extremely low birthweight. A newborn whose weight is < 1000 g.

Term neonate. A neonate born any time after 37 completed weeks of gestation and up until 42 completed weeks of gestation (260 to 294 days). The American College of Obstetricians and Gynecologists (2013b) and the Society for Maternal-Fetal Medicine endorse and encourage specific gestational age designations. Early term refers to neonates born at 37 completed weeks up to 38\(\frac{6}{7}\) weeks. Full term denotes those born at 39 completed weeks up to 40\(\frac{6}{7}\) weeks. Last, late term describes neonates born at 41 completed weeks up to 41\(\frac{6}{7}\) weeks.

Preterm neonate. A neonate born before 37 completed weeks (the 259th day).

Postterm neonate. A neonate born anytime after completion of the 42nd week, beginning with day 295.

Abortus. A fetus or embryo removed or expelled from the uterus during the first half of gestation—20 weeks or less, or in the absence of accurate dating criteria, born weighing < 500 g.

Induced termination of pregnancy. The purposeful interruption of an intrauterine pregnancy that has the intention other than to produce a liveborn neonate and that does not result in a live birth. This definition excludes retention of products of conception following fetal death.

Direct maternal death. The death of the mother that results from obstetrical complications of pregnancy, labor, or the puerperium and from interventions, omissions, incorrect treatment, or a chain of events resulting from any of these factors. An example is maternal death from exsanguination after uterine rupture.

Indirect maternal death. A maternal death that is not directly due to an obstetrical cause. Death results from previously existing disease or a disease developing during pregnancy, labor, or the puerperium that was aggravated by maternal physiological adaptation to pregnancy. An example is maternal death from complications of mitral valve stenosis.
Nonmaternal death. Death of the mother that results from accidental or incidental causes not related to pregnancy. An example is death from an automobile accident or concurrent malignancy.

Maternal mortality ratio. The number of maternal deaths that result from the reproductive process per 100,000 live births. Used more commonly, but less accurately, are the terms *maternal mortality rate* or *maternal death rate*. The term *ratio* is more accurate because it includes in the numerator the number of deaths regardless of pregnancy outcome—for example, live births, stillbirths, and ectopic pregnancies—whereas the denominator includes the number of live births.

Pregnancy-associated death. The death of a woman, from any cause, while pregnant or within 1 calendar year of termination of pregnancy, regardless of the duration and the site of pregnancy.

Pregnancy-related death. A pregnancy-associated death that results from: (1) complications of pregnancy itself, (2) the chain of events initiated by pregnancy that led to death, or (3) aggravation of an unrelated condition by the physiological or pharmacological effects of pregnancy and that subsequently caused death.

### PREGNANCY IN THE UNITED STATES

#### Pregnancy Rates

Data from diverse sources have been used to provide the following snapshot of pregnancy in the United States during the first two decades of the 21st century. According to the Centers for Disease Control and Prevention, the fertility rate in the United States in 2011 of women aged 15 to 44 years was 63.2 live births per 1000 women (Sutton, 2011). As shown in Figure 1-1, this rate began slowly trending downward in 1990 and has now decreased below that for replacement births, indicating a population decline (Hamilton, 2012). There were 3.9 million births in 2011, and this constituted the lowest birth rate ever recorded for the United States of 12.7 per 1000 population. The birth rate decreased for all major ethnic and racial groups, for adolescents and unmarried women, and for those aged 20 to 24 years. For women older than 30 years, the birth rate was either unchanged or it increased slightly. Virtually half of newborns in 2010 in the United States were minorities: Hispanic—25 percent, African-American—14 percent, and Asian—4 percent (Frey, 2011).
The total number of pregnancies and their outcomes in 2008 are shown in Table 1-2. Of the 6,578,000 total pregnancies, most—65 percent—ended with live births. Of births in the United States, approximately 37 percent are unintended at the time of conception (Mosher, 2012). Importantly, the overall proportion of unintended births has not declined significantly since 1982. Unmarried women, black women, and women with less education or income are more likely to have unplanned pregnancies. That said, of the remaining pregnancies in 2008, 35 percent were almost equally divided into induced or spontaneous abortions. The induced abortion information is based on CDC abortion surveillance data from 45 states combined with Guttmacher Institute data on induced abortion. These data have been collected beginning in 1976. If the annual totals for 1976 to 2008 are tabulated, it can be estimated that approximately 46,657,000 women in the United States have elected induced abortions since Roe v. Wade legalization of abortion (Chap. 18, p. 363). Thus, legalized abortions have been chosen by more than 46 million American women. As discussed later, this provides a compelling argument for easily accessible family planning.

Data from Ventura, 2012.
Perinatal Mortality

There are a number of indices—several among the vital statistic definitions described above—that are used as a yardstick of obstetrical and perinatal outcomes to assess quality of care.

As previously defined, the perinatal mortality rate includes the numbers of stillbirths and neonatal deaths per 1000 total births. According to the National Vital Statistics Reports by MacDorman and colleagues (2012a), the perinatal mortality rate in 2006 was 10.5 per 1000 births (Fig. 1-2). There were 25,972 fetal deaths in gestations 20 weeks or older. Fetal deaths at 28 weeks or more have been declining since 1990, whereas the rates for those between 20 and 27 weeks have been static (Fig. 1-3). By way of comparison, there were a total of 19,041 neonatal deaths in 2006—meaning that nearly 60 percent of the perinatal deaths in the United States were fetal. Thus, it is seen that fetal deaths have eclipsed neonatal deaths as a cause of perinatal mortality.

**FIGURE 1-2** Perinatal mortality rate: United States, 1990–2006. *Perinatal* includes infant deaths under age 28 days and fetal deaths at 20 weeks or more. (From MacDorman, 2012a.)
Infant Deaths

There were 6.1 infant deaths per 1000 live births in 2011 compared with 6.8 in 2001 (Hamilton, 2012). The three leading causes of infant death—congenital malformations, low birthweight, and sudden infant death syndrome—accounted for almost half of all deaths. Infants born at the lowest gestational ages and birthweights add substantively to these mortality rates. For example, 55 percent of all infant deaths in 2005 were in the 2 percent of infants born before 32 weeks’ gestation. Indeed, the percentage of infant deaths related to preterm birth increased from 34.6 percent in 2000 to 36.5 percent in 2005. When analyzed by birthweight, two thirds of infant deaths were in low-birthweight neonates. Of particular interest are those birthweights < 500 g, for which neonatal intensive care can now be offered. In 2001, there were 6450 liveborns weighing less than 500 g, but 86 percent of these newborns died during the first 28 days of life. Of the 1044 who survived the first 28 days of life, there were 934 who lived for at least 1 year. Thus, only 14 percent of all neonates weighing < 500 g survived infancy. Importantly, adverse developmental and neurological sequelae are common in the survivors (Chap. 42, p. 832).

More than a decade ago, St. John and associates (2000) estimated the total cost of initial newborn care in the United States to be $10.2 billion annually. Almost 60 percent of this expenditure is attributed to preterm births before 37 weeks, and 12 percent is spent on neonates born between 24 and 26 weeks.

Maternal Mortality

As shown in Figure 1-4, maternal mortality rates decreased precipitously in the United States during the 20th century. Pregnancy and childbirth have never been safer for women in this country.
In fact, pregnancy-related deaths are so uncommon as to be measured per 100,000 births. The CDC since 1979 has maintained data on pregnancy-related deaths in its *Pregnancy Mortality Surveillance System* (Mackay, 2005). In the latest report, Berg and coworkers (2010) described 4693 pregnancy-related deaths during the 8-year period 1998 to 2005. Approximately 5 percent were early-pregnancy deaths due to ectopic gestation or abortive outcomes. The deadly obstetrical triad of hemorrhage, preeclampsia, and infection accounted for a third of all deaths (*Table 1-3*). Thromboembolism, cardiomyopathy, and other cardiovascular disease together accounted for another third (*Fig. 1-5*). Other significant contributors in this group were amnionic fluid embolism (7.5 percent) and cerebrovascular accidents (6.3 percent). Anesthesia-related deaths were at an all-time low of only 1.2 percent. It is also important to consider the role that the increasing cesarean delivery rate has on maternal mortality risks (Clark, 2008; Deneux-Tharaux, 2006; Lang 2008).

![Figure 1-4](image-url)  
FIGURE 1-5 Six common causes of maternal deaths for the United States, 1998–2005. (Data from Berg, 2010.)

TABLE 1-3. Causes of Pregnancy-Related Maternal Deaths in the United States<sup>a,b</sup> During Two Time Periods
The pregnancy-related mortality ratio for this 1998 to 2005 period of 14.5 per 100,000 live births is the highest during the previous 20 years (Berg, 2010). This simply may mean more women are dying, however, it may be due to improved reporting or to an artificial increase caused by the new International Statistical Classification of Diseases, 10th Revision (ICD-10), implemented in 1999. There is no doubt that maternal deaths are notoriously underreported, possibly by as much as half (Koonin, 1997).

A second important consideration is the obvious disparity of increased mortality rates in African-American compared with white women as shown in Figure 1-6. The disparity with indigent women is exemplified by the study of maternal deaths in women cared for in a third-party payer system, the Hospital Corporation of America. In this study of nearly 1.5 million pregnant women, Clark and associates (2008) reported an impressively low maternal mortality rate of 6.5 per 100,000.

<sup>e</sup>Includes cardiovascular, pulmonary, neurological, and other medical conditions.
The third important consideration is that many of the reported maternal deaths are considered preventable. In an earlier report, Berg and colleagues (2005) stated that this may be up to a third of pregnancy-related deaths in white women and up to half of those in African-American women. And even in the insured women described above and reported by Clark, 28 percent of 98 maternal deaths were judged preventable. Thus, although significant progress has been made, measures to prevent more deaths are imperative for obstetrics in the 21st century.

Severe Maternal Morbidity

Because maternal deaths have become so uncommon, the practice of analyzing severe maternal morbidity evolved as a surrogate to improve obstetrical and perinatal care. Because avoidance of medical errors serves to decrease the risks for maternal mortality or severe maternal morbidity, the concept of near misses or close calls was also introduced. These are defined by the Joint Commission and the Institution for Safe Medication and Practices (2009) as unplanned events caused by error that do not result in patient injury but have the potential to do so. These are much more common than injury events, but for obvious reasons, they are more difficult to identify and quantify. Systems designed to encourage reporting have been installed in various institutions and allow focused safety efforts. One example is the system described by Clark and associates (2012) and used for more than 200,000 annual deliveries within the Hospital Corporation of America.
There are now a number of statistical data systems that measure indicators of unplanned events caused by errors that had potential to injure patients. This evolution followed inadequacies in how well hospitalization coding reflected the severity of maternal complications. Thus, coding indicators or modifiers are used to allow analysis of serious adverse clinical events (Clark, 2012; King, 2012). Such a system was implemented by the World Health Organization. It has been validated in Brazil and accurately reflects maternal death rates (Souza, 2012). Similar systems are in use in Britain as the UK Obstetric Surveillance System—UKOSS (Knight, 2005, 2008). Australia and New Zealand have also devised such a system—the Australasian Maternity Outcomes Surveillance System—AMOSS (Halliday, 2013). As emphasized by Tuncalp and coworkers (2012) after their systematic review, different locoregional approaches are needed to lower the rates of near misses.

In the United States, to study severe morbidity the CDC analyzed more than 50 million maternity records from the Nationwide Inpatient Sample from 1998 to 2009 (Callaghan, 2012). Selective International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) code were used to tabulate a number of severe morbidities. The frequencies of some of those most commonly encountered are listed in Table 1-5. These investigators reported that 129 per 10,000 of these nearly 50 million pregnant women had at least one indicator for severe morbidity. Thus, for every maternal death, approximately 200 women experience severe morbidity.

### TABLE 1-5. Severe Obstetrical Morbidities Identified During Nearly 50 Million Hospitalizations for Delivery—United States, 1998–2009
Various topics have been in the forefront for obstetrical providers in the 4 years since the last edition of this textbook. Of these, the ills of our health-care system are especially concerning for women’s health (Hale, 2010). To cite but a few examples, uninsured women with breast cancer were up to 50 percent more likely than insured women to die from the disease. There were more than 17 million uninsured American women aged 18 to 64 years in 2008. Similarly, women without health-care insurance had a 60-percent greater risk of late-stage cervical cancer. Lack of medical insurance also has severe effects on pregnant women. Those without insurance have a 31-percent higher risk of adverse outcomes such as preterm delivery, neonatal death, and maternal mortality. Of American women aged 18 to 64 years in a recent study of 11 industrialized countries, 43 percent skipped seeing a doctor or did not take medicine due to costs (Robertson, 2012). This was the highest percentage of all 11 countries studied. By comparison, just 7 percent of British women and 17 percent of Canadian and French women refrained from seeking health care because of costs. Of the 11 countries studied, only the United States did not have universal health-care coverage.

There is also a geopolitical consequence of such increased adverse outcomes for American women. The World Health Organization analyzed neonatal mortality rates in 2009 for 193 countries (Oestergaard, 2011). The United States ranked 41st in 2009, dropping from 28th in 1990. The highest newborn death rate in the world was in Afghanistan, where one of every 19 babies died before their 1-month birthday. In comparison, one of every 233 newborns dies in the United
States. This is far better than the rate in Afghanistan, but not as good as the rate in Japan—1 in 909, France—1 in 455, Lithuania—1 in 385, or Cuba—1 in 345. Some reasons given for the United States results include difficulty in accessing prenatal care, which contributes to the current high rate of preterm births.

There have been dramatic changes in women’s health care regarding obstetrical and gynecological procedures during the past 30 years in the United States. Shown in Figure 1-7 are the rates per 1000 adult American women for the commonest gynecological procedures performed between 1979 and 2006. The rates are adjusted for age to correct for population changes over time. The dramatic decreases in the rates of gynecological procedures were thought largely due to changed criteria for these procedures. Changed criteria resulted from the health maintenance organization (HMO) movement of the 1980s. With this, health-care insurers of all types exercised increasing control over the indications for these procedures. Shown in Figure 1-8 are the rates per 1000 adult women for obstetrical procedures also from 1979 to 2006. Episiotomy use plummeted, as did operative vaginal delivery rates. Cesarean deliveries per 1000 women greatly increased. These rates changes are discussed more fully in Chapters 27, 29, and 30, which cover these delivery routes.

**FIGURE 1-7** Age-adjusted rates of gynecological procedures in the United States, 1979–2006. (Data from Oliphant, 2010.)
There are only two federal programs dedicated solely to health care of women and their infants, and every obstetrician should know about these programs (Lu, 2012). The first is the Title V Maternal and Child Health Services Block Grant, which is the only federal program focused on improving the health of mothers, children, and their families. It was enacted by Congress in 1935 as part of the Social Security Act. Title V provides for state-level block grants in which states match with $3 every $4 in federal money. In 2009, states reported that 2.5 million primarily low-income pregnant women and 35 million children were served by these state block grants.

The second federal program dedicated to women’s health care is the Title X Family Planning Program. This is the only federal program focused on providing women with comprehensive family planning and related preventative health services. Title X was enacted in 1970, and in 2010, it served more than 5.2 million primarily low-income women.

Beginning with implementation of the 2003 United States Standard Birth Certificate described earlier, the principal source of payment for births was reported. In 2010, it was estimated that Medicaid financed 48 percent of the births in the United States (Markus, 2013). Importantly, Medicaid covered a disproportionate number of complicated births. Specifically, Medicaid paid for more than half of all hospital stays for preterm and low-birthweight infants and approximately 45 percent of infant hospital stays due to birth defects.

So, what is the “bottom line” for obstetrical health care in the United States for women and their infants? In 2008, the total national hospital bill was almost $1.2 trillion (Wier, 2011). These
charges involved 39.9 million hospital stays but do not include outpatient care, emergency care for patients not admitted to the hospital, or physician fees. Medicare and Medicaid paid for 60 percent of the 2008 national hospital bill. Specifically, Medicare covered 46.2 percent and Medicaid 13.8 percent. The hospital bills for the mother’s pregnancy and delivery plus care of the newborn exceeded $98 billion, representing 8 percent of all hospital bills. This bill for women and their infants is more than twice that of any other diagnosis across the entire spectrum of American health care and attests to the impact of health care for pregnant women in this country.

### The Affordable Care Act

In the last edition of *Williams Obstetrics*, the Obama Administration was poised to pass universal health insurance—so-called Obamacare. This history-making legislation debuted on March 23, 2010, with passage into law of *The Patient Protection and Affordable Care Act*—PPACA. Although constitutional challenges followed, the Supreme Court upheld most aspects of the law in its ruling in 2012 of *National Federation of Independent Business* v. *Sebelius*. Implementation of this complex legislation began in 2010 and will continue over the current decade (Fig. 1-9). Indeed, initially registration began with a rocky start in late 2013.
As outlined by the Society for Maternal-Fetal Medicine, the act will expand obstetrical care of indigent women (Grande, 2013). The American College of Obstetricians and Gynecologists (2013a) estimates that nearly 20 million uninsured women aged 18 to 64 years have less than optimal access to prenatal care, family planning services, and breast and cervical cancer screening. Many of these women will have improved access to these services because of the expanded Medicaid coverage funded through the Act. The College encourages individual states to expand their Medicaid coverage and improve reimbursement rates.

One “fly in the ointment” of the Affordable Care Act is funding. Although it has been declared “budget neutral,” the Congressional Budget Office has calculated that 30 million Americans will remain uninsured. For these and a multitude of fiscal reasons—and we certainly do not profess to be economists—we, like Oberlander (2012) and others, remain nervous concerning costs and adequate funding for “universal health care.”

### Rising Cesarean Delivery Rate

In 2009, the cesarean delivery rate climbed to the highest level ever reported in the United States—32.9 percent (Centers for Disease Control and Prevention, 2013). After that, it appears to have stabilized. This rise in the total rate was a result of upward trends in both the primary and the repeat cesarean delivery rates. Indeed, more than 90 percent of women with a prior cesarean delivery now undergo a repeat procedure. The forces involved in these changes in cesarean delivery rates are multi-factorial and complex. We cite a few examples:

1. The major indication for primary cesarean delivery is dystocia, and there is evidence that this diagnosis has increased. This is discussed in Chapter 23 (p. 455).
2. The sharp decline in vaginal births after cesarean (VBAC) delivery is closely related to the uterine rupture risk associated labor with a prior uterine incision. This is discussed throughout Chapter 31.
3. The controversial cesarean delivery on maternal request (CDMR) contributes to the rise. This is defined as a cesarean delivery at term for a singleton pregnancy on maternal request in the absence of any medical or obstetrical indication (Reddy, 2006). This is discussed in Chapter 30 (p. 589).
4. Near-term and term pregnancy labor induction is commonplace, and failed inductions contribute to the cesarean delivery rate. This is discussed in Chapter 26 (p. 524).

It is not possible to precisely measure the contribution of each of these components to the all-time-high cesarean delivery rate. The American College of Obstetricians and Gynecologists and the Maternal-Fetal Medicine Units Network have addressed these in an attempt to curtail the rising rate. The National Institute of Child Health and Human Development convened a State-of-the Science Conference in 2006 to provide an in-depth evaluation of the evidence regarding cesarean delivery on maternal request. To date, there have been no evidence-based guidelines. Recognizing that repeat operations constitute a large percentage of cesarean deliveries, the National Institutes of Health (2010) convened a consensus conference entitled *Vaginal Birth after Cesarean: New Insights*. The findings are discussed in detail in Chapter 31 (p. 609), but to summarize, they
supported a trial of labor for many selected women with a prior cesarean hysterotomy scar and recommended that this option be made more available. It is too early to conclude if this recommendation has significantly altered the cesarean delivery rate.

Genomic Technology

Recent breakthroughs in fetal testing and diagnosis are truly stunning. In one recent issue of the *New England Journal of Medicine*, there were three reports in which prenatal gene microarray techniques were used for clinical management (Dugoff, 2012). The advantages of these techniques are outlined in Chapters 13 and 14. Wapner and coworkers (2012) compared microarray analysis of maternal blood with karyotyping for chromosomal anomalies. Reddy and associates (2012) applied this technology to stillbirth evaluation and reported it to be superior to karyotyping. The third report by Talkowski and colleagues (2012) described whole-genome sequencing of a fetus using maternal blood.

Added to these possibilities is the specter of made-to-order embryos (Cohen, 2013). These are but a few examples that illustrate the power of genomic technology to pursue fetal diagnosis and possible therapy. At this juncture, there are complex obstacles to overcome, but with rapid advancement of these technologies, success is almost assured.

Electronic Health Records

Rising costs, inconsistent quality, and patient safety issues are significant challenges to the delivery of health care in the United States. Electronic health records (EHR) have been identified as a means of improving provider efficiency and effectiveness (Jha, 2009). Methods to speed the adoption of health information technology have received bipartisan support in Congress, and the *American Recovery and Reinvestment Act of 2009* has made such a system a national priority. This was soon followed by the *Health Information Technology for Economic and Clinical Health (HITECH) Act*. Recent surveys indicate that approximately half of outpatient practices and hospitals in the United States are now using EHR. This act also introduced the concept of “meaningful use” EHRs by providers. Classen and Bates (2011) appropriately note, however, that “meaningful use” does not necessarily equate with “meaningful benefits.” According to the American College of Obstetricians and Gynecologists (2010), studies of effectiveness are critically needed to justify the safe implementation of these costly electronic computerized systems.

Health-Care Outcomes Research

Although per capita health-care expenditures in the United States are the highest in the world, health-care outcomes frequently lag behind those in nations spending far less. A major factor in this disparity is thought to be expenditure overuse, underuse, and misuse driven by rationale-based instead of evidence-based health care. Buried within the 2400 pages of the landmark health-care reform bill signed into law by President Barack Obama are several provisions that touch on clinical research (Kaiser, 2010). Two are aimed at determining which health-care interventions work best and identifying financial conflicts of researchers. A third provision funds acceleration of new drug development. Proponents hope these research studies will improve the quality and lower the cost of health care by identifying the best treatments. We applaud this effort. Indeed, we are of the view that systematic prospective measurement of health-care outcomes as related to
treatments prescribed should be an on-going requirement for the practice of medicine.

Much publicity followed the report by the Institute of Medicine entitled *To Err Is Human* (Kohn, 2000). This report greatly increased interest in measuring health-care outcomes and adverse events (Grobman, 2006). Even the United States Congress has determined that reimbursements by Medicare and Medicaid should be indexed to selected health-care outcomes. Specifically, a wide, often dizzying spectrum of benchmarks has been proposed to measure the quality and safety of obstetrical care. In our view, the greatest impediment to deriving meaningful measures of obstetrical care is the continued use of administrative and financial data—instead of clinical data—to set benchmarks for outcomes.

Regulatory bodies typically evaluate hospital quality using obstetrical outcomes derived from administrative (financial) datasets not designed to measure clinical results. Accordingly, the Maternal-Fetal Medicine Units Network of the National Institute of Child Health and Human Development undertook an unprecedented and unparalleled study of obstetrical outcomes based on carefully collected *clinical data* (Bailit, 2013). The purpose was to establish risk-adjusted models for five obstetrical outcomes and then determine if hospital performance could be reliably measured so that hospitals could be compared. Outcomes studied included postpartum hemorrhage, peripartum infection, severe perineal laceration, neonatal morbidity, and venous thromboembolism. This study included 115,502 mother-infant pairs managed for 3 years at 25 hospitals. Clinical data were abstracted from medical records by specially trained research nurses using a prespecified manual of operations. The study clearly demonstrated that differences between obstetrical outcomes at different hospitals, when clinically adjusted for preexisting patient characteristics, *cannot* be used to accurately compare obstetrical care among hospitals.

So, what does this mean? It means that the widespread current practice of ranking obstetrical care at different hospitals based on single outcomes, such as third- or fourth-degree perineal lacerations, is useless when accurate data are used. Moreover, use of up to four obstetrical outcomes did not improve the ability to rank hospitals. Actually, use of more than one outcome greatly confused the ranking. A given hospital might rank number one out of 25 hospitals for one obstetrical outcome and 25 out of 25 for a second outcome. Thus, a given hospital could be both very good and very bad depending on the obstetrical outcome analyzed!

### Medical Liability

Approximately 12 percent of obstetrician-gynecologists had at least one malpractice claim each year from 1991 through 2005 (Jena, 2011). The American College of Obstetricians and Gynecologists periodically surveys its fellows concerning the effect of liability on their practice. The 2012 Survey on Professional Liability is the 11th such survey since 1983 (Klagholz, 2012). The survey reflects experiences of more than 9000 members, and 58 percent of these fellows responded that some aspect(s) of the liability environment had caused them to alter their practice since the last survey. Undoubtedly not all of these changes were positive. Those cited included an increased cesarean delivery rate, fewer trials of labor after a prior cesarean delivery, and a decreased number of high-risk patients and total deliveries (Amon, 2014). Others have chosen to forego obstetrical practice entirely. Some of these changes have been linked to states with higher liability premiums (Zwecker, 2011).

Thus, by all accounts, there is still a “liability crisis,” and the reasons for it are complex. Because it is largely driven by money and politics, a consensus seems unlikely. Although some interests are diametrically opposite, other factors contribute to the complexity of the crisis. For example, each state has its own laws and opinions of “tort reform.” Meanwhile, liability claims
remain a “hot button” in obstetrics because of their inherent adversarial nature and the sometimes outlandish plaintiff verdicts that contribute to increasing liability insurance premiums. In some states, annual premiums for obstetricians approach $300,000—expenses that at least partially are borne by the patient and certainly by the entire health-care system. Liability issues are daunting, and in 2008, all tort costs in the United States totaled nearly $255 billion. This is an astounding 1.8 percent of the gross domestic product and averages $838 per citizen (Towers Perrin, 2009). Annas (2013) has provided an interesting review of two centuries of malpractice law history. Interestingly, he compares medical malpractice litigation to the white whale in Melville’s *Moby-Dick*—evil, ubiquitous, and seemingly immoral!

The American College of Obstetricians and Gynecologists has taken a lead in adopting a fair system for malpractice litigation—or *maloccurrence litigation*. The Committee on Professional Liability has produced several related documents that help fellows cope with the stresses of litigation, that provide advice for the obstetrician giving expert testimony, and that outline recommendations for disclosure of any adverse events (American College of Obstetricians and Gynecologists, 2013c,d,e).

National liability reform likely will come in some form with the push for universal medical insurance coverage. President Obama, in his 2009 address to the American Medical Association, indicated that national malpractice liability reform was negotiable. United States Congressmar Michael Burgess—an obstetrician-gynecologist—asked the president to reaffirm this commitment. We applaud these efforts and wish for their success.

### Home Births

Following a slight decline from 1990 through 2004, according to the National Center for Health Statistics, the percentage of home births in the United States increased from 0.56 to 0.72 percent—almost 70 percent—through 2009 (MacDorman, 2012b). But, as is so often the case with data analysis, the “devil is in the details.” Only 62 percent of these 24,970 home births were attended by midwives—19 percent by certified nurse midwives and 43 percent by so-called lay midwives with minimal formal training. The remaining 38 percent of home births were *unplanned*—that is, the result of accidental delivery at home attended by a family member or emergency medical technician. So is home birth a good idea? Those currently conducted in the United States in which women are not attended by trained and certified personnel cannot be considered acceptable. There have been no randomized trials to test the safety of home deliveries (Olsen, 2012). Proponents of home births cite success from laudatory observational data from European countries such as England and The Netherlands (Van der Kooy, 2011). Data from the United States, however, are less convincing and indicate a higher incidence of perinatal morbidity and mortality (Grünebaum, 2013, 2014; Wasden, 2014; Wax, 2010). These findings have led Chervenak and coworkers (2013) to question the ethics of participation in planned home births.

### Family Planning Services

Politics and religion over the years have led to various governmental interferences with the reproductive rights of women. These intrusions have disparately affected indigent women and adolescents. One example was the consideration by Congress in 1998 for the Title X Parental Notification Act. Reddy and colleagues (2002) estimated this bill would have dissuaded almost half of adolescents younger than 17 years from seeking contraceptive services and care for sexually transmitted disease.
Another example is the tug-of-war over emergency contraception, and more specifically over the *morning-after pill* (Chap. 38, p. 714). Efforts begun in 2004 by the Bush Administration to curtail *Plan B* for over-the-counter sales to women 17 years and younger was decried appropriately by editorials in the *New England Journal of Medicine* (Drazen, 2004; Steinbrook, 2004). This issue was not settled until April 2013 when a federal district court in New York ordered the Food and Drug Administration to make emergency contraception available for over-the-counter sales to all women regardless of age. The decision was quickly applauded by the American College of Obstetricians and Gynecologists (2013f). The decision was editorialized as “science prevails” in a subsequent issue of *Nature* (2013).

Perhaps the most egregious example of both federal and state governmental intrusion into women’s reproductive rights is the often poor availability of federally funded family planning services for indigent women. This is despite all reports of the overwhelming success of such programs. According to the Guttmacher Institute, publicly funded family planning services in 2010 prevented nearly 2.2 million unintended pregnancies and 760,000 abortions in the United States. They concluded that without such funding the abortion rate would be nearly two-thirds higher for all women, and nearly 70-percent higher for adolescents (Frost, 2013). The American College of Obstetricians and Gynecologists (2012) has recently reviewed these and other barriers to emergency contraception access.

## Abortion

It continues to be a preventable fact that up to a fifth of pregnancies in this country are terminated by elective abortion (see Table 1-1). According to the American College of Obstetricians and Gynecologists (2011): “The most effective way to reduce the number of abortions is to prevent unwanted and unintended pregnancies.” Importantly, the negative attitudes, beliefs, and policies toward family planning services and sex education discussed above have helped to contribute to the more than 800,000 abortions performed yearly in the United States.

The history of legislative regulation and federal court decisions regarding abortions is considered in Chapter 18 (p. 363). The *Partial Birth Abortion Ban Act of 2003* has become law, and in 2007, the Supreme Court ruled that the ban—officially known as *Gonzales v. Carhart*—is constitutional. This again caused editorialists in the *New England Journal of Medicine* to decry the intrusion of government into medicine (Charo, 2007; Drazen, 2007; Greene, 2007). More ominous are restrictive state laws—many of which have been or will be ruled unconstitutional—which according to some will drive *Roe v. Wade* back to the Supreme Court.

## REFERENCES

American College of Obstetricians and Gynecologists: Access to emergency contraception. Committee Opinion No. 542, November 2012

American College of Obstetricians and Gynecologists: Benefits to women of Medicaid expansion through the Affordable Care Act. Committee Opinion No. 552, January 2013a

An understanding of female pelvic and lower abdominal wall anatomy is essential for obstetrical practice. Although consistent relationships between these structures are the norm, there may be marked variation in individual women. This is especially true for major blood vessels and nerves.

### ANTENOR ABDOMINAL WALL

#### Skin, Subcutaneous Layer, and Fascia

The anterior abdominal wall confines abdominal viscera, stretches to accommodate the expanding uterus, and provides surgical access to the internal reproductive organs. Thus, a comprehensive knowledge of its layered structure is required to surgically enter the peritoneal cavity.

Langer lines describe the orientation of dermal fibers within the skin. In the anterior abdominal wall, they are arranged transversely. As a result, vertical skin incisions sustain increased lateral tension and thus, in general, develop wider scars. In contrast, low transverse incisions, such as the Pfannenstiel, follow Langer lines and lead to superior cosmetic results.

The subcutaneous layer can be separated into a superficial, predominantly fatty layer—Camper fascia, and a deeper membranous layer—Scarpa fascia. Camper fascia continues onto the perineum to provide fatty substance to the mons pubis and labia majora and then to blend with the fat of the ischioanal fossa. Scarpa fascia continues inferiorly onto the perineum as Colles fascia (p. 22). As a result, perineal infection or hemorrhage superficial to Colles fascia has the ability to extend upward to involve the superficial layers of the abdominal wall.

Beneath the subcutaneous layer, the anterior abdominal wall muscles consist of the midline rectus abdominis and pyramidalis muscles as well as the external oblique, internal oblique, and transversus abdominis muscles, which extend across the entire wall (Fig. 2-1). The fibrous aponeuroses of these three latter muscles form the primary fascia of the anterior abdominal wall. These fuse in the midline at the linea alba, which normally measures 10 to 15 mm wide below the
umbilicus (Beer, 2009). An abnormally wide separation may reflect diastasis recti or hernia.

These three aponeuroses also invest the rectus abdominis muscle as the rectus sheath. The construction of this sheath varies above and below a boundary, termed the arcuate line (Fig. 2-2). Cephalad to this border, the aponeuroses invest the rectus abdominis bellies on both dorsal and ventral surfaces. Caudal to this line, all aponeuroses lie ventral or superficial to the rectus abdominis muscle, and only the thin transversalis fascia and peritoneum lie beneath the rectus (Loukas, 2008). This transition of rectus sheath composition can be seen best with a midline abdominal incision. Last, the paired small triangular pyramidalis muscles originate from the pubic crest, insert into the linea alba, and lie atop the rectus abdominis muscle but beneath the anterior rectus sheath.
Blood Supply

The superficial epigastric, superficial circumflex iliac, and superficial external pudendal arteries arise from the femoral artery just below the inguinal ligament within the femoral triangle. These vessels supply the skin and subcutaneous layers of the anterior abdominal wall and mons pubis. Of surgical importance, the superficial epigastric vessels, from their origin, course diagonally toward...
the umbilicus. With a low transverse skin incision, these vessels can usually be identified at a depth halfway between the skin and the anterior rectus sheath, above Scarpa fascia, and several centimeters from the midline.

In contrast, the inferior “deep” epigastric vessels and deep circumflex iliac vessels are branches of the external iliac vessels. They supply the muscles and fascia of the anterior abdominal wall. Of surgical relevance, the inferior epigastric vessels initially course lateral to, then posterior to the rectus abdominis muscles, which they supply. These vessels then pass ventral to the posterior rectus sheath and course between the sheath and the rectus muscles. Near the umbilicus, these vessels anastomose with the superior epigastric artery and veins, which are branches of the internal thoracic vessels. When a Maylard incision is used for cesarean delivery, the inferior epigastric artery may be lacerated lateral to the rectus belly during muscle transection. These vessels rarely may rupture following abdominal trauma and create a rectus sheath hematoma (Tolcher, 2010).

On each side of the lower anterior abdominal wall, Hesselbach triangle is the region bounded laterally by the inferior epigastric vessels, inferiorly by the inguinal ligament, and medially by the lateral border of the rectus muscle. Hernias that protrude through the abdominal wall in Hesselbach triangle are termed direct inguinal hernias. In contrast, indirect inguinal hernias do so through the deep inguinal ring, which lies lateral to this triangle, and then may exit out the superficial inguinal ring.

**Innervation**

The anterior abdominal wall is innervated by intercostal nerves (T7–11), the subcostal nerve (T12), and the iliohypogastric and the ilioinguinal nerves (L1). Of these, the intercostal and subcostal nerves are anterior rami of the thoracic spinal nerves and run along the lateral and then anterior abdominal wall between the transversus abdominis and internal oblique muscles. This space is termed the transversus abdominis plane. Near the rectus abdominis lateral borders, these nerve branches pierce the posterior sheath, rectus muscle, and then anterior sheath to reach the skin. Thus, these nerve branches may be severed during a Pfannenstiel incision at the point in which the overlying anterior rectus sheath is separated from the rectus muscle.

In contrast, the iliohypogastric and ilioinguinal nerves originate from the anterior ramus of the first lumbar spinal nerve. They emerge lateral to the psoas muscle and travel retroperitoneally across the quadratus lumborum inferomedially toward the iliac crest. Near this crest, both nerves pierce the transversus abdominis muscle and course ventrally. At a site 2 to 3 cm medial to the anterior superior iliac spine, the nerves then pierce the internal oblique muscle and course superficial to it toward the midline (Whiteside, 2003). The iliohypogastric nerve perforates the external oblique aponeurosis near the lateral rectus border to provide sensation to the skin over the suprapubic area. The ilioinguinal nerve in its course medially travels through the inguinal canal and exits through the superficial inguinal ring, which forms by splitting of external abdominal oblique aponeurosis fibers. This nerve supplies the skin of the mons pubis, upper labia majora, and medial upper thigh.

The ilioinguinal and iliohypogastric nerves can be severed during a low transverse incision or entrapped during closure, especially if incisions extend beyond the lateral borders of the rectus muscle (Rahn, 2010). These nerves carry sensory information only, and injury leads to loss of sensation within the areas supplied. Rarely, however, chronic pain may develop.

The T10 dermatome approximates the level of the umbilicus. As discussed in Chapter 25 (p.
511), regional analgesia for cesarean delivery or for puerperal sterilization ideally blocks T_{10} through L_{1} levels. In addition, a transversus abdominis plane block can provide broad blockade to the nerves that traverse this plane and may be placed postcesarean to reduce analgesia requirements (Mishriky, 2012). There are also reports of rectus sheath block or ilioinguinal-iliohypogastric nerve block to decrease postoperative pain (Mei, 2011; Sviggum, 2012; Wolfson, 2012).

### EXTERNAL GENERATIVE ORGANS

#### Vulva

**Mons Pubis, Labia, and Clitoris**

The pudenda—commonly designated the vulva—includes all structures visible externally from the symphysis pubis to the perineal body. This includes the mons pubis, labia majora and minora, clitoris, hymen, vestibule, urethral opening, greater vestibular or Bartholin glands, minor vestibular glands, and paraurethral glands (Fig. 2-3). The embryology of the external genitalia is discussed in Chapter 7 (p. 144), and its innervations and vascular support are described with the pudendal nerve (p. 24).
The mons pubis, also called the mons veneris, is a fat-filled cushion overlying the symphysis pubis. After puberty, the mons pubis skin is covered by curly hair that forms the escutcheon. In women, hair is distributed in a triangle, whose base covers the upper margin of the symphysis pubis and whose tip ends at the clitoris. In men and some hirsute women, the escutcheon is not so well circumscribed and extends onto the anterior abdominal wall toward the umbilicus.

Embryologically, the labia majora are homologous with the male scrotum. Labia vary somewhat in appearance, principally according to the amount of fat they contain. They are 7 to 8 cm in length, 2 to 3 cm in depth, and 1 to 1.5 cm in thickness. They are continuous directly with the mons pubis superiorly, and the round ligaments terminate at their upper borders. Posteriorly, the labia majora taper and merge into the area overlying the perineal body to form the posterior commissure.
Hair covers the labia majora outer surface but is absent on their inner surface. In addition, apocrine, eccrine, and sebaceous glands are abundant. Beneath the skin, there is a dense connective tissue layer, which is nearly void of muscular elements but is rich in elastic fibers and adipose tissue. This mass of fat provides bulk to the labia majora and is supplied with a rich venous plexus. During pregnancy, this vasculature commonly develops varicosities, especially in parous women, from increased venous pressure created by the enlarging uterus. They appear as engorged tortuous veins or as small grapelike clusters, but they are typically asymptomatic.

Each labium minus is a thin tissue fold that lies medial to each labium majus. In males, its homologue forms the ventral shaft of the penis. The labia minora extend superiorly, where each divides into two lamellae. From each side, the lower lamellae fuse to form the frenulum of the clitoris, and the upper merge to form the prepuce. Inferiorly, the labia minora extend to approach the midline as low ridges of tissue that join to form the fourchette. The size of the labia minora varies greatly among individuals, with lengths from 2 to 10 cm and widths from 1 to 5 cm (Lloyd, 2005).

Structurally, the labia minora are composed of connective tissue with numerous vessels, elastin fibers, and very few smooth muscle fibers. They are supplied with many nerve endings and are extremely sensitive (Ginger, 2011a). The epithelia of the labia minora vary with location. Thinly keratinized stratified squamous epithelium covers the outer surface of each labium. On their inner surface, the lateral portion is covered by this same epithelium up to a demarcating line—Hart line. Medial to this line, each labium is covered by squamous epithelium that is nonkeratinized. The labia minora lack hair follicles, eccrine glands, and apocrine glands. However, there are many sebaceous glands (Wilkinson, 2011).

The clitoris is the principal female erogenous organ and is the erectile homologue of the penis. It is located beneath the prepuce, above the frenulum and urethra, and projects downward and inward toward the vaginal opening. The clitoris rarely exceeds 2 cm in length and is composed of a glans, a corpus or body, and two crura (Verkauf, 1992). The glans is usually less than 0.5 cm in diameter, is covered by stratified squamous epithelium, and is richly innervated. The clitoral body contains two corpora cavernosa. Extending from the clitoral body, each corpus cavernosum diverges laterally to form a long, narrow crus. Each crus lies along the inferior surface of its respective ischiopubic ramus and deep to the ischiocavernosus muscle. The clitoral blood supply stems from branches of the internal pudendal artery. Specifically, the deep artery of the clitoris supplies the clitoral body, whereas the dorsal artery of the clitoris supplies the glans and prepuce.

Vestibule
This is the functionally mature female structure derived from the embryonic urogenital membrane. In adult women, it is an almond-shaped area that is enclosed by Hart line laterally, the external surface of the hymen medially, the clitoral frenulum anteriorly, and the fourchette posteriorly. The vestibule usually is perforated by six openings: the urethra, the vagina, two Bartholin gland ducts, and at times, two ducts of the largest paraurethral glands—the Skene glands. The posterior portion of the vestibule between the fourchette and the vaginal opening is called the fossa navicularis. It is usually observed only in nulliparas.

The bilateral Bartholin glands, also termed greater vestibular glands, are major glands that measure 0.5 to 1 cm in diameter. On their respective side, each lies inferior to the vascular vestibular bulb and deep to the inferior end of the bulbocavernosus muscle. The duct from each measures 1.5 to 2 cm long and opens distal to the hymeneal ring—one at 5 and the other at 7 o’clock on the vestibule. Following trauma or infection, either duct may swell and obstruct to form a cyst or, if infected, an abscess. In contrast, the minor vestibular glands are shallow glands lined
by simple mucin-secreting epithelium and open along Hart line.

The paraurethral glands are a collective arborization of glands whose multiple small ducts open predominantly along the entire inferior aspect of the urethra. The two largest are called Skene glands, and their ducts typically lie distally and near the urethral meatus. Clinically, inflammation and duct obstruction of any of the paraurethral glands can lead to urethral diverticulum formation.

The lower two thirds of the urethra lie immediately above the anterior vaginal wall. The urethral opening or meatus is in the midline of the vestibule, 1 to 1.5 cm below the pubic arch, and a short distance above the vaginal opening.

**Vagina and Hymen**

In adult women, the hymen is a membrane of varying thickness that surrounds the vaginal opening more or less completely. It is composed mainly of elastic and collagenous connective tissue, and both outer and inner surfaces are covered by nonkeratinized stratified squamous epithelium. The aperture of the intact hymen ranges in diameter from pinpoint to one that admits one or even two fingertips. Imperforate hymen is a rare malformation in which the vaginal orifice is occluded completely, causing retention of menstrual blood (Chap. 3, p. 38). As a rule, the hymen is torn at several sites during first coitus. However, identical tears may occur by other penetration, for example, by tampons used during menstruation. The edges of the torn tissue soon reepithelialize. In pregnant women, the hymeneal epithelium is thick and rich in glycogen. Changes produced in the hymen by childbirth are usually readily recognizable. For example, over time, the hymen transforms into several nodules of various sizes, termed hymeneal or myrtiform caruncles.

Proximal to the hymen, the vagina is a musculomembranous tube that extends to the uterus and is interposed lengthwise between the bladder and the rectum (Fig. 2-4). Anteriorly, the vagina is separated from the bladder and urethra by connective tissue—the vesicovaginal septum. Posteriorly, between the lower portion of the vagina and the rectum, there are similar tissues that together form the rectovaginal septum. The upper fourth of the vagina is separated from the rectum by the rectouterine pouch, also called the cul-de-sac or pouch of Douglas.
FIGURE 2-4 Vagina and surrounding anatomy. (From Corton, 2012, with permission.)

Normally, the anterior and posterior walls of the vaginal lumen lie in contact, with only a slight space intervening at the lateral margins. Vaginal length varies considerably, but commonly, the anterior wall measures 6 to 8 cm, whereas the posterior vaginal wall is 7 to 10 cm. The upper end of the vaginal vault is subdivided into anterior, posterior, and two lateral fornices by the cervix. These are of considerable clinical importance because the internal pelvic organs usually can be palpated through the thin walls of these fornices. Moreover, the posterior fornix provides surgical access to the peritoneal cavity.

At the midportion of the vagina, its lateral walls are attached to the pelvis by visceral connective tissue. These lateral attachments blend into investing fascia of the levator ani. In doing so, they create the anterior and posterior lateral vaginal sulci. These run the length of the vaginal
sidewalls and give the vagina an H shape when viewed in cross section.

The vaginal lining is composed of nonkeratinized stratified squamous epithelium and underlying lamina propria. In premenopausal women, this lining is thrown into numerous thin transverse ridges, known as rugae, which line the anterior and posterior vaginal walls along their length. Deep to this, there is a muscular layer, which contains smooth muscle, collagen, and elastin. Beneath this muscularis lies an adventitial layer consisting of collagen and elastin (Weber, 1997).

There are no vaginal glands. Instead, the vagina is lubricated by a transudate that originates from the vaginal subepithelial capillary plexus and crosses the permeable epithelium (Kim, 2011). Due to increased vascularity during pregnancy, vaginal secretions are notably increased. At times, this may be confused with amniotic fluid leakage, and clinical differentiation of these two is described in Chapter 22 (p. 448).

After birth-related epithelial trauma and healing, fragments of stratified epithelium occasionally are embedded beneath the vaginal surface. Similar to its native tissue, this buried epithelium continues to shed degenerated cells and keratin. As a result, firm epidermal inclusion cysts, which are filled with keratin debris, may form and are a common vaginal cyst.

The vagina has an abundant vascular supply. The proximal portion is supplied by the cervical branch of the uterine artery and by the vaginal artery. The latter may variably arise from the uterine or inferior vesical or directly from the internal iliac artery. The middle rectal artery contributes supply to the posterior vaginal wall, whereas the distal walls receive contributions from the internal pudendal artery. At each level, blood supply from each side forms anastomoses on the anterior and posterior vaginal walls with contralateral corresponding vessels.

An extensive venous plexus immediately surrounds the vagina and follows the course of the arteries. Lymphatics from the lower third, along with those of the vulva, drain primarily into the inguinal lymph nodes. Those from the middle third drain into the internal iliac nodes, and those from the upper third drain into the external, internal, and common iliac nodes.

**Perineum**

This diamond-shaped area between the thighs has boundaries that mirror those of the bony pelvic outlet: the pubic symphysis anteriorly, ischiopubic rami and ischial tuberosities anterolaterally, sacrotuberous ligaments posterolaterally, and coccyx posteriorly. An arbitrary line joining the ischial tuberosities divides the perineum into an anterior triangle, also called the urogenital triangle, and a posterior triangle, termed the anal triangle.

The perineal body is a fibromuscular mass found in the midline at the junction between these anterior and posterior triangles (Fig. 2-5). Also called the central tendon of the perineum, the perineal body measures 2 cm tall and wide and 1.5 cm thick. It serves as the junction for several structures and provides significant perineal support (Shafik, 2007; Woodman, 2002). Superficially, the bulbocavernosus, superficial transverse perineal, and external anal sphincter muscles converge on the central tendon. More deeply, the perineal membrane, portions of the pubococcygeus muscle, and internal anal sphincter contribute (Larson, 2010). The perineal body is incised by an episiotomy incision and is torn with second-, third-, and fourth-degree lacerations.
### Superficial Space of the Anterior Triangle

This triangle is bounded by the pubic rami superiorly, the ischial tuberosities laterally, and the superficial transverse perineal muscles posteriorly. It is divided into superficial and deep spaces by the perineal membrane. This membranous partition is a dense fibrous sheet that was previously known as the inferior fascia of the urogenital diaphragm. The perineal membrane attaches laterally to the ischiopubic rami, medially to the distal third of the urethra and vagina, posteriorly to the perineal body, and anteriorly to the arcuate ligament of the pubis.

The superficial space of the anterior triangle is bounded deeply by the perineal membrane and superficially by Colles fascia. As noted earlier, Colles fascia is the continuation of Scarpa fascia onto the perineum. On the perineum, Colles fascia securely attaches laterally to the pubic rami and fascia lata of the thigh, inferiorly to the superficial transverse perineal muscle and inferior border of the perineal membrane, and medially to the urethra, clitoris, and vagina. As such, the superficial space of the anterior triangle is a relatively closed compartment, and expanding infection or hematoma within it may bulge yet remains contained.

This superficial pouch contains several important structures, which include the Bartholin glands, vestibular bulbs, clitoral body and crura, branches of the pudendal vessels and nerve, and...
the ischiocavernosus, bulbocavernosus, and superficial transverse perineal muscles. Of these muscles, the ischiocavernosus muscles each attach on their respective side to the medial aspect of the ischial tuberosity inferiorly and the ischiopubic ramus laterally. Anteriorly, each attaches to a clitoral crus and may help maintain clitoral erection by compressing the crus to obstruct venous drainage. The bilateral bulbocavernosus muscles overlie the vestibular bulbs and Bartholin glands. They attach to the body of the clitoris anteriorly and the perineal body posteriorly. The muscles constrict the vaginal lumen and aid release of secretions from the Bartholin glands. They also may contribute to clitoral erection by compressing the deep dorsal vein of the clitoris. The bulbocavernosus and ischiocavernosus muscles also pull the clitoris downward. Last, the superficial transverse perineal muscles are narrow strips that attach to the ischial tuberosities laterally and the perineal body medially. They may be attenuated or even absent, but when present, they contribute to the perineal body (Corton, 2012).

Embryologically, the vestibular bulbs correspond to the corpora spongiosa of the penis. These almond-shaped aggregations of veins are 3 to 4 cm long, 1 to 2 cm wide, and 0.5 to 1 cm thick and lie beneath the bulbocavernosus muscle on either side of the vestibule. The bulbs terminate inferiorly at approximately the middle of the vaginal opening and extend upward toward the clitoris. Their anterior extensions merge in the midline, below the clitoral body. During childbirth, veins in the vestibular bulbs may be lacerated or even rupture to create a vulvar hematoma enclosed within the superficial space of the anterior triangle.

**Deep Space of the Anterior Triangle**

This space lies deep to the perineal membrane and extends up into the pelvis (Fig. 2-6) (Mirilas, 2004). In contrast to the superficial perineal space, the deep space is continuous superiorly with the pelvic cavity (Corton, 2005). It contains portions of urethra and vagina, certain portions of internal pudendal artery branches, and the compressor urethrae and urethrovaginal sphincter muscles, which comprise part of the striated urogenital sphincter complex.
Figure 2-6 Deep space of the anterior triangle of the perineum. Structures on the right side of the image can be seen after removal of the perineal membrane. Also shown are structures that attach to the perineal body: bulbocavernosus, superficial transverse perineal, external anal sphincter, and puboperinealis muscles as well as the perineal membrane. (From Corton, 2012, with permission.)

Pelvic Diaphragm

Found deep to the anterior and posterior triangles, this broad muscular sling provides substantial support to the pelvic viscera. The pelvic diaphragm is composed of the levator ani and the coccygeus muscle. The levator ani is composed of the pubococcygeus, puborectalis, and iliococcygeus muscles. The pubococcygeus muscle is also termed the pubovisceral muscle and is subdivided based on points of insertion and function. These include the pubovaginalis, puboperinealis, and puboanal is muscles, which insert into the vaginal, perineal body, and anus, respectively (Kearney, 2004).

Vaginal birth conveys significant risk for damage to the levator ani or to its innervation (DeLancey, 2003; Weidner, 2006). Of these muscles, the pubovisceral muscle is more commonly
Evidence supports that these injuries may predispose women to greater risk of pelvic organ prolapse or urinary incontinence (DeLancey, 2007a,b; Rortveit, 2003). For this reason, current research efforts are aimed at minimizing these injuries.

**Posterior Triangle**

This triangle contains the ischioanal fossae, anal canal, and anal sphincter complex, which consists of the internal anal sphincter, external anal sphincter, and puborectalis muscle. Branches of the pudendal nerve and internal pudendal vessels are also found within this triangle.

**Ischioanal Fossae.** Also known as ischiorectal fossae, these two fat-filled wedge-shaped spaces are found on either side of the anal canal and comprise the bulk of the posterior triangle (Fig. 2-7). Each fossa has skin as its superficial base, whereas its deep apex is formed by the junction of the levator ani and obturator internus muscle. Other borders include: laterally, the obturator internus muscle fascia and ischial tuberosity; inferomedially, the anal canal and sphincter complex; superomedially, the inferior fascia of the downwardly sloping levator ani; posteriorly, the gluteus maximus muscle and sacrotuberous ligament; and anteriorly, the inferior border of the anterior triangle.

![Figure 2-7 Anal canal and ischioanal fossa. (From Corton, 2012, with permission.)](image)

The fat found within each fossa provides support to surrounding organs yet allows rectal distention during defecation and vaginal stretching during delivery. Clinically, injury to vessels in the posterior triangle can lead to hematoma formation in the ischioanal fossa, and the potential for
large accumulation in these easily distensible spaces. Moreover, the two fossae communicate dorsally, behind the anal canal. This can be especially important because an episiotomy infection or hematoma may extend from one fossa into the other.

**Anal Canal.** This distal continuation of the rectum begins at the level of levator ani attachment to the rectum and ends at the anal skin. Along this 4- to 5-cm length, the mucosa consists of columnar epithelium in the uppermost portion, but at the dentate or pectinate line, simple stratified squamous epithelium begins and continues to the anal verge. Here, keratin and skin adnexa join the squamous epithelium.

The anal canal has several lateral tissue layers. Inner layers include the anal mucosa, the internal anal sphincter, and an intersphincteric space that contains continuation of the rectum’s longitudinal smooth muscle layer. An outer layer contains the puborectalis muscle as its cephalad component and the external anal sphincter caudally.

Within the anal canal, three highly vascularized submucosal arteriovenous plexuses termed anal cushions aid complete closure of the canal and fecal continence when apposed. Increasing uterine size, excessive straining, and hard stool create increased pressure that ultimately leads to degeneration and subsequent laxity of the cushion’s supportive connective tissue base. These cushions then protrude into and downward through the anal canal. This leads to venous engorgement within the cushions—now termed hemorrhoids. Venous stasis results in inflammation, erosion of the cushion’s epithelium, and then bleeding.

External hemorrhoids are those that arise distal to the pectinate line. They are covered by stratified squamous epithelium and receive sensory innervation from the inferior rectal nerve. Accordingly, pain and a palpable mass are typical complaints. Following resolution, a hemorrhoidal tag may remain and is composed of redundant anal skin and fibrotic tissue. In contrast, internal hemorrhoids are those that form above the dentate line and are covered by insensitive anorectal mucosa. These may prolapse or bleed but rarely become painful unless they undergo thrombosis or necrosis.

**Anal Sphincter Complex.** Two sphincters surround the anal canal to provide fecal continence—the external and internal anal sphincters. Both lie proximate to the vagina, and one or both may be torn during vaginal delivery. The internal anal sphincter (IAS) is a distal continuation of the rectal circular smooth muscle layer. It receives predominantly parasympathetic fibers, which pass through the pelvic splanchnic nerves. Along its length, this sphincter is supplied by the superior, middle, and inferior rectal arteries. The IAS contributes the bulk of anal canal resting pressure for fecal continence and relaxes prior to defecation. The IAS measures 3 to 4 cm in length, and at its distal margin, it overlaps the external sphincter for 1 to 2 cm (DeLancey, 1997; Rociu, 2000). The distal site at which this overlap ends, called the intersphincteric groove, is palpable on digital examination.

In contrast, the external anal sphincter (EAS) is a striated muscle ring that anteriorly attaches to the perineal body and that posteriorly connects to the coccyx via the anococcygeal ligament. The EAS maintains a constant resting contraction to aid continence, provides additional squeeze pressure when continence is threatened, yet relaxes for defecation. Traditionally, the EAS has been described as three parts, which include the subcutaneous, superficial, and deep portions. However, many consider the deep portion to be composed fully or in part by the puborectalis muscle (Raizada, 2008). The external sphincter receives blood supply from the inferior rectal artery, which is a branch of the internal pudendal artery. Somatic motor fibers from the inferior rectal branch of the pudendal nerve supply innervation. Clinically, the IAS and EAS may be
involved in fourth-degree laceration during vaginal delivery, and reunion of these rings is integral to defect repair (Chap. 27, p. 548).

**Pudendal Nerve**

This is formed from the anterior rami of S₂–₄ spinal nerves (Fig. 2-8). It courses between the piriformis and coccygeus muscles and exits through the greater sciatic foramen at a location posterior to the sacrospinous ligament and just medial to the ischial spine (Barber, 2002). Thus, when injecting local anesthetic for a pudendal nerve block, the ischial spine serves an identifiable landmark (Chap. 25, p. 508). The pudendal nerve then runs beneath the sacrospinous ligament and above the sacrotuberous ligament as it reenters the lesser sciatic foramen to course along the obturator internus muscle. Atop this muscle, the nerve lies within the pudendal canal, also known as Alcock canal, which is formed by splitting of the obturator internus investing fascia (Shafik, 1999). In general, the pudendal nerve is relatively fixed as it courses behind the sacrospinous ligament and within the pudendal canal. Accordingly, it may be at risk of stretch injury during downward displacement of the pelvic floor during childbirth (Lien, 2005).

**FIGURE 2-8** Pudendal nerve and vessels. (From Corton, 2012, with permission.)
The pudendal nerve leaves this canal to enter the perineum and divides into three terminal branches. Of these, the dorsal nerve of the clitoris runs between the ischiocavernosus muscle and perineal membrane to supply the clitoral glans (Ginger, 2011b). The perineal nerve runs superficial to the perineal membrane (Montoya, 2011). It divides into posterior labial branches and muscular branches, which serve the labial skin and the anterior perineal triangle muscles, respectively. The inferior rectal branch runs through the ischioanal fossa to supply the external anal sphincter, the anal mucosa, and the perianal skin (Mahakkanukrauh, 2005). The major blood supply to the perineum is via the internal pudendal artery, and its branches mirror the divisions of the pudendal nerve.

**INTERNAL GENERATIVE ORGANS**

**Uterus**

The nonpregnant uterus is situated in the pelvic cavity between the bladder anteriorly and the rectum posteriorly. Almost the entire posterior wall of the uterus is covered by serosa, that is, visceral peritoneum (Fig. 2-9). The lower portion of this peritoneum forms the anterior boundary of the rectouterine cul-de-sac, or pouch of Douglas. Only the upper portion of the anterior wall of the uterus is so covered. The peritoneum in this area reflects forward onto the bladder dome to create the vesicouterine pouch. The lower portion of the anterior uterine wall is united to the posterior wall of the bladder by a well-defined loose connective tissue layer—the vesicouterine space. Clinically, during cesarean delivery, the peritoneum of the vesicouterine pouch is sharply incised, and the vesicouterine space is entered. Dissection caudally within this space lifts the bladder off the lower uterine segment for hysterotomy and delivery (Chap. 30, p. 593).
The uterus is pear shaped and consists of two major but unequal parts. There is an upper triangular portion—the body or corpus, and a lower, cylindrical portion—the cervix, which projects into the vagina. The isthmus is the union site of these two. It is of special obstetrical significance because it forms the lower uterine segment during pregnancy. At each superolateral margin of the body is a uterine cornu, from which a fallopian tube emerges. Also in this area are the origins of the round and uteroovarian ligaments. Between the points of fallopian tube insertion is the convex upper uterine segment termed the fundus.

The bulk of the uterine body, but not the cervix, is muscle. The inner surfaces of the anterior and posterior walls lie almost in contact, and the cavity between these walls forms a mere slit. The nulligravid uterus measures 6 to 8 cm in length compared with 9 to 10 cm in multiparous women. The uterus averages 60 g and typically weighs more in parous women (Langlois, 1970; Sheikazadi, 2010). In nulligravidas, the fundus and cervix are approximately equal in length, but in multiparas, the cervix is only a little more than a third of the total length.

Pregnancy stimulates remarkable uterine growth due to muscle fiber hypertrophy. The uterine fundus, a previously flattened convexity between tubal insertions, now becomes dome shaped. Moreover, the round ligaments appear to insert at the junction of the middle and upper thirds of the organ. The fallopian tubes elongate, but the ovaries grossly appear unchanged.
Cervix

The cervical portion of the uterus is fusiform and open at each end by small apertures—the internal and external cervical ora. Proximally, the upper boundary of the cervix is the internal os, which corresponds to the level at which the peritoneum is reflected up onto the bladder. The upper cervical segment—the portio supravaginalis, lies above the vagina’s attachment to the cervix (Fig. 2-10). It is covered by peritoneum on its posterior surface, the cardinal ligaments attach laterally, and it is separated from the overlying bladder by loose connective tissue. The lower cervical portion protrudes into the vagina as the portio vaginalis. Before childbirth, the external cervical os is a small, regular, oval opening. After labor, especially vaginal childbirth, the orifice is converted into a transverse slit that is divided such that there are the so-called anterior and posterior cervical lips. If torn deeply during labor or delivery, the cervix may heal in such a manner that it appears irregular, nodular, or stellate.

**FIGURE 2-10** Uterus, adnexa, and associated anatomy. (From Corton, 2012, with permission.)
The portion of the cervix exterior to the external os is called the ectocervix and is lined predominantly by nonkeratinized stratified squamous epithelium. In contrast, the endocervical canal is covered by a single layer of mucin-secreting columnar epithelium, which creates deep cleftlike infoldings or “glands.” Commonly during pregnancy, the endocervical epithelium moves out and onto the ectocervix in a physiological process termed eversion (Chap. 4, p. 48).

The cervical stroma is composed mainly of collagen, elastin, and proteoglycans, but very little smooth muscle. Changes in the amount, composition, and orientation of these components lead to cervical ripening prior to labor onset. In early pregnancy, increased vascularity within the cervix stroma beneath the epithelium creates an ectocervical blue tint that is characteristic of Chadwick sign. Cervical edema leads to softening—Goodell sign, whereas isthmic softening is Hegar sign.

**Myometrium and Endometrium**

Most of the uterus is composed of myometrium, which is smooth muscle bundles united by connective tissue containing many elastic fibers. Interlacing myometrial fibers surround myometrial vessels and contract to compress these. As shown in Figure 2-11, this anatomy is integral to hemostasis at the placental site during the third stage of labor.
The number of myometrial muscle fibers varies by location (Schwalm, 1966). Levels progressively diminish caudally such that, in the cervix, muscle makes up only 10 percent of the tissue mass. In the uterine body inner wall, there is relatively more muscle than in outer layers. And, in the anterior and posterior walls, there is more muscle than in the lateral walls. During pregnancy, the upper myometrium undergoes marked hypertrophy, but there is no significant change in cervical muscle content.

The uterine cavity is lined with endometrium, which is composed of an overlying epithelium, invaginating glands, and a supportive, vascular stroma. As discussed in Chapter 5 (p. 84), the endometrium varies greatly throughout the menstrual cycle and during pregnancy. This layer is divided into a functionalis layer, which is sloughed with menses, and a basalis layer, which serves to regenerate the functionalis layer following each menses.
Ligaments

There are several ligaments that extend from the uterine surface toward the pelvic sidewalls and include the round, broad, cardinal, and uterosacral ligaments (Figs. 2-9 and 2-12). The round ligament corresponds embryologically to the male gubernaculum testis (Acién, 2011). It originates somewhat below and anterior to the origin of the fallopian tubes. Clinically, this orientation can aid in fallopian tube identification during puerperal sterilization. This is important if pelvic adhesions limit tubal mobility and thus, limit fimbria visualization prior to tubal ligation. Each round ligament extends laterally and downward into the inguinal canal, through which it passes, to terminate in the upper portion of the labium majus. Sampson artery, a branch of the uterine artery, runs within this ligament. In nonpregnant women, the round ligament varies from 3 to 5 mm in diameter and is composed of smooth muscle bundles separated by fibrous tissue septa (Mahran, 1965). During pregnancy, these ligaments undergo considerable hypertrophy and increase appreciably in both length and diameter.
The broad ligaments are two winglike structures that extend from the lateral uterine margins to the pelvic sidewalls. With vertical sectioning through this ligament proximate to the uterus, a triangular shape can be seen, and the uterine vessels and ureter are found at its base. The broad ligaments divide the pelvic cavity into anterior and posterior compartments. Each broad ligament consists of a fold of peritoneum termed the anterior and posterior leaves. This peritoneum drapes over structures extending from each cornu. Peritoneum that overlies the fallopian tube is termed the mesosalpinx, that around the round ligament is the mesoteres, and that over the uteroovarian ligament is the mesovarium. Peritoneum that extends beneath the fimbriated end of the fallopian tube toward the pelvic wall forms the infundibulopelvic ligament or suspensory ligament of the...
ovary. This contains nerves and the ovarian vessels, and during pregnancy, these vessels, especially the venous plexuses, are dramatically enlarged. Specifically, the diameter of the ovarian vascular pedicle increases from 0.9 cm to reach 2.6 cm at term (Hodgkinson, 1953).

The cardinal ligament—also called the transverse cervical ligament or Mackenrodt ligament—is the thick base of the broad ligament. Medially, it is united firmly to the uterus and upper vagina.

Each uterosacral ligament originates with a posterolateral attachment to the supravaginal portion of the cervix and inserts into the fascia over the sacrum, with some variations (Ramanah, 2012; Umek, 2004). These ligaments are composed of connective tissue, small bundles of vessels and nerves, and some smooth muscle. Covered by peritoneum, these ligaments form the lateral boundaries of the pouch of Douglas.

The term parametrium is used to describe the connective tissues adjacent and lateral to the uterus within the broad ligament. Paracervical tissues are those adjacent to the cervix, whereas paracolpium is that tissue lateral to the vaginal walls.

### Blood Supply

During pregnancy, there is marked hypertrophy of the uterine vasculature, which is supplied principally from the uterine and ovarian arteries (see Fig. 2-9). The uterine artery, a main branch of the internal iliac artery—previously called the hypogastric artery—enters the base of the broad ligament and makes its way medially to the side of the uterus. Approximately 2 cm lateral to the cervix, the uterine artery crosses over the ureter. This proximity is of great surgical significance as the ureter may be injured or ligated during hysterectomy when the vessels are clamped and ligated.

Once the uterine artery has reached the supravaginal portion of the cervix, it divides. The smaller cervicovaginal artery supplies blood to the lower cervix and upper vagina. The main branch turns abruptly upward and extends as a highly convoluted vessel that traverses along the lateral margin of the uterus. A branch of considerable size extends into the upper portion of the cervix, whereas numerous other branches penetrate the body of the uterus to form the arcuate arteries. These encircle the organ by coursing within the myometrium just beneath the serosal surface. These vessels from each side anastomose at the uterine midline. From the arcuate arteries, radial branches originate at right angles, traverse inward through the myometrium, enter the endometrium, and branch there to become basal arteries or coiled spiral arteries. The spiral arteries supply the functionalis layer. These vessels respond—especially by vasoconstriction and dilatation—to a number of hormones and thus serve an important role in menstruation. Also called the straight arteries, the basal arteries extend only into the basalis layer and are not responsive to hormonal influences.

Just before the main uterine artery vessel reaches the fallopian tube, it divides into three terminal branches. The ovarian branch of the uterine artery forms an anastomosis with the terminal branch of the ovarian artery; the tubal branch makes its way through the mesosalpinx and supplies part of the fallopian tube; and the fundal branch penetrates the uppermost uterus.

In addition to the uterine artery, the uterus receives blood supply from the ovarian artery. This artery is a direct branch of the aorta and enters the broad ligament through the infundibulopelvic ligament. At the ovarian hilum, it divides into smaller branches that enter the ovary. As the ovarian artery runs along the hilum, it also sends several branches through the mesosalpinx to supply the fallopian tubes. Its main stem, however, traverses the entire length of the broad ligament and makes its way to the uterine cornu. Here, it forms an anastomosis with the ovarian branch of the uterine artery. This dual uterine blood supply creates a vascular reserve to prevent uterine ischemia if ligation of the uterine or internal iliac artery is performed to control postpartum hemorrhage.
Uterine veins accompany their respective arteries. As such, the arcuate veins unite to form the uterine vein, which empties into the internal iliac vein and then the common iliac vein. Some of the blood from the upper uterus, the ovary, and the upper part of the broad ligament is collected by several veins. Within the broad ligament, these veins form the large pampiniform plexus that terminates in the ovarian vein. From here, the right ovarian vein empties into the vena cava, whereas the left ovarian vein empties into the left renal vein.

Blood supply to the pelvis is predominantly supplied from branches of the internal iliac artery. These branches are organized into anterior and posterior divisions, and subsequent branches are highly variable between individuals (Fig. 2-13). The anterior division provides blood supply to the pelvic organs and perineum and includes the inferior gluteal, internal pudendal, middle rectal, vaginal, uterine, and obturator arteries, as well as the umbilical artery and its continuation as the superior vesical artery. The posterior division branches extend to the buttock and thigh and include the superior gluteal, lateral sacral, and iliolumbar arteries. For this reason, during internal iliac artery ligation, many advocate ligation distal to the posterior division to avoid compromised blood flow to the areas supplied by this division (Bleich, 2007).
Lymphatics

The endometrium is abundantly supplied with lymphatic vessels that are confined largely to the basalis layer. The lymphatics of the underlying myometrium are increased in number toward the serosal surface and form an abundant lymphatic plexus just beneath it. Lymphatics from the cervix terminate mainly in the internal iliac nodes, which are situated near the bifurcation of the common iliac vessels. The lymphatics from the uterine corpus are distributed to two groups of nodes. One
set of vessels drains into the internal iliac nodes. The other set, after joining certain lymphatics from the ovarian region, terminates in the paraaortic lymph nodes.

### Innervation

As a brief review, the peripheral nervous system is divided in a somatic division, which innervates skeletal muscle, and an autonomic division, which innervates smooth muscle, cardiac muscle, and glands. Pelvic visceral innervation is predominantly autonomic. The autonomic portion is further divided in sympathetic and parasympathetic components.

Sympathetic innervation to pelvic viscera begins with the superior hypogastric plexus, also termed the presacral nerve (Fig. 2-14). Beginning below the aortic bifurcation and extending downward retroperitoneally, this plexus is formed by sympathetic fibers arising from spinal levels T10 through L2. At the level of the sacral promontory, this superior hypogastric plexus divides into a right and a left hypogastric nerve, which run downward along the pelvis side walls (Açar, 2012; Moszkowicz, 2011).

**FIGURE 2-14** Pelvic innervation. (From Corton, 2012, with permission.)
In contrast, parasympathetic innervation to the pelvic viscera derives from neurons at spinal levels S₂ through S₄. Their axons exit as part of the anterior rami of the spinal nerves for those levels. These combine on each side to form the pelvic splanchnic nerves, also termed nervi erigentes.

Blending of the two hypogastric nerves (sympathetic) and the two pelvic splanchnic nerves (parasympathetic) gives rise to the inferior hypogastric plexus, also termed the pelvic plexus. This retroperitoneal plaque of nerves lies at the S₄ and S₅ level (Spackman, 2007). From here, fibers of this plexus accompany internal iliac artery branches to their respective pelvic viscera. Thus, the inferior hypogastric plexus divides into three plexuses. The vesical plexus innervates the bladder and the middle rectal travels to the rectum, whereas the uterovaginal plexus, also termed Frankenhäuser plexus, reaches the proximal fallopian tubes, uterus, and upper vagina. Extensions of the inferior hypogastric plexus also reach the perineum along the vagina and urethra to innervate the clitoris and vestibular bulbs (Montoya, 2011). Of these, the uterovaginal plexus is composed of variably sized ganglia, but particularly of a large ganglionic plate that is situated on either side of the cervix, proximate to the uterosacral and cardinal ligaments (Ramanah, 2012).

Most afferent sensory fibers from the uterus ascend through the inferior hypogastric plexus and enter the spinal cord via T₁₀ through T₁₂ and L₁ spinal nerves. These transmit the painful stimuli of contractions to the central nervous system. The sensory nerves from the cervix and upper part of the birth canal pass through the pelvic splanchnic nerves to the second, third, and fourth sacral nerves. Those from the lower portion of the birth canal pass primarily through the pudendal nerve. As described earlier (p. 24), anesthetic blocks used in labor and delivery target this innervation.

### Ovaries

Compared with each other, as well as between women, the ovaries differ considerably in size. During childbearing years, they measure 2.5 to 5 cm in length, 1.5 to 3 cm in breadth, and 0.6 to 1.5 cm in thickness. Their position also varies, but they usually lie in the upper part of the pelvic cavity and rest in a slight depression on the lateral wall of the pelvis. This ovarian fossa of Waldeyer is between the divergent external and internal iliac vessels.

The uteroovarian ligament originates from the lateral and upper posterior portion of the uterus, just beneath the tubal insertion level, and extends to the uterine pole of the ovary. Usually, this ligament is a few centimeters long and 3 to 4 mm in diameter. It is made up of muscle and connective tissue and is covered by peritoneum—the mesovarium. As described on page 28, blood supply traverses to and from the ovary through this double-layered mesovarium to enter the ovarian hilum.

The ovary consists of a cortex and medulla. In young women, the outermost portion of the cortex is smooth, has a dull white surface, and is designated the tunica albuginea. On its surface, there is a single layer of cuboidal epithelium, the germinal epithelium of Waldeyer. Beneath this epithelium, the cortex contains oocytes and developing follicles. The medulla is the central portion, which is composed of loose connective tissue. There are a large number of arteries and veins in the medulla and a small number of smooth muscle fibers.

The ovaries are supplied with both sympathetic and parasympathetic nerves. The sympathetic nerves are derived primarily from the ovarian plexus that accompanies the ovarian vessels and originates in the renal plexus. Others are derived from the plexus that surrounds the ovarian branch of the uterine artery. Parasympathetic input is from the vagus nerve. Sensory afferents follow the ovarian artery and enter at T₁₀ spinal cord level.
Fallopian Tubes

Also called oviducts, these serpentine tubes extend 8 to 14 cm from the uterine cornua and are anatomically classified along their length as an interstitial portion, isthmus, ampulla, and infundibulum (Fig. 2-15). Most proximal, the interstitial portion is embodied within the uterine muscular wall. Next, the narrow 2- to 3-mm isthmus adjoins the uterus and widens gradually into the 5- to 8-mm, more lateral ampulla. Last, the infundibulum is the funnel-shaped fimbriated distal extremity of the tube, which opens into the abdominal cavity. The latter three extrauterine portions are covered by the mesosalpinx at the superior margin of the broad ligament.

FIGURE 2-15 The fallopian tube of an adult woman with cross-sectioned illustrations of the gross...
structure in several portions: (A) isthmus, (B) ampulla, and (C) infundibulum. Below these are photographs of corresponding histological sections. (Photographs contributed by Dr. Kelley S. Carrick.)

In cross section, the extrauterine fallopian tube contains a mesosalpinx, myosalpinx, and endosalpinx. The outer of these, the mesosalpinx, is a single-cell mesothelial layer functioning as visceral peritoneum. In the myosalpinx, smooth muscle is arranged in an inner circular and an outer longitudinal layer. In the distal tube, the two layers are less distinct and are replaced near the fimbriated extremity by sparse interlacing muscular fibers. The tubal musculature undergoes rhythmic contractions constantly, the rate of which varies with cyclical ovarian hormonal changes.

The tubal mucosa or endosalpinx is a single columnar epithelium composed of ciliated and secretory cells resting on a sparse lamina propria. It is in close contact with the underlying myosalpinx. The ciliated cells are most abundant at the fimbriated extremity, but elsewhere, they are found in discrete patches. There also are differences in the proportions of these two cell types in the different ovarian cycle phases. The mucosa is arranged in longitudinal folds that become progressively more complex toward the fimbria. In the ampulla, the lumen is occupied almost completely by the arborescent mucosa. The current produced by the tubal cilia is such that the direction of flow is toward the uterine cavity. Tubal peristalsis created by cilia and muscular layer contraction is believed to be an important factor in ovum transport (Croxatto, 2002).

The tubes are supplied richly with elastic tissue, blood vessels, and lymphatics. Sympathetic innervation of the tubes is extensive, in contrast to their parasympathetic innervation. This nerve supply derives partly from the ovarian plexus and partly from the uterovaginal plexus. Sensory afferent fibers ascend to T₁₀ spinal cord levels.

MUSCULOSKELETAL PELVIC ANATOMY

Pelvic Bones

The pelvis is composed of four bones—the sacrum, coccyx, and two innominate bones. Each innominate bone is formed by the fusion of three bones—the ilium, ischium, and pubis (Fig. 2-16). Both innominate bones are joined to the sacrum at the sacroiliac synchondroses and to one another at the symphysis pubis.
The pelvis is conceptually divided into false and true components. The false pelvis lies above the linea terminalis, and the true pelvis is below this anatomical boundary (Fig. 2-17). The false pelvis is bounded posteriorly by the lumbar vertebra and laterally by the iliac fossa. In front, the boundary is formed by the lower portion of the anterior abdominal wall.
The true pelvis is the portion important in childbearing and can be described as an obliquely truncated, bent cylinder with its greatest height posteriorly. The linea terminalis serves as the superior border, whereas the pelvic outlet is the inferior margin. The posterior boundary is the anterior surface of the sacrum, and the lateral limits are formed by the inner surface of the ischial bones and the sacrosciatic notches and ligaments. In front, the true pelvis is bounded by the pubic bones, by the ascending superior rami of the ischial bones, and by the obturator foramina.

The sidewalls of the true pelvis of an adult woman converge somewhat. Extending from the middle of the posterior margin of each ischium are the ischial spines. These are of great obstetrical importance because the distance between them usually represents the shortest diameter of the true pelvis. They also serve as valuable landmarks in assessing the level to which the presenting part of the fetus has descended into the true pelvis (Chap. 22, p. 449). Last, as described earlier, these aid pudendal nerve block placement.

The sacrum forms the posterior wall of the true pelvis. Its upper anterior margin corresponds to the promontory that may be felt during bimanual pelvic examination in women with a small pelvis. It can provide a landmark for clinical pelvimetry. Normally, the sacrum has a marked vertical and a less pronounced horizontal concavity, which in abnormal pelves may undergo important variations. A straight line drawn from the promontory to the tip of the sacrum usually measures 10 cm, whereas the distance along the concavity averages 12 cm.

Pelvic Joints

Anteriorly, the pelvic bones are joined together by the symphysis pubis. This structure consists of fibrocartilage and the superior and inferior pubic ligaments. The latter ligament is frequently
designated the arcuate ligament of the pubis. Posteriorly, the pelvic bones are joined by articulations between the sacrum and the iliac portion of the innominate bones to form the sacroiliac joints.

These joints in general have a limited degree of mobility. However, during pregnancy, there is remarkable relaxation of these joints at term, caused by upward gliding of the sacroiliac joint (Borell, 1957). The displacement, which is greatest in the dorsal lithotomy position, may increase the diameter of the outlet by 1.5 to 2.0 cm. This is the main justification for placing a woman in this position for a vaginal delivery. But this pelvic outlet diameter increase occurs only if the sacrum is allowed to rotate posteriorly. Thus, it will not occur if the sacrum is forced anteriorly by the weight of the maternal pelvis against the delivery table or bed (Russell, 1969, 1982). Sacroiliac joint mobility is also the likely reason that the McRoberts maneuver often is successful in releasing an obstructed shoulder in a case of shoulder dystocia (Chap. 27, p. 541). These changes have also been attributed to the success of the modified squatting position to hasten second-stage labor (Gardosi, 1989). The squatting position may increase the interspinous diameter and the pelvic outlet diameter (Russell, 1969, 1982). These latter observations are unconfirmed, but this position is assumed for birth in many societies.

**Planes and Diameters of the Pelvis**

The pelvis is described as having four imaginary planes:

1. The plane of the pelvic inlet—the superior strait.
2. The plane of the pelvic outlet—the inferior strait.
3. The plane of the midpelvis—the least pelvic dimensions.
4. The plane of greatest pelvic dimension—of no obstetrical significance.

**Pelvic Inlet**

Also called the superior strait, the pelvic inlet is also the superior plane of the true pelvis. As noted earlier, it is bounded posteriorly by the promontory and alae of the sacrum, laterally by the linea terminalis, and anteriorly by the horizontal pubic rami and the symphysis pubis. During labor, fetal head engagement is defined by the fetal head’s biparietal diameter passing through this plane. To aid this passage, the inlet of the female pelvis—compared with the male pelvis—typically is more nearly round than ovoid. Caldwell (1934) identified a nearly round or gynecoid pelvic inlet in approximately half of white women.

Four diameters of the pelvic inlet are usually described: anteroposterior, transverse, and two oblique diameters. Of these, distinct anteroposterior diameters have been described using specific landmarks. Most cephalad, the anteroposterior diameter, termed the true conjugate, extends from the uppermost margin of the symphysis pubis to the sacral promontory. The clinically important obstetrical conjugate is the shortest distance between the sacral promontory and the symphysis pubis. Normally, this measures 10 cm or more, but unfortunately, it cannot be measured directly with examining fingers. Thus, for clinical purposes, the obstetrical conjugate is estimated indirectly by subtracting 1.5 to 2 cm from the diagonal conjugate, which is determined by measuring the distance from the lowest margin of the symphysis to the sacral promontory (Fig. 2-18).
FIGURE 2-18 Vaginal examination to determine the diagonal conjugate. P = sacral promontory; S = symphysis pubis.

The transverse diameter is constructed at right angles to the obstetrical conjugate and represents the greatest distance between the linea terminalis on either side. It usually intersects the obstetrical conjugate at a point approximately 5 cm in front of the promontory and measures approximately 13 cm. Each of the two oblique diameters extends from one sacroiliac synchondrosis to the contralateral iliopubic eminence. Each eminence is a minor elevation that marks the union site of the ilium and pubis. These oblique diameters average less than 13 cm.

Midpelvis and Pelvic Outlet
The midpelvis is measured at the level of the ischial spines, also called the midplane or plane of least pelvic dimensions (Fig. 2-19). During labor, the degree of fetal head descent into the true pelvis may be described by station, and the midpelvis and ischial spines serve to mark zero station. The interspinous diameter is 10 cm or slightly greater, is usually the smallest pelvic diameter, and, in cases of obstructed labor, is particularly important. The anteroposterior diameter
through the level of the ischial spines normally measures at least 11.5 cm.

**FIGURE 2-19** Adult female pelvis demonstrating the interspinous diameter of the midpelvis. The anteroposterior and transverse diameters of the pelvic inlet are also shown.

The pelvic outlet consists of two approximately triangular areas whose boundaries mirror those of the perineal triangle described earlier (p. 21). They have a common base, which is a line drawn between the two ischial tuberosities. The apex of the posterior triangle is the tip of the sacrum, and the lateral boundaries are the sacrotuberous ligaments and the ischial tuberosities. The anterior triangle is formed by the descending inferior rami of the pubic bones. These rami unite at an angle of 90 to 100 degrees to form a rounded arch under which the fetal head must pass. Clinically, three diameters of the pelvic outlet usually are described—the anteroposterior, transverse, and posterior sagittal. Unless there is significant pelvic bony disease, the pelvic outlet seldom obstructs vaginal delivery.

### Pelvic Shapes

The Caldwell-Moloy (1933, 1934) anatomical classification of the pelvis is based on shape, and its concepts aid in an understanding of labor mechanisms. Specifically, the greatest transverse diameter of the inlet and its division into anterior and posterior segments are used to classify the pelvis as gynecoid, anthropoid, android, or platypelloid. The posterior segment determines the type of pelvis, whereas the anterior segment determines the tendency. These are both determined because many pelves are not pure but are mixed types. For example, a gynecoid pelvis with an android tendency means that the posterior pelvis is gynecoid and the anterior pelvis is android shaped.

From viewing the four basic types in **Figure 2-20**, the configuration of the gynecoid pelvis would intuitively seem suited for delivery of most fetuses. Indeed, Caldwell (1939) reported that the gynecoid pelvis was found in almost half of women.
FIGURE 2-20 The four parent pelvic types of the Caldwell–Moloy classification. A line passing through the widest transverse diameter divides the inlets into posterior (P) and anterior (A) segments.

REFERENCES

Integral to successful reproduction is a normally functioning genital tract, both anatomically and physiologically. A number of developmental abnormalities can lead to infertility, subfertility, spontaneous abortion, or midpregnancy and preterm delivery. To care for affected women, it is imperative that the clinician have a working knowledge of genitourinary system development.

**UTERINE FLEXION**

Embryologically in females, the external genitalia, gonads, and müllerian ducts each derive from different primordia and in close association with the urinary tract and hindgut. Abnormal embryogenesis of these is thought to be multifactorial and can lead to sporadic anomalies. Normal genitourinary development is summarized in Figure 3-1 and also discussed in Chapter 7 (p. 144).
Between the 3rd and 5th gestational weeks, an elevation of intermediate mesoderm on each side of the fetus—the urogenital ridge—begins development into the urogenital tract. This further divides into the gonadal or genital ridge, which will become the ovary, and into the nephrogenic cord, which is subsequently described. The müllerian ducts become the fallopian tubes, uterus, and
upper vagina and derive from coelomic epithelium covering the nephrogenic cord. It is because of this separate gonadal and müllerian derivation that women with müllerian defects typically have functionally normal ovaries and are phenotypic females.

The urinary tract develops from the mesonephros or wolfian ducts situated within each nephrogenic cord and connects the mesonephric kidney to the cloaca (Fig. 3-1A). Recall that evolution of the renal system passes sequentially through the pronephric and mesonephric stages to reach the permanent metanephric system. Between the 4th and 5th weeks, each mesonephric duct gives rise to a ureteric bud, which grows cephalad toward its respective mesonephros (Fig. 3-1B). As each bud lengthens, it induces differentiation of the metanephros, which will become the final kidney (Fig. 3-1C). Each mesonephros degenerates near the end of the first trimester, and without testosterone, the mesonephric ducts regress as well.

The cloaca begins as a common opening for the embryonic urinary, genital, and alimentary tracts. By the 7th week it becomes divided by the urorectal septum to create the rectum and the urogenital sinus (Fig. 3-1D). The urogenital sinus is considered in three parts: (1) the cephalad or vesicle portion, which will form the urinary bladder; (2) the middle or pelvic portion, which creates the female urethra; and (3) the caudal or phallic part, which will give rise to the distal vagina and to the greater vestibular (Bartholin) and paraurethral (Skene) glands.

**Embryology of the Genital Tract**

Development of the genital tract begins as the müllerian ducts, also termed paramesonephric ducts, form lateral to each mesonephros. These ducts extend downward and then turn medially to meet and fuse together in the midline. The uterus is formed by this union of the two müllerian ducts at approximately the 10th week (Fig. 3-1E). Fusion begins in the middle and then extends caudally and cephalad. With cellular proliferation at the upper portion, a thick wedge of tissue creates the characteristic piriform uterine shape. At the same time, dissolution of cells at the lower pole forms the first uterine cavity (Fig. 3-1F). As the upper wedge-shaped septum is slowly reabsorbed, the final uterine cavity is usually shaped by the 20th week. If the two müllerian ducts fail to fuse, then there are separate uterine horns. In contrast, resorption failure of the common tissue between them results in various degrees of persistent uterine septum.

As the distal end of the fused müllerian ducts contacts the urogenital sinus, this induces endodermal outgrowths termed the sinovaginal bulbs. These bulbs proliferate and fuse to form the vaginal plate, which later resorbs to form the vaginal lumen. This vaginal canalization is generally completed by the 20th week. However, the lumen remains separated from the urogenital sinus by the hymeneal membrane. This membrane further degenerates to leave only the hymeneal ring.

The close association of the mesonephric (wolfian) and paramesonephric (müllerian) ducts explains why there are commonly simultaneous abnormalities involving these structures. In an older study, Kenney and colleagues (1984) showed that up to half of females with uterovaginal malformations have associated urinary tract defects. Anomalies most frequently associated with renal defects are unicornuate uterus, uterine didelphys, and agenesis syndromes, whereas arcuate and bicornuate are less commonly linked (Reichman, 2010). When these are identified, the urinary system can be evaluated with magnetic resonance (MR) imaging, sonography, or intravenous pyelography (Hall-Craggs, 2013). Finally, in these cases, ovaries are functionally normal but have a higher incidence of anatomical maldescent into the pelvis (Allen, 2012; Dabirashrafi, 1994).

**MESONEPHRIC REMNANTS**
As discussed, the mesonephric ducts usually degenerate, however, persistent remnants may become clinically apparent. Mesonephric or wolffian vestiges can persist as Gartner duct cysts. These are typically located in the proximal anterolateral vaginal wall but may be found at other sites along the vaginal length. They can be further characterized by magnetic resonance (MR) imaging. Most are asymptomatic and benign, and although they may measure up to 7 cm in diameter, they usually do not require surgical excision. An infected cyst occasionally requires marsupialization.

Intraabdominal wolffian remnants in the female include a few blind tubules in the mesovarium—the epoöphoron—as well as similar ones adjacent to the uterus—collectively the paroöphoron (Moore, 2013). The epoöphoron or paroöphoron may develop into clinically identifiable cysts and are included in the differential diagnosis of an adnexal mass (Chap. 63, p. 1226).

**BLADDER AND PERINEAL ABNORMALITIES**

Very early during embryo formation, a bilaminar cloacal membrane lies at the caudal end of the germinal disc and forms the infraumbilical abdominal wall. Normally, an ingrowth of mesoderm between the ectodermal and endodermal layers of the cloacal membrane leads to formation of the lower abdominal musculature and pelvic bones. Without reinforcement, the cloacal membrane may prematurely rupture, and depending on the extent of the infraumbilical defect, cloacal extrophy, bladder extrophy, or epispadias may result. Of these, cloacal extrophy is rare and includes the triad of omphalocele, bladder extrophy, and imperforate anus.

Bladder extrophy is characterized by an exposed bladder lying outside the abdomen. Associated findings commonly include a widened symphysis pubis, caused by outward innominate bone rotation, and abnormal external genitalia. For example, the urethra and vagina are typically short, and the vaginal orifice is frequently stenotic and displaced anteriorly. The clitoris is duplicated or bifid, and the labia, mons pubis, and clitoris are divergent. At the same time, however, the uterus, fallopian tubes, and ovaries are typically normal except for occasional müllerian duct fusion defects.

Pregnancy with bladder extrophy is associated with greater risk for antepartum pyelonephritis, urinary retention, ureteral obstruction, pelvic organ prolapse, and breech presentation. Due to the extensive adhesions from prior repair and altered anatomy typically encountered, some recommend planned cesarean delivery at a tertiary center (Deans, 2012; Greenwell, 2003).

Epispadias without bladder extrophy includes anomalies that include a widened, patulous urethra; absent or bifid clitoris; nonfused labial folds; and flattened mons pubis. Vertebral abnormalities and pubic symphysis diasthesia are also common.

Clitoral anomalies are unusual. One is clitoral duplication or bifid clitoris, which is rare and usually develops in association with bladder extrophy or epispadias. With female phallic urethra, the urethra opens at the clitoral tip. Last, clitoromegaly noted at birth is suggestive of fetal exposure to excessive androgens (Chap. 7, p. 148). In some preterm neonates, the clitoris may appear large, but then regresses as the infant grows. Other causes of newborn clitoromegaly include breech presentation with vulvar swelling, chronic severe vulvovaginitis, and neurofibromatosis (Dershwitz, 1984; Greer, 1981).
Hymeneal anomalies include imperforate, microperforate, cribriform (sievelike), navicular (boatshaped), and septate hymens. They result from failure of the inferior end of the vaginal plate—the hymeneal membrane—to canalize. Their incidences approximate one in 1000 to 2000 females (American College of Obstetricians and Gynecologists, 2013). During the neonatal period, significant amounts of mucus can be secreted due to maternal estrogen stimulation. With an imperforate hymen, secretions collect to form a bulging, translucent yellow-gray mass, termed hydro- or mucocolpos, at the vaginal introitus. Most are asymptomatic and resolve as mucus is reabsorbed and estrogen levels decrease, but occasionally they must be differentiated from a hymeneal cyst (Breech, 2009; Nazir, 2006). Problems with imperforate hymen are uncommon in neonates, and most become apparent during adolescence with classic findings of amenorrhea, cyclic abdominal pain, and a bulging bluish introital membrane.

MÜLLERIAN ABNORMALITIES

There are four principal deformities that arise from defective müllerian duct embryological steps: (1) agenesis of both ducts, either focally or along the entire duct length; (2) unilateral maturation of one müllerian duct with incomplete or absent development of the opposite side; (3) absent or faulty midline fusion of the ducts; or (4) defective canalization. Various classifications of these have been proposed, and shown in Table 3-1 is the one used by the American Fertility Society as derived by Buttram and Gibbons (1979). It separates anomalies into groups with similar clinical characteristics, prognosis for pregnancy, and treatment. It also includes one for abnormalities associated with fetal exposure to diethylstilbestrol (DES).

<tr>
<th>TABLE 3-1. Classification of Müllerian Anomalies</th>
</tr>
</thead>
</table>
Initially, müllerian anomalies may be suspected by symptoms or clinical findings. First, these defects are frequently identified during pelvic examination. Sonography is initially done to search for associated lesions. However, MR imaging is often required to more fully delineate anatomy, especially with obstructive lesions requiring surgery. Amenorrhea may be an initial complaint for those with agenesis of a müllerian component. For those with complete agenesis, karyotyping is typically indicated to exclude XY disorders of sex development, which were formerly termed male pseudohermaphroditism (Hughes, 2006). Last, pelvic pain due to occult blood accumulation may arise from functioning endometrium with outlet obstruction.

**Müllerian Agenesis**

Class I segmental defects can be caused by müllerian hypoplasia or agenesis as shown in Figure 3-2. These developmental defects can affect the vagina, cervix, uterus, or fallopian tubes and may be isolated or may coexist with other müllerian defects.
Vaginal Abnormalities

In addition to vaginal agenesis, there are two types of congenital septa. One is a longitudinal septum, which arises from a fusion or resorption defect. The other, a transverse septum, results...
either from incomplete canalization or from vertical fusion failure between the down-growing müllerian duct system and the up-growing urogenital sinus. All of these defects may be isolated or associated with other müllerian anomalies. One example is the Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, in which upper vaginal agenesis is typically associated with hypoplasia or uterine agenesis. This syndrome may also display abnormalities of the renal, skeletal, and auditory systems. This triad is known by the acronym MURCS - müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia (Duncan, 1979).

The obstetrical significance of vaginal anomalies depends greatly on the degree of obstruction. For example, complete vaginal agenesis, unless corrected operatively, precludes pregnancy by vaginal intercourse. With MRKH syndrome, a functional vagina can be created, but childbearing is impossible. In these women, however, ova can be retrieved for in vitro fertilization (IVF) in a surrogate mother.

With longitudinal septa, most are complete. When partial, they are high in the vagina. Septa are typically associated with other müllerian anomalies (Haddad, 1997). A complete longitudinal vaginal septum usually does not cause dystocia because the vaginal side through which the fetus descends dilates satisfactorily. An incomplete or partially obstructed longitudinal septum, however, may interfere with descent.

A transverse septum causes an obstruction of variable thickness, and it may develop at any depth within the vagina. Occasionally, the upper vagina is separated from the rest of the canal by a septum with a small opening. Gibson (2003) reported this in association with miscarriage and described dilatation of the septal opening to permit evacuation of products. In labor, such strictures may be mistaken for the upper limit of the vaginal vault, and the septal opening is misidentified as an undilated cervical os. If encountered during labor, and after the external os has dilated completely, the head impinges on the septum and causes it to bulge downward. If the septum does not yield, slight pressure on its opening usually leads to further dilatation, but occasionally cruciate incisions are required to permit delivery (Blanton, 2003). If there is a thick transverse septum, however, cesarean delivery may be necessary.

**Cervical Abnormalities**

Developmental abnormalities of the cervix include partial or complete agenesis, duplication, and longitudinal septa. Uncorrected complete agenesis is incompatible with pregnancy, and IVF with gestational surrogacy is an option. Surgical correction by uterovaginal anastomosis has resulted in successful pregnancy (Deffarges, 2001; Fedele, 2008). There are significant complications with this corrective surgery, and the need for clear preoperative anatomy delineation has been emphasized by Rock (2010) and Roberts (2011) and their colleagues. For this reason, they recommend hysterectomy for complete cervical agenesis and reserve reconstruction attempts for carefully selected patients with cervical dysgenesis.

**Uterine Abnormalities**

From a large variety, a few of the more common congenital uterine malformations are shown in Table 3-1. Accurate population prevalences of these are difficult to assess because the best diagnostic techniques are invasive. The reported population prevalence ranges from 0.4 to 5 percent, and rates in women with recurrent miscarriage are significantly higher (Acién, 1997; Byrne, 2000; Chan, 2011b). In a review of 22 studies with more than 573,000 women who were screened for these malformations, Nahum (1998) reported the distribution of uterine anomalies as
follows: bicornuate, 39 percent; septate, 34 percent; didelphic, 11 percent; arcuate, 7 percent; unicortuate, 5 percent; and hypo- or aplastic, 4 percent.

Müllerian anomalies may be discovered at routine pelvic examinations, cesarean delivery, during laparoscopy for tubal sterilization, or during infertility evaluation. Depending on clinical presentation, diagnostic tools may include hysterosalpingography, sonography, MR imaging, laparoscopy, and hysteroscopy. Each has limitations, and these may be used in combination to completely define anatomy. In women undergoing fertility evaluation, hysterosalpingography (HSG) is commonly selected for uterine cavity and tubal patency assessment. That said, HSG poorly defines the external uterine contour and can delineate only patent cavities. It is contraindicated during pregnancy.

In most clinical settings, sonography is initially performed. Transabdominal views may help to maximize the viewing field, but transvaginal sonography (TVS) provides better image resolution. For this indication, the pooled accuracy for TVS is 90 to 92 percent (Pellerito, 1992). Saline infusion sonography (SIS) improves delineation of the endometrium and internal uterine morphology, but only with a patent endometrial cavity. Also, SIS is contraindicated in pregnancy. Three-dimensional (3-D) sonography is more accurate than 2-D sonography because it provides uterine images from virtually any angle. Thus, coronal images can be constructed, and these are essential in evaluating both internal and external uterine contours (Olpin, 2009). Both 2-D and 3-D sonography are suitable for pregnancy. In gynecological patients, these are ideally completed during the luteal phase when the secretory endometrium provides contrast from increased thickness and echogenicity (Caliskan, 2010).

Several investigators have reported very good concordance between 3-D TVS and MR imaging of müllerian anomalies, although MR imaging is currently preferred for imaging such defects (Bermejo, 2010; Ghi, 2009). MR imaging provides clear delineation of both the internal and external uterine anatomy and has a reported accuracy of up to 100 percent in the evaluation of müllerian anomalies (Fedele, 1989; Pellerito, 1992). Moreover, complex anomalies and commonly associated secondary diagnoses such as renal or skeletal anomalies can be concurrently evaluated. Precautions with MR imaging in pregnancy are discussed in Chapter 46 (p. 934).

In some women undergoing an infertility evaluation, hysteroscopy and laparoscopy may be selected to assess for müllerian anomalies; screen for endometriosis, which is often coexistent; and exclude other tubal or uterine cavity pathologies (Puscheck, 2008; Saravelos, 2008). However, hysteroscopy is contraindicated in pregnancy.

**Unicornuate Uterus (Class II)**

With this anomaly, the underdeveloped or rudimentary horn may be absent. If present, it may or may not be communicating and may or may not contain an endometrium-lined cavity (see Fig. 3-2). General population estimates cite that a unicornuate uterus develops in 1 in 4000 women (Reichman, 2009). It may be detected during fertility evaluation by HSG. Although this study can define the primary cavity contour, noncommunicating or noncavitary rudimentary horns may not fill with dye. Conventional sonography may be difficult for less-experienced sonographers as the smaller size and lateral deviation of an isolated unicornuate uterus or a rudimentary horn may not be appreciated. If suspected, 3-D sonography increases diagnostic accuracy, but MR imaging is often preferred (Fig. 3-3). Importantly, 40 percent of affected women will have renal anomalies, and evaluation for these is indicated (Fedele, 1996a).
This müllerian anomaly carries significant obstetrical risks, including first- and second-trimester miscarriage, malpresentation, fetal-growth restriction, fetal demise, prematurely ruptured membranes, and preterm delivery (Chan, 2011a; Hua, 2011; Reichman, 2009). Abnormal uterine blood flow, cervical incompetence, and diminished cavity size and muscle mass of the hemiuterus are postulated to underlie these risks (Donderwinkel, 1992).

Rudimentary horns also increase the risk of an ectopic pregnancy within the remnant, which may be disastrous. This risk includes noncommunicating cavitary rudiments because of transperitoneal sperm migration (Nahum, 2004). In a report of 70 such pregnancies, Rolen and associates (1966) found that the rudimentary uterine horn ruptured prior to 20 weeks in most. Nahum (2002) reviewed the literature from 1900 to 1999 and identified 588 rudimentary horn pregnancies. Half had uterine rupture, and 80 percent did so before the third trimester. Of the total 588, neonatal survival was only 6 percent.

Imaging allows an earlier diagnosis of rudimentary horn pregnancy so that it can be treated either medically or surgically before rupture (Edelman, 2003; Khati, 2012; Worley, 2008). If diagnosed in a nonpregnant woman, most recommend prophylactic excision of a horn that has a cavity (Fedele, 2005; Rackow, 2007).

**Uterine Didelphys (Class III)**

This interesting müllerian anomaly arises from a complete lack of fusion that results in two entirely separate hemiuteri, cervices, and usually two vaginas (see Fig. 3-2). Most women have a double vagina or a longitudinal vaginal septum (Heinonen, 1984). Uterine didelphys may be isolated or part of a triad that has an obstructed hemivagina and ipsilateral renal agenesis (OHVIRA), also known as Herlyn-Werner-Wunderlich syndrome (Smith, 2007; Tong, 2013). Didelphys derives from the Greek *di*—two + *delphus*—uterus. The term was once used to refer to
all marsupials, but now only to one genus that includes the American possum—*Didelphys virginiana*—one of several mammalian species in which the female has a double uterus, cervix, and vagina.

These anomalies may be suspected on pelvic examination by identification of a longitudinal vaginal septum and two cervices. During HSG for fertility evaluation, contrast shows two separate endocervical canals. These open into separate noncommunicating fusiform endometrial cavities that each ends with a solitary fallopian tube. In women without fertility issues, sonography is a logical initial imaging tool, and separate divergent uterine horns with a large intervening fundal cleft are seen. Endometrial cavities are uniformly separate. MR imaging may be valuable in cases without classic findings.

Adverse obstetrical outcomes associated with uterine didelphys are similar but less frequent than those seen with unicornuate uterus. Increased risks include miscarriage, preterm birth, and malpresentation (Chan, 2011a; Grimbizis, 2001; Hua, 2011). Metroplasty for either uterine didelphys or bicornuate uterus involves resection of intervening myometrium and fundal recombination. These are uncommon surgeries and chosen for highly selected patients with otherwise unexplained miscarriages. Unfortunately, there is no evidence-based support to confirm efficacy of such surgical repair.

**Bicornuate Uterus (Class IV)**

This relatively common anomaly forms as lack of fundal fusion results in two hemiuteri, with only one cervix and vagina (see Fig. 3-2). As with uterine didelphys, a coexistent longitudinal vaginal septum is not uncommon. Radiological discrimination of bicornuate uterus from the septate uterus can be challenging. However, it is important because septate uterus can be treated with hysteroscopic septal resection. Widely diverging horns seen on HSG may suggest a bicornuate uterus. An intercornual angle greater than 105 degrees suggests bicornuate uterus, whereas one less than 75 degrees indicates a septate uterus. However, MR imaging is necessary to define fundal contour. With this, an intrafundal downward cleft measuring 1 cm or more is indicative of bicornuate uterus, whereas a cleft depth less than 1 cm indicates a septate uterus. Use of 3-D sonography also allows internal and external uterine assessment.

There are increased risks for adverse obstetrical outcomes with bicornuate uterus that include miscarriage, preterm birth, and malpresentation. As discussed earlier, surgical correction by metroplasty is reserved for highly selected patients.

**Septate Uterus (Class V)**

This anomaly is caused when a resorption defect leads to a persistent complete or partial longitudinal uterine cavity septum (see Fig. 3-2). In rare cases, a complete vaginocervicouterine septum is found (Darwish, 2009). Many septate uteri are identified during evaluation of infertility or recurrent pregnancy loss. Although an abnormality may be identified with HSG, MR imaging or 3-D sonography is typically required to differentiate this from a bicornuate uterus (see Fig. 3-3).

Septate anomalies are associated with diminished fertility as well as increased risks for adverse pregnancy outcomes that include miscarriage, preterm delivery, and malpresentation. The poorly vascularized uterine septum likely causes abnormal implantation or defective early embryo development and miscarriage (Fedele, 1996b). Hysteroscopic septal resection has been shown to improve pregnancy rates and outcomes (Grimbizis, 2001; Mollo, 2009; Pabuçcu, 2004). From their metaanalysis, Nouri and colleagues (2010) reported a 60-percent pregnancy rate and 45-percent live birth rate in those so treated.
Arcuate Uterus (Class VI)
This malformation is a mild deviation from the normally developed uterus (see Fig. 3-3). Although some studies report no increased adverse associated outcomes, others have found excessive second-trimester losses, preterm labor, and malpresentation (Chan, 2011a; Mucowski, 2010; Woelfer, 2001).

Treatment with Cerclage
Some women with uterine anomalies and repetitive pregnancy losses may benefit from transvaginal or transabdominal cervical cerclage (Golan, 1992; Groom, 2004). Some women with partial cervical atresia or hypoplasia may also benefit (Hampton, 1990; Ludmir, 1991; Mackey, 2001). Candidacy for cerclage is determined by the same criteria used for women without such defects, which is discussed in Chapter 18 (p. 361).

Diethylstilbestrol Reproductive Tract Abnormalities (Class VII)
During the 1960s, a synthetic nonsteroidal estrogen–diethylstilbestrol (DES)–was used to treat pregnant women for threatened abortion, preterm labor, preeclampsia, and diabetes. The treatment was remarkably ineffective. In addition, it was later discovered that women exposed as fetuses had increased risks of developing a number of specific reproductive-tract anomalies. These included vaginal clear cell adenocarcinoma, cervical intraepithelial neoplasia, small-cell cervical carcinoma, and vaginal adenosis. A fourth of affected women had identifiable structural variations in the cervix and vagina to include transverse septa, circumferential ridges, and cervical collars. Even more anomalies were smaller uterine cavities, shortened upper uterine segments, T-shaped and other irregular cavities, and fallopian tube abnormalities (see Fig. 3-2) (Barranger, 2002).

These women also had fertility issues that included impaired conception rates and higher rates of miscarriage, ectopic pregnancy, and preterm delivery, especially in those with structural abnormalities (Goldberg, 1999; Palmer, 2001). Now, more than 50 years after DES use was proscribed, most affected women are past childbearing age, but higher rates of earlier menopause and breast cancer have been reported in exposed women (Hatch, 2006; Hoover, 2011).

Fallopian Tube Abnormalities
The fallopian tubes develop from the unpaired distal ends of the müllerian ducts. Congenital anomalies include accessory ostia, complete or segmental tubal agenesis, and several embryonic cystic remnants (Woodruff, 1969). The most common is a small, benign cyst attached by a pedicle to the distal end of the fallopian tube—the hydatid of Morgagni (Zheng, 2009). In other cases, benign paratubal cysts may be of mesonephric or mesothelial origin. Last, in utero exposure to DES has been associated with various tubal abnormalities. Of these, short, tortuous tubes or ones with shriveled fimbria and small ostia have been linked to infertility (DeCherney, 1981).

UTERINE FLEXION

Anteflexion
This is defined by anterior flexion of the uterine fundus relative to the cervix in the sagittal plane.
Mild or moderate flexion is typically without clinical consequence, but congenital or acquired extremes may lead to pregnancy complications. Exaggerated degrees of anteflexion usually pose no problem in early pregnancy. Later, however, particularly when the abdominal wall is lax such as with diastasis recti or ventral hernia, the uterus may fall forward. This may be so extreme that the fundus lies below the lower margin of the symphysis. Sometimes this abnormal uterine position prevents proper transmission of labor contractions, but this is usually overcome by repositioning and application of an abdominal binder.

**Retroflexion**

This is posterior uterine fundal flexion in the sagittal plane. A growing retroflexed uterus will occasionally become incarcerated in the hollow of the sacrum. Symptoms include abdominal discomfort, pelvic pressure, and voiding dysfunction that may include urinary frequency or retention. On bimanual pelvic examination, the cervix will be anterior and behind the symphysis pubis, whereas the uterus is appreciated as a mass wedged in the pelvis. Sonography or MR imaging may be necessary to confirm the clinical diagnosis (Gardner, 2013; Grossenburg, 2011; van Beekhuizen, 2003).

The incarcerated uterus must be repositioned to its normal anatomical position. After bladder catheterization, the uterus can usually be pushed out of the pelvis when the woman is placed in the knee-chest position. Often, this is best accomplished by digital pressure applied through the rectum. Conscious sedation, spinal analgesia, or general anesthesia may be necessary. Following repositioning, the catheter is left in place until bladder tone returns. Insertion of a soft pessary for a few weeks usually prevents reincarceration. Lettieri and colleagues (1994) described seven cases of uterine incarceration not amenable to these simple procedures. In two women, laparoscopy was used at 14 weeks to reposition the uterus using the round ligaments for traction. Alternatively, in two case series, colonoscopy was used to dislodge an incarcerated uterus (Dierickx, 2011; Seubert, 1999).

**Sacculation**

Persistent entrapment of the pregnant uterus in the pelvis may lead to extensive lower uterine segment dilatation to accommodate the fetus. An example of *anterior sacculation* is shown in Figure 3-4. In these extreme cases, sonography and MR imaging are typically required to define anatomy (Gottschalk, 2008; Lee, 2008). Cesarean delivery is necessary when there is marked sacculation, and Spearing (1978) stressed the importance of identifying the distorted anatomy. An elongated vagina passing above the level of a fetal head that is deeply placed into the pelvis suggests a sacculation or an abdominal pregnancy. The Foley catheter is frequently palpated above the level of the umbilicus! Spearing (1978) recommended extending the abdominal incision above the umbilicus and delivering the entire uterus from the abdomen before hysterotomy. This will restore correct anatomical relationships and prevent inadvertent incisions into and through the vagina and bladder. Unfortunately, this may not always be possible (Singh, 2007).
Friedman and associates (1986) described a rare case of posterior sacculation following aggressive treatment for intrauterine adhesions. Finally, uterine retroversion and a true uterine diverticulum have been mistaken for uterine sacculations (Hill, 1993; Rajiah, 2009).

Uterine Torsion

It is common during pregnancy for the uterus to rotate to the right side. Rarely, uterine rotation exceeds 180 degrees to cause torsion. Most cases of torsion result from uterine leiomyomas, müllerian anomalies, fetal malpresentation, pelvic adhesions, and laxity of the abdominal wall or uterine ligaments. Jensen (1992) reviewed 212 cases and reported that associated symptoms may include obstructed labor, intestinal or urinary complaints, abdominal pain, uterine hypertonus, vaginal bleeding, and hypotension. Both maternal and fetal complications were more common with early gestation and with greater degrees of torsion.

Most cases of uterine torsion are found at the time of cesarean delivery. In some women, torsion can be confirmed preoperatively with MR imaging, which shows a twisted vagina that appears X-shaped rather than its normal H-shape (Nicholson, 1995). As with uterine incarceration, during cesarean delivery, a severely displaced uterus should be repositioned anatomically before hysterotomy. In some cases, an inability to reposition may require that a posterior hysterotomy incision be done (Albayrak, 2011; De Ioris, 2010; Picone, 2006).
REFERENCES

The anatomical, physiological, and biochemical adaptations to pregnancy are profound. Many of these remarkable changes begin soon after fertilization and continue throughout gestation, and most occur in response to physiological stimuli provided by the fetus and placenta. Equally astounding is that the woman who was pregnant is returned almost completely to her prepregnancy state after delivery and lactation. Many of these physiological adaptations could be perceived as abnormal in the nonpregnant woman. For example, cardiovascular changes during pregnancy normally include substantive increases in blood volume and cardiac output, which may mimic thyrotoxicosis. On the other hand, these same adaptations may lead to ventricular failure during pregnancy if there is underlying heart disease. Thus, physiological adaptations of normal pregnancy can be misinterpreted as pathological but can also unmask or worsen preexisting disease.

During normal pregnancy, virtually every organ system undergoes anatomical and functional changes that can alter appreciably criteria for disease diagnosis and treatment. Thus, the understanding of these pregnancy adaptations remains a major goal of obstetrics, and without such knowledge, it is almost impossible to understand the disease processes that can threaten women
reproductive tract

uterus

in the nonpregnant woman, the uterus weighs approximately 70 g and is almost solid, except for a cavity of 10 mL or less. during pregnancy, the uterus is transformed into a relatively thin-walled muscular organ of sufficient capacity to accommodate the fetus, placenta, and amnionic fluid. the total volume of the contents at term averages approximately 5 L but may be 20 L or more. by the end of pregnancy, the uterus has achieved a capacity that is 500 to 1000 times greater than in the non-pregnant state. the corresponding increase in uterine weight is such that, by term, the organ weighs nearly 1100 g.

during pregnancy, uterine enlargement involves stretching and marked hypertrophy of muscle cells, whereas the production of new myocytes is limited. accompanying the increase in myocyte size is an accumulation of fibrous tissue, particularly in the external muscle layer, together with a considerable increase in elastic tissue content. this network adds strength to the uterine wall.

although the walls of the corpus become considerably thicker during the first few months of pregnancy, they then begin to thin gradually. by term, the myometrium is only 1 to 2 cm thick. in these later months, the uterus is changed into a muscular sac with thin, soft, readily indentable walls through which the fetus usually can be palpated.

uterine hypertrophy early in pregnancy probably is stimulated by the action of estrogen and perhaps progesterone. the hypertrophy of early pregnancy does not occur entirely in response to mechanical distention by the products of conception, because similar uterine changes are observed with ectopic pregnancy (chap. 19, p. 379). but after approximately 12 weeks, the uterine size increase is related predominantly to pressure exerted by the expanding products of conception.

uterine enlargement is most marked in the fundus. in the early pregnancy months, the fallopian tubes and the ovarian and round ligaments attach only slightly below the apex of the fundus. in later months, they are located slightly above the middle of the uterus. the position of the placenta also influences the extent of uterine hypertrophy. the portion of the uterus surrounding the placental site enlarges more rapidly than does the rest.

myocyte arrangement

the uterine musculature during pregnancy is arranged in three strata. the first is an outer hoodlike layer, which arches over the fundus and extends into the various ligaments. the middle layer is composed of a dense network of muscle fibers perforated in all directions by blood vessels. last is an internal layer, with sphincter-like fibers around the fallopian tube orifices and internal cervical os.

most of the uterine wall is formed by the middle layer. each cell in this layer has a double curve so that the interlacing of any two gives approximately the form of a figure eight. this arrangement is crucial because when the cells contract after delivery, they constrict penetrating blood vessels and thus act as ligatures (fig. 2-11, p. 27).

uterine size, shape, and position

for the first few weeks, the uterus maintains its original piriform or pear shape. but, as pregnancy
advances, the corpus and fundus become more globular and almost spherical by 12 weeks' gestation. Subsequently, the organ increases more rapidly in length than in width and assumes an ovoid shape. By the end of 12 weeks, the uterus has become too large to remain entirely within the pelvis. As the uterus enlarges, it contacts the anterior abdominal wall, displaces the intestines laterally and superiorly, and ultimately reaches almost to the liver. With uterine ascent from the pelvis, it usually rotates to the right. This dextrorotation likely is caused by the rectosigmoid on the left side of the pelvis. As the uterus rises, tension is exerted on the broad and round ligaments.

With the pregnant woman standing, the longitudinal axis of the uterus corresponds to an extension of the pelvic inlet axis. The abdominal wall supports the uterus and, unless it is quite relaxed, maintains this relation between the long axis of the uterus and the axis of the pelvic inlet. When the pregnant woman is supine, the uterus falls back to rest on the vertebral column and the adjacent great vessels.

**Uterine Contractility**

Beginning in early pregnancy, the uterus undergoes irregular contractions that are normally painless. During the second trimester, these contractions may be detected by bimanual examination. Because attention was first called to this phenomenon in 1872 by J. Braxton Hicks the contractions have been known by his name. Such contractions appear unpredictably and sporadically and are usually nonrhythmic. Their intensity varies between approximately 5 and 25 mm Hg (Alvarez, 1950). Until the last several weeks of pregnancy, these *Braxton Hicks contractions* are infrequent, but their number increases during the last week or two. At this time, the uterus may contract as often as every 10 to 20 minutes and with some degree of rhythmicity. Correspondingly, studies of uterine electrical activity have shown low and uncoordinated patterns early in gestation, which become progressively more intense and synchronized by term (Garfield, 2005). Late in pregnancy, these contractions may cause some discomfort and account for so-called false labor (Chap. 21, p. 409).

**Uteroplacental Blood Flow**

The delivery of most substances essential for fetal and placental growth, metabolism, and waste removal is dependent on adequate perfusion of the placental intervillous space (Chap. 5, p. 96). Accurate estimation of actual uteroplacental blood flow is technically challenging. Placental perfusion is dependent on total uterine blood flow, and simultaneous measurement of uterine, ovarian, and collateral vessels is currently not possible, even using magnetic resonance angiography (Pates, 2010). Using indirect measures, such as clearance rates of androstenedione and xenon-133, uteroplacental blood flow was found to increase progressively during pregnancy. Estimates range from 450 to 650 mL/min near term (Edman, 1981; Kauppila, 1980). These estimates are remarkably similar to those obtained with invasive methods—500 to 750 mL/min (Assali, 1953; Browne, 1953; Metcalfe, 1955). Putting this remarkable rate of blood flow in context, one recalls that the blood flow in the entire circulation of a nonpregnant woman is approximately 5000 mL/min.

The results of studies conducted in rats by Page and colleagues (2002) show that the uterine veins also significantly adapt during pregnancy. Specifically, their remodeling includes reduced elastin content and adrenergic nerve density. This creates increased venous caliber and distensibility. Logically, such changes are necessary to accommodate the massively increased uteroplacental blood flow.

Studying the effects of labor on uteroplacental blood flow, Assali and coworkers (1968) placed electromagnetic flow probes directly on a uterine artery in sheep and dogs at term. They found that
uterine contractions, either spontaneous or induced, caused a decrease in uterine blood flow that was approximately proportional to the contraction intensity. They also showed that a tetanic contraction caused a precipitous fall in uterine blood flow. Harbert and associates (1969) made a similar observation in pregnant monkeys. In humans, uterine contractions appear to affect fetal circulation much less (Brar, 1988).

**Uteroplacental Blood Flow Regulation.** Maternal-placental blood flow progressively increases during gestation principally by means of vasodilation. Palmer and associates (1992) showed that uterine artery diameter doubled by 20 weeks and that concomitant mean Doppler velocimetry was increased eightfold. Recall that blood flow within a vessel increases in proportion to the fourth power of the radius. Thus, slight diameter increases in the uterine artery produces a tremendous blood flow capacity increase (Guyton, 1981). As reviewed by Mandala and Osol (2011), the vessels that supply the uterine corpus widen and elongate while preserving contractile function. In contrast, the spiral arteries, which directly supply the placenta, widen but completely lose contractility. This presumably results from endovascular trophoblast invasion that destroys the intramural muscular elements (Chap. 5, p. 93).

The vasodilation during pregnancy is at least in part the consequence of estrogen stimulation. For example, 17β-estradiol has been shown to promote uterine artery vasodilation and reduce uterine vascular resistance (Sprague, 2009). Jauniaux and colleagues (1994) found that estradiol and progesterone, as well as relaxin, contribute to the downstream fall in vascular resistance in women with advancing gestational age.

The downstream fall in vascular resistance leads to an acceleration of flow velocity and shear stress in upstream vessels. In turn, shear stress leads to circumferential vessel growth, and nitric oxide—a potent vasodilator—appears to play a key role regulating this process (p. 61). Indeed, endothelial shear stress, estrogen, placental growth factor (PIGF), and vascular endothelial growth factor (VEGF)—a promoter of angiogenesis—all augment endothelial nitric oxide synthase (eNOS) and nitric oxide production (Grummer, 2009; Mandala, 2011). As an important aside, VEGF and PIGF signaling is attenuated in response to excess placental secretion of their soluble receptor—soluble FMS-like tyrosine kinase 1 (sFlt-1). As detailed in Chapter 40 (p. 735), increased maternal sFlt-1 levels inactivate and decrease circulating PIGF and VEGF concentrations and have been shown to be an important factor in preeclampsia pathogenesis.

Normal pregnancy is also characterized by vascular refractoriness to the pressor effects of infused angiotensin II and norepinephrine (p. 61). This insensitivity also serves to increase uteroplacental blood flow (Rosenfeld, 1981, 2012). Recent studies also suggest that relaxin may help mediate uterine artery compliance (Vodstrcil, 2012). Moreover, Rosenfeld and associates (2005, 2008) have discovered that large-conductance potassium channels expressed in uterine vascular smooth muscle also contribute to uteroplacental blood flow regulation through several mediators, including estrogen and nitric oxide. In contrast, uterine blood flow and placental perfusion in sheep significantly decline following nicotine and catecholamine infusions (Rosenfeld, 1976, 1977; Xiao, 2007). The placental perfusion decrease likely results from greater uteroplacental vascular bed sensitivity to epinephrine and norepinephrine compared with that of the systemic vasculature.

**Cervix**
As early as 1 month after conception, the cervix begins to undergo pronounced softening and cyanosis. These changes result from increased vascularity and edema of the entire cervix, together
with hypertrophy and hyperplasia of the cervical glands (Straach, 2005). Although the cervix contains a small amount of smooth muscle, its major component is connective tissue. Rearrangement of this collagen-rich connective tissue is necessary to permit functions as diverse as maintenance of a pregnancy to term, dilatation to aid delivery, and repair following parturition so that a successful pregnancy can be repeated (Timmons, 2007; Word, 2007). As detailed in Chapter 21 (p. 410), the cervical ripening process involves connective tissue remodeling that decreases collagen and proteoglycan concentrations and increases water content compared with the nonpregnant cervix. This process appears to be regulated in part by localized estrogen and progesterone metabolism (Andersson, 2008).

As shown in Figure 4-1, the cervical glands undergo marked proliferation, and by the end of pregnancy, they occupy up to one half of the entire cervical mass. This contrasts with their rather small fraction in the nonpregnant state. These normal pregnancy-induced changes represent an extension, or eversion, of the proliferating columnar endocervical glands. This tissue tends to be red and velvety and bleeds even with minor trauma, such as with Pap smear sampling.

**FIGURE 4-1** Cervical eversion of pregnancy as viewed through a colposcope. The eversion represents columnar epithelium on the portio of the cervix. (Photograph contributed by Dr. Claudia Werner.)

The endocervical mucosal cells produce copious tenacious mucus that obstruct the cervical canal soon after conception. As discussed on page 56, this mucus is rich in immunoglobulins and
cytokines and may act as an immunological barrier to protect the uterine contents against infection (Hein, 2005). At the onset of labor, if not before, this mucus plug is expelled, resulting in a bloody show. Moreover, the cervical mucus consistency changes during pregnancy. Specifically, in most pregnant women, as a result of progesterone, when cervical mucus is spread and dried on a glass slide, it is characterized by poor crystallization, or beading. In some women, an arborization of crystals, or ferning, is observed as a result of amnionic fluid leakage (Fig. 4-2).

![FIGURE 4-2 Cervical mucus arborization or ferning. (Photograph contributed by Dr. James C. Glenn.)](image)

During pregnancy, basal cells near the squamocolumnar junction are likely to be prominent in size, shape, and staining qualities. These changes are considered to be estrogen induced. In addition, pregnancy is associated with both endocervical gland hyperplasia and hypersecretory appearance—the Arias-Stella reaction—which makes the differentiation of these and atypical glandular cells on Pap smear particularly difficult (Connolly, 2005).

**Pelvic Organ Prolapse**

As a result of apical prolapse, the cervix, and occasionally a portion of the uterine body, may protrude variably from the vulva during early pregnancy. With further growth, the uterus usually rises above the pelvis and may draw the cervix up with it. If the uterus persists in its prolapsed position, symptoms of incarceration may develop at 10 to 14 weeks. As a prevention measure, the
uterus can be replaced early in pregnancy and held in position with a suitable pessary.

In contrast, attenuation of fascial support between the vagina and the bladder can lead to prolapse of the bladder into the vagina, that is, a cystocele. Urinary stasis with a cystocele predisposes to infection. Pregnancy may also worsen associated urinary stress incontinence because urethral closing pressures do not increase sufficiently to compensate for the progressively increased bladder pressure (Iosif, 1981). Attenuation of rectovaginal fascia results in a rectocele. A large defect may fill with feces that occasionally can be evacuated only manually. During labor, a cystocele or rectocele can block fetal descent unless they are emptied and pushed out of the way. In rare instances, an enterocele of considerable size may complicate pregnancy. If symptomatic, the protrusion should be replaced, and the woman kept in a recumbent position. If the mass interferes with delivery, it should be pushed up or held out of the way.

Ovaries

Ovulation ceases during pregnancy, and maturation of new follicles is suspended. The single corpus luteum found in pregnant women functions maximally during the first 6 to 7 weeks of pregnancy—4 to 5 weeks postovulation—and thereafter contributes relatively little to progesterone production. These observations have been confirmed by surgical removal of the corpus luteum before 7 weeks—5 weeks postovulation. Removal results in a rapid fall in maternal serum progesterone levels and spontaneous abortion (Csapo, 1973). After this time, however, corpus luteum excision ordinarily does not cause abortion, and even bilateral oophorectomy at 16 weeks does not cause pregnancy loss (Villaseca, 2005). Interestingly in such cases, follicle-stimulating hormone (FSH) levels do not reach perimenopausal levels until approximately 5 weeks postpartum.

An extrauterine decidual reaction on and beneath the surface of the ovaries is common in pregnancy and is usually observed at cesarean delivery. These elevated patches of tissue bleed easily and may, on first glance, resemble freshly torn adhesions. Similar decidual reactions are seen on the uterine serosa and other pelvic, or even extrapelvic, abdominal organs (Bloom, 2010). These areas arise from subcoelomic mesenchyme as a result of progesterone stimulation and histologically appear similar to progestin-stimulated intrauterine endometrial stroma described in Chapter 5 (p. 86)(Russell, 2009).

The enormous caliber of the ovarian veins viewed at cesarean delivery is startling. Hodgkinson (1953) found that the diameter of the ovarian vascular pedicle increased during pregnancy from 0.9 cm to approximately 2.6 cm at term. Again, recall that flow in a tubular structure increases exponentially as the diameter enlarges.

Relaxin

As discussed in Chapter 5 (p. 105), this protein hormone is secreted by the corpus luteum as well as the decidua and the placenta in a pattern similar to that of human chorionic gonadotropin (hCG). It is also expressed in a variety of non-reproductive tissues, including brain, heart, and kidney. It is mentioned here because its secretion by the corpus luteum appears to play a key role in facilitating many maternal physiological adaptations (Conrad, 2013). One of its biological actions appears to be remodeling of reproductive-tract connective tissue to accommodate parturition (Park, 2005). Relaxin also appears important in the initiation of augmented renal hemodynamics, decreased serum osmolality, and increased uterine artery compliance associated with normal pregnancy (Conrad, 2011a,b). Despite its name, serum relaxin levels do not contribute to increasing peripheral joint laxity during pregnancy (Marnach, 2003).
Theca-Lutein Cysts

These benign ovarian lesions result from exaggerated physiological follicle stimulation—termed hyperreactio luteinalis. These usually bilateral cystic ovaries are moderately to massively enlarged. The reaction is usually associated with markedly elevated serum levels of hCG. Thus not surprisingly, theca-lutein cysts are found frequently with gestational trophoblastic disease (Chap. 20, p. 398). They are also more likely found with a large placenta such as with diabetes, anti-D alloimmunization, and Multiple gestations (Tanaka, 2001). Theca-lutein cysts have also been reported in chronic renal failure as a result of reduced hCG clearance and in hyperthyroidism as a result of the structural homology between hCG and thyroid-stimulating hormone (Coccia, 2003; Gherman, 2003). However, they also are encountered in women with otherwise uncomplicated pregnancies and are thought to result from an exaggerated response of the ovaries to normal levels of circulating hCG (Langer, 2007).

Although usually asymptomatic, hemorrhage into the cysts may cause abdominal pain (Amoah, 2011). Maternal virilization may be seen in up to 30 percent of women, however, virilization of the fetus has not yet been described (Kaňová, 2011). Maternal findings including temporal balding, hirsutism, and clitoromegaly are associated with massively elevated levels of androstenedione and testosterone. The diagnosis typically is based on sonographic findings of bilateral enlarged ovaries containing multiple cysts in the appropriate clinical settings. The condition is self-limited, and resolution follows delivery. Their management was reviewed by Phelan and Conway (2011) and is discussed further in Chapter 63 (p. 1228).

Fallopian Tubes

Fallopian tube musculature undergoes little hypertrophy during pregnancy. However, the epithelium of the tubal mucosa becomes somewhat flattened. Decidual cells may develop in the stroma of the endosalpinx, but a continuous decidual membrane is not formed. Rarely, the increasing size of the gravid uterus, especially in the presence of paratubal or ovarian cysts, may result in fallopian tube torsion (Batukan, 2007).

Vagina and Perineum

During pregnancy, increased vascularity and hyperemia develop in the skin and muscles of the perineum and vulva, with softening of the underlying abundant connective tissue. Also, Bartholin gland duct cysts of 1-cm size are common (Berger, 2012). Increased vascularity prominently affects the vagina and results in the violet color characteristic of Chadwick sign. The vaginal walls undergo striking changes in preparation for the distention that accompanies labor and delivery. These changes include a considerable increase in mucosal thickness, loosening of the connective tissue, and smooth muscle cell hypertrophy. The papillae of the vaginal epithelium undergo hypertrophy to create a fine, hobnailed appearance. Studies in pregnant mice have shown that vaginal distention results in increased elastic fiber degradation and an increase in the proteins necessary for new elastic fiber synthesis. In the absence of this synthesis, rapid progression of vaginal wall prolapse ensues (Rahn, 2008a,b).

The considerably increased volume of cervical secretions within the vagina during pregnancy consists of a somewhat thick, white discharge. The pH is acidic, varying from 3.5 to 6. This results from increased production of lactic acid from glycogen in the vaginal epithelium by the action of Lactobacillus acidophilus. As discussed in Chapter 65 (p. 1276), pregnancy is associated with a 10- to 20-fold increase in the prevalence of vulvovaginal candidiasis (Farage, 2011).
In the early weeks of pregnancy, women often experience breast tenderness and paresthesias. After the second month, the breasts increase in size, and delicate veins become visible just beneath the skin. The nipples become considerably larger, more deeply pigmented, and more erectile. After the first few months, a thick, yellowish fluid—colostrum—can often be expressed from the nipples by gentle massage. During the same months, the areolae become broader and more deeply pigmented. Scattered through the areolae are a number of small elevations, the glands of Montgomery, which are hypertrophic sebaceous glands. If the increase in breast size is extensive, striations similar to those observed in the abdomen may develop. Rarely, breast enlargement may become so pathologically extensive—as referred to as gigantomastia as shown in Figure 4-3—that it requires postpartum surgical intervention (Antevski, 2011; Pasrija, 2006; Shoma, 2011; Vidaeff, 2003).

For most normal pregnancies, prepregnancy breast size and volume of milk production do not correlate (Hytten, 1995). Histological and functional changes of the breasts induced by pregnancy and lactation are further discussed in Chapter 36 (p. 672).

There are several changes in the skin during pregnancy. These sometimes are noticeable and may provoke anxiety in some women. Skin changes are common, and Rathore and coworkers (2011)
conducted a detailed dermatological examination of 2000 randomly selected asymptomatic women attending a prenatal clinic in India. They found at least one physiological cutaneous change in 87 percent of the women.

**Abdominal Wall**

Beginning after midpregnancy, reddish, slightly depressed streaks commonly develop in the abdominal skin and sometimes in the skin over the breasts and thighs. These are called *striae gravidarum* or *stretch marks*. In multiparous women, in addition to the reddish striae of the present pregnancy, glistening, silvery lines that represent the cicatrices of previous striae frequently are seen. In a study of 110 primiparous patients, Osman and colleagues (2007) reported that 48 percent developed striae gravidarum on their abdomen; 25 percent on their breasts; and 25 percent on their thighs. The strongest associated risk factors were weight gain during pregnancy, younger maternal age, and family history. The etiology of striae gravidarum is unknown, and there are no definitive treatments (Soltanipoor, 2012).

Occasionally, the muscles of the abdominal walls do not withstand the tension to which they are subjected. As a result, rectus muscles separate in the midline, creating *diastasis recti* of varying extent. If severe, a considerable portion of the anterior uterine wall is covered by only a layer of skin, attenuated fascia, and peritoneum to form a ventral hernia.

**Hyperpigmentation**

This develops in up to 90 percent of women. It is usually more accentuated in those with a darker complexion (Muallem, 2006). The midline of the anterior abdominal wall skin—*linea alba*—takes on dark brown-black pigmentation to form the *linea nigra*. Occasionally, irregular brownish patches of varying size appear on the face and neck, giving rise to *chloasma* or *melasma gravidarum*—the so-called *mask of pregnancy*. Pigmentation of the areolae and genital skin may also be accentuated. These pigmentary changes usually disappear, or at least regress considerably, after delivery. Oral contraceptives may cause similar pigmentation (Sheth, 2011).

Little is known of the etiology of these pigmentary changes. However, levels of melanocyte-stimulating hormone, a polypeptide similar to corticotropin, are elevated remarkably throughout pregnancy. Estrogen and progesterone also are reported to have melanocyte-stimulating effects.

**Vascular Changes**

Angiomas, called *vascular spiders*, develop in approximately two thirds of white women and approximately 10 percent of black women. Particularly common on the face, neck, upper chest, and arms, these are minute, red skin elevations, with radicles branching out from a central lesion. The condition is often designated as nevus, angioma, or telangiectasis. *Palmar erythema* is encountered during pregnancy in approximately two thirds of white women and one third of black women. These two conditions are of no clinical significance and disappear in most women shortly after pregnancy. They are most likely the consequence of hyperestrogenemia.

In addition to these discrete lesions, increased cutaneous blood flow in pregnancy serves to dissipate excess heat generated by increased metabolism.
Metabolic Changes

In response to the increased demands of the rapidly growing fetus and placenta, the pregnant woman undergoes metabolic changes that are numerous and intense. Certainly no other physiological event induces such profound metabolic alterations. By the third trimester, maternal basal metabolic rate is increased by 10 to 20 percent compared with that of the nonpregnant state. This is increased by an additional 10 percent in women with a twin gestation (Shinagawa, 2005). Viewed another way, an analysis by the World Health Organization (2004) estimates that the additional total pregnancy energy demands associated with normal pregnancy are approximately 77,000 kcal or 85 kcal/day, 285 kcal/day, and 475 kcal/day during the first, second, and third trimester, respectively (Table 4-1). In addition to the corresponding increased caloric requirements, Löf (2011) found that the increased energy demands were also compensated for, in part, by normal pregnant women gravitating to less physically demanding activities.

Weight Gain

Most of the normal increase in weight during pregnancy is attributable to the uterus and its...
A smaller fraction results from metabolic alterations that increase accumulation of cellular water, fat, and protein—so-called *maternal reserves*. Hytten (1991) reported that the average weight gain during pregnancy is approximately 12.5 kg or 27.5 lb (Table 4-2). Maternal aspects of weight gain are considered in greater detail in Chapter 9 (p. 177).

### Water Metabolism

Increased water retention is a normal physiological alteration of pregnancy. It is mediated, at least in part, by a fall in plasma osmolality of approximately 10 mOsm/kg induced by a resetting of osmotic thresholds for thirst and vasopressin secretion (Heenan, 2003; Lindheimer, 1995). As shown in Figure 4-4, this phenomenon is functioning by early pregnancy.
At term, the water content of the fetus, placenta, and amnionic fluid approximates 3.5 L. Another 3.0 L accumulates from increases in maternal blood volume and in the size of the uterus and breasts. Thus, the minimum amount of extra water that the average woman accrues during normal pregnancy is approximately 6.5 L. Clearly demonstrable pitting edema of the ankles and legs is seen in most pregnant women, especially at the end of the day. This fluid accumulation, which may amount to a liter or so, is caused by increased venous pressure below the level of the uterus as a consequence of partial vena cava occlusion. A decrease in interstitial colloid osmotic pressure induced by normal pregnancy also favors edema late in pregnancy (Øian, 1985).

Longitudinal studies of body composition have shown a progressive increase in total body water and fat mass during pregnancy. Both initial maternal weight and weight gained during pregnancy are highly associated with birthweight. It is unclear, however, what role maternal fat or water have in fetal growth. Studies in well-nourished women suggest that maternal body water, rather than fat, contributes more significantly to infant birthweight (Lederman, 1999; Mardones-Santander, 1998).

**Protein Metabolism**

The products of conception, the uterus, and maternal blood are relatively rich in protein rather than
fat or carbohydrate. At term, the fetus and placenta together weigh about 4 kg and contain approximately 500 g of protein, or about half of the total pregnancy increase (Hytten, 1971). The remaining 500 g is added to the uterus as contractile protein, to the breasts primarily in the glands, and to maternal blood as hemoglobin and plasma proteins.

Amino acid concentrations are higher in the fetal than in the maternal compartment (Cetin, 2005; van den Akker, 2009). This increased concentration is largely regulated by the placenta. The placenta not only concentrates amino acids into the fetal circulation, but also is involved in protein synthesis, oxidation, and transamination of some nonessential amino acids (Galan, 2009).

Mojtahedi and associates (2002) measured nitrogen balance across pregnancy in 12 healthy women. It increased with gestational age and thus suggested a more efficient use of dietary protein. They also found that urinary excretion of 3-methylhistidine did not change, indicating that maternal muscle breakdown is not required to meet metabolic demands. Further support that pregnancy is associated with nitrogen conservation comes from Kalhan and coworkers (2003), who found that the turnover rate of nonessential serine decreases across gestation. The daily requirements for dietary protein intake during pregnancy are discussed in Chapter 9 (p. 179).

Carbohydrate Metabolism

Normal pregnancy is characterized by mild fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia (Fig. 4-5). This increased basal level of plasma insulin in normal pregnancy is associated with several unique responses to glucose ingestion. For example, after an oral glucose meal, gravid women demonstrate prolonged hyperglycemia and hyperinsulinemia as well as a greater suppression of glucagon (Phelps, 1981). This cannot be explained by an increased metabolism of insulin because its half-life during pregnancy is not changed (Lind, 1977). Instead, this response is consistent with a pregnancy-induced state of peripheral insulin resistance, the purpose of which is likely to ensure a sustained postprandial supply of glucose to the fetus. Indeed, insulin sensitivity in late normal pregnancy is 45 to 70 percent lower than that of nonpregnant women (Butte, 2000; Freemark, 2006).
The mechanism(s) responsible for insulin resistance is not completely understood. Progesterone and estrogen may act, directly or indirectly, to mediate this insensitivity. Plasma levels of placental lactogen increase with gestation, and this protein hormone is characterized by growth hormone–like action. Higher levels may increase lipolysis and liberation of free fatty acids (Freinkel, 1980). The increased concentration of circulating free fatty acids also may aid increased tissue resistance to insulin (Freemark, 2006).

The pregnant woman changes rapidly from a postprandial state characterized by elevated and sustained glucose levels to a fasting state characterized by decreased plasma glucose and some amino acids. Simultaneously, plasma concentrations of free fatty acids, triglycerides, and cholesterol are higher. Freinkel and colleagues (1985) have referred to this pregnancy-induced switch in fuels from glucose to lipids as accelerated starvation. Certainly, when fasting is prolonged in the pregnant woman, these alterations are exaggerated and ketonemia rapidly appears.

Fat Metabolism
The concentrations of lipids, lipoproteins, and apolipoproteins in plasma increase appreciably during pregnancy (Appendix, p. 1291). Increased insulin resistance and estrogen stimulation during pregnancy are responsible for the maternal hyperlipidemia. As reviewed by Ghio and associates (2011), increased lipid synthesis and food intake contribute to maternal fat accumulation during the first two trimesters. In the third trimester, however, fat storage declines or ceases. This is a consequence of enhanced lipolytic activity, and decreased lipoprotein lipase activity reduces circulating triglyceride uptake into adipose tissue. This transition to a catabolic state favors maternal use of lipids as an energy source and spares glucose and amino acids for the fetus.

Maternal hyperlipidemia is one of the most consistent and striking changes of lipid metabolism during late pregnancy. Triacylglycerol and cholesterol levels in very-low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs) are increase during the third trimester compared with those in nonpregnant women. During the third trimester, average total serum cholesterol, LDL-C, HDL-C, and triglyceride levels are approximately 267 ± 30 mg/dL, 136 ± 33 mg/dL, 81 ± 17 mg/dL, and 245 ± 73 mg/dL, respectively (Lippi, 2007). After delivery, the concentrations of these lipids, as well as lipoproteins and apolipoproteins, decrease. Lactation speeds the change in levels of many of these (Darmady, 1982).

Hyperlipidemia is theoretically a concern because it is associated with endothelial dysfunction. From their studies, however, Saarelainen and coworkers (2006) found that endothelium-dependent vasodilation responses actually improve across pregnancy. This was partly because increased HDL-cholesterol concentrations likely inhibit LDL oxidation and thus protect the endothelium. Their findings suggest that the increased cardiovascular disease risk in multiparous women may be related to factors other than maternal hypercholesterolemia.

**Leptin**

In nonpregnant humans, this peptide hormone is primarily secreted by adipose tissue. It plays a key role in body fat and energy expenditure regulation. Leptin deficiency is associated with anovulation and infertility, however, pregnancy in a woman with a leptin-receptor mutation has been reported (Maguire, 2012; Nizard, 2012).

Maternal serum leptin levels increase and peak during the second trimester and plateau until term in concentrations two to four times higher than those in nonpregnant women. This increase is only partially due to pregnancy weight gain, because leptin also is produced in significant amounts by the placenta (Maymó, 2011). Moreover, and as discussed in Chapter 5 (p. 106), placental weight is significantly correlated with leptin levels measured in umbilical cord blood (Pighetti, 2003).

Hauguel-de Mouzon and associates (2006) have hypothesized that increased leptin production may be critical for the regulation of increased maternal energy demands. As discussed in Chapter 48 (p. 961), leptin and adiponectin—a cytokine involved with energy homeostasis and lipid metabolism—may also help to regulate fetal growth (Henson, 2006; Karakosta, 2010; Nakano, 2012). As reviewed by Miehle and colleagues (2012), abnormally elevated leptin levels have been associated with preeclampsia (Chap. 40, p. 729) and gestational diabetes (Chap. 57, p. 1136).

**Ghrelin**

This peptide is secreted principally by the stomach in response to hunger. It cooperates with other neuroendocrine factors, such as leptin, in energy homeostasis modulation. It is also expressed in the placenta and likely has a role in fetal growth and cell proliferation (Chap. 5, p. 105). Maternal
serum ghrelin levels increase and peak at midpregnancy and then decrease until term (Fuglsang, 2008). This is explicable in that ghrelin levels are known to be decreased in other insulin-resistant states such as metabolic syndrome and gestational diabetes mellitus (Baykus, 2012; Riedl, 2007). Muccioli and coworkers (2011) have provided an excellent review of the many functions of ghrelin in the regulation of reproductive function.

Electrolyte and Mineral Metabolism

During normal pregnancy, nearly 1000 mEq of sodium and 300 mEq of potassium are retained (Lindheimer, 1987). Although the glomerular filtration of sodium and potassium is increased, the excretion of these electrolytes is unchanged during pregnancy as a result of enhanced tubular resorption (Brown, 1986, 1988). And although there are increased total accumulations of sodium and potassium, their serum concentrations are decreased slightly because of expanded plasma volume (Appendix, p. 1289). Still, these levels remain very near the normal range for nonpregnant women (Kametas, 2003a).

Total serum calcium levels, which include both ionized and nonionized calcium, decline during pregnancy. This reduction follows lowered plasma albumin concentrations and, in turn, a consequent decrease in the amount of circulating protein-bound nonionized calcium. Serum ionized calcium levels, however, remain unchanged (Power, 1999). The developing fetus imposes a significant demand on maternal calcium homeostasis. For example, the fetal skeleton accretes approximately 30 g of calcium by term, 80 percent of which is deposited during the third trimester. This demand is largely met by a doubling of maternal intestinal calcium absorption mediated, in part, by 1,25-dihydroxyvitamin D₃ (Kovacs, 2006). In addition, dietary intake of sufficient calcium is necessary to prevent excess depletion from the mother (Table 9-6, p. 179). This is especially important for pregnant adolescents, in whom bones are still developing (Repke, 1994).

Serum magnesium levels also decline during pregnancy. Bardicef and colleagues (1995) concluded that pregnancy is actually a state of extracellular magnesium depletion. Compared with nonpregnant women, they found that both total and ionized magnesium concentrations were significantly lower during normal pregnancy. Serum phosphate levels lie within the nonpregnant range (Kametas, 2003a). The renal threshold for inorganic phosphate excretion is elevated in pregnancy due to increased calcitonin levels (Weiss, 1998).

Iodine requirements increase during normal pregnancy for several reasons (Leung, 2011; Zimmermann, 2012). First, maternal thyroxine (T₄) production increases to maintain maternal euthyroidism and to transfer thyroid hormone to the fetus early in gestation before the fetal thyroid is functioning (Chap. 58, p. 1147). Second, fetal thyroid hormone production increases during the second half of pregnancy. This contributes to increased maternal iodine requirements because iodide readily crosses the placenta. Third, the primary route of iodine excretion is through the kidney. Beginning in early pregnancy, the iodide glomerular filtration rate increases by 30 to 50 percent. Thus, because of increased thyroid hormone production, the iodine requirement of the fetus, and greater renal clearance, dietary iodine requirements are higher during normal gestation. Moreover, Burns and associates (2011) have reported that the placenta has the ability to store iodine. Whether placental iodine functions to protect the fetus from inadequate maternal dietary iodine, however, is currently unknown. Iodine deficiency is discussed later in this chapter (p. 69) as well as in Chapter 58 (p. 1155).

With respect to most other minerals, pregnancy induces little change in their metabolism other than their retention in amounts equivalent to those needed for growth (Chap. 7, p. 134 and Chap. 9, p. 179). An important exception is the considerably increased requirement for iron, which is
HEMATOLOGICAL CHANGES

Blood Volume

The well-known hypervolemia associated with normal pregnancy averages 40 to 45 percent above the nonpregnant blood volume after 32 to 34 weeks (Pritchard, 1965; Zeeman, 2009). In individual women, expansion varies considerably. In some there is only a modest increase, whereas in others the blood volume nearly doubles. A fetus is not essential for this because increased blood volume develops in some women with hydatidiform mole.

Pregnancy-induced hypervolemia has several important functions. First, it meets the metabolic demands of the enlarged uterus and its greatly hypertrophied vascular system. Second, it provides abundant nutrients and elements to support the rapidly growing placenta and fetus. Increased intravascular volume also protects the mother, and in turn the fetus, against the deleterious effects of impaired venous return in the supine and erect positions. Last, it safeguards the mother against the adverse effects of parturition-associated blood loss.

Maternal blood volume begins to increase during the first trimester. By 12 menstrual weeks, plasma volume expands by approximately 15 percent compared with that of prepregnancy (Bernstein, 2001). As shown in Figure 4-6, maternal blood volume expands most rapidly during the second trimester. It then rises at a much slower rate during the third trimester to plateau during the last several weeks of pregnancy.
Blood volume expansion results from an increase in both plasma and erythrocytes. Although more plasma than erythrocytes is usually added to the maternal circulation, the increase in erythrocyte volume is considerable and averages 450 mL (Pritchard, 1960). Moderate erythroid hyperplasia is present in the bone marrow, and the reticulocyte count is elevated slightly during normal pregnancy. As discussed in Chapter 56 (p. 1101), these changes are almost certainly related to an elevated maternal plasma erythropoietin level. This peaks early during the third trimester and corresponds to maximal erythrocyte production (Clapp, 2003; Harstad, 1992).

Hemoglobin Concentration and Hematocrit

Because of great plasma augmentation, hemoglobin concentration and hematocrit decrease slightly during pregnancy (Appendix, p. 1287). As a result, whole blood viscosity decreases (Huisman, 1987). Hemoglobin concentration at term averages 12.5 g/dL, and in approximately 5 percent of women, it is below 11.0 g/dL (Fig. 56-1, p. 1102). Thus, a hemoglobin concentration below 11.0 g/dL, especially late in pregnancy, should be considered abnormal and usually due to iron deficiency rather than pregnancy hypervolemia.

Iron Metabolism

Storage Iron

The total iron content of normal adult women ranges from 2.0 to 2.5 g, or approximately half that found normally in men. Most of this is incorporated in hemoglobin or myoglobin, and thus, iron stores of normal young women are only approximately 300 mg (Pritchard, 1964).

Iron Requirements

Of the approximate 1000 mg of iron required for normal pregnancy, about 300 mg are actively transferred to the fetus and placenta, and another 200 mg are lost through various normal excretion routes, primarily the gastrointestinal tract. These are obligatory losses and accrue even when the mother is iron deficient. The average increase in the total circulating erythrocyte volume—about 450 mL—requires another 500 mg. Recall that each 1 mL of erythrocytes contains 1.1 mg of iron. Because most iron is used during the latter half of pregnancy, the iron requirement becomes large after midpregnancy and averages 6 to 7 mg/day (Pritchard, 1970). In most women, this amount is usually not available from iron stores. Thus, without supplemental iron, the optimal increase in maternal erythrocyte volume will not develop, and the hemoglobin concentration and hematocrit will fall appreciably as plasma volume increases. At the same time, fetal red cell production is not impaired because the placenta transfers iron even if the mother has severe iron deficiency anemia. In severe cases, we have documented maternal hemoglobin values of 3 g/dL, and at the same time, fetuses had hemoglobin concentrations of 16 g/dL. The complex mechanisms of placental iron transport and regulation have recently been reviewed by Gambling (2011) and Lipiński (2013) and all of their coworkers.

It follows that the amount of dietary iron, together with that mobilized from stores, will be insufficient to meet the average demands imposed by pregnancy. If the nonanemic pregnant woman is not given supplemental iron, then serum iron and ferritin concentrations decline after midpregnancy. The early pregnancy increases in serum iron and ferritin are likely due to minimal
early iron demands combined with the positive iron balance from amenorrhea (Kaneshige, 1981).

The Puerperium

Generally, not all the maternal iron added in the form of hemoglobin is lost with normal delivery. During vaginal delivery and the first postpartum days, only approximately half of the added erythrocytes are lost from most women. These normal losses are from the placental implantation site, episiotomy or lacerations, and lochia. On average, maternal erythrocytes corresponding to approximately 500 to 600 mL of predelivery whole blood are lost with vaginal delivery of a single fetus (Pritchard, 1965; Ueland, 1976). The average blood loss associated with cesarean delivery or with the vaginal delivery of twins is approximately 1000 mL (Fig. 41-1, p. 781).

Immunological Functions

Pregnancy is thought to be associated with suppression of various humoral and cell-mediated immunological functions to accommodate the “foreign” semiallogeneic fetal graft (Redman, 2014; Thellin, 2003). This is discussed further in Chapter 5 (p. 97). In reality, pregnancy is both a proinflammatory and antiinflammatory condition, depending upon the stage of gestation. Indeed, Mor and colleagues (2010, 2011) have proposed that pregnancy can be divided into three distinct immunological phases. First, early pregnancy is proinflammatory. During implantation and placentation, the blastocyst must break through the uterine cavity epithelial lining to invade endometrial tissue. Trophoblast must then replace the endothelium and vascular smooth muscle of the maternal blood vessels to secure an adequate blood supply for the placenta (Chap. 5, p. 90). All these activities create a veritable “battleground” of invading cells, dying cells, and repairing cells. And, an inflammatory environment is required to secure cellular debris removal and adequate repair of the uterine epithelium. In contrast, midpregnancy is antiinflammatory. During this period of rapid fetal growth and development, the predominant immunological feature is induction of an antiinflammatory state. Last, parturition is characterized by an influx of immune cells into the myometrium to promote recrudescence of an inflammatory process.

An important antiinflammatory component of pregnancy appears to involve suppression of T-helper (Th) 1 and T-cytotoxic (Tc) 1 cells, which decreases secretion of interleukin-2 (IL-2), interferon-γ, and tumor necrosis factor-β (TNF-β). There is also evidence that a suppressed Th1 response is requisite for pregnancy continuation. It also may explain pregnancy-related remission of some autoimmune disorders such as rheumatoid arthritis, multiple sclerosis, and Hashimoto thyroiditis—which are Th1-mediated diseases (Kumru, 2005). As discussed in Chapter 40 (p. 733), failure of Th1 immune suppression may be related to preeclampsia development (Jonsson, 2006).

In contrast to suppression of Th1 cells, there is upregulation of Th2 cells to increase secretion of IL-4, IL-6, and IL-13 (Michimata, 2003). In cervical mucus, peak levels of immunoglobulins A and G (IgA and IgG) are significantly higher during pregnancy. Similarly, the amount of interleukin-1β found in cervical and vaginal mucus during the first trimester is approximately tenfold greater than that in nonpregnant women (Anderson, 2013).

Leukocytes

Beginning in the second trimester and continuing throughout pregnancy, some polymorphonuclear leukocyte chemotaxis and adherence functions are depressed (Krause, 1987). Although incompletely understood, this activity suppression may be partly related to the finding that relaxin impairs neutrophil activation (Masini, 2004). It is possible that these depressed leukocyte
functions also account in part for the improvement of some autoimmune disorders.

As shown in the Appendix (p. 1287), leukocyte count ranges during pregnancy are higher than nonpregnant values, and the upper values approach 15,000/μL. During labor and the early puerperium, values may become markedly elevated, attaining levels of 25,000/μL or even more. However, values average 14,000 to 16,000/μL (Taylor, 1981). The cause for this marked increase is not known, but the same response occurs during and after strenuous exercise. It probably represents the reappearance of leukocytes previously shunted out of active circulation.

In addition to normal variations in the leukocyte count, the distribution of cell types is altered significantly during pregnancy. Specifically, during the third trimester, the percentages of granulocytes and CD8 T lymphocytes are significantly increased, along with a concomitant reduction in the percentages of CD4 T lymphocytes and monocytes. Moreover, circulating leukocytes undergo significant phenotypic changes including, for example, the upregulation of certain adhesion molecules (Luppi, 2002).

**Inflammatory Markers**

Many tests performed to diagnose inflammation cannot be used reliably during pregnancy. For example, *leukocyte alkaline phosphatase* levels are used to evaluate myeloproliferative disorders and are increased beginning early in pregnancy. The concentration of *C-reactive protein*, an acute-phase serum reactant, rises rapidly in response to tissue trauma or inflammation. Anderson (2013), Watts (1991), and all their associates measured C-reactive protein levels across pregnancy and found that median values were higher than for nonpregnant women. In the latter study, levels were also found to be elevated further during labor. Of nonlaboring women, 95 percent had levels of 1.5 mg/dL or less, and gestational age did not affect serum levels. Another marker of inflammation, the *erythrocyte sedimentation rate (ESR)*, is increased in normal pregnancy because of elevated plasma globulins and fibrinogen (Hyttén, 1971). Complement factors C3 and C4 also are significantly elevated during the second and third trimesters (Gallery, 1981; Richani, 2005). Last, levels of *procalcitonin*, a normal precursor of calcitonin, increase at the end of the third trimester and through the first few postpartum days (p. 70). Procalcitonin levels are elevated in severe bacterial infections but remain low in viral infections and nonspecific inflammatory disease. Based on their longitudinal study, Paccolat and colleagues (2011) concluded that a threshold of 0.25 μg/L can be used during the third trimester and peripartum to exclude infection.

**Coagulation and Fibrinolysis**

During normal pregnancy, both coagulation and fibrinolysis are augmented but remain balanced to maintain hemostasis (Appendix, p. 1288). They are even more enhanced in Multiple gestation (Morikawa, 2006). Evidence of activation includes increased concentrations of all clotting factors except factors XI and XIII (*Table 4-3*). The clotting time of whole blood, however, does not differ significantly in normal pregnant women. Considering the substantive physiological increase in plasma volume in normal pregnancy, such increased concentrations represent a markedly augmented production of these procoagulants (Kenny, 2014). In a longitudinal study of 20 healthy nulligravid women, for example, McLean and coworkers (2012) demonstrated progressive increases in the level and rate of thrombin generation throughout gestation. These returned to preconceptional levels by 1 year after pregnancy.

| TABLE 4-3. Changes in Measures of Hemostasis During Normal Pregnancy |
In normal nonpregnant women, plasma fibrinogen (factor I) averages 300 mg/dL and ranges from 200 to 400 mg/dL. During normal pregnancy, fibrinogen concentration increases approximately 50 percent. In late pregnancy, it averages 450 mg/dL, with a range from 300 to 600 mg/dL. The percentage of high-molecular-weight fibrinogen is unchanged (Manten, 2004). This contributes greatly to the striking increase in the erythrocyte sedimentation rate as discussed previously. Some of the pregnancy-induced changes in the levels of coagulation factors can be duplicated by the administration of estrogen plus progestin contraceptive tablets to nonpregnant women.

The end product of the coagulation cascade is fibrin formation, and the main function of the fibrinolytic system is to remove excess fibrin. Tissue plasminogen activator (tPA) converts plasminogen into plasmin, which causes fibrinolysis and produces fibrin-degradation products such as D-dimers. Studies of the fibrinolytic system in pregnancy have produced conflicting results, but most evidence suggests that fibrinolytic activity is actually reduced in normal pregnancy (Kenny, 2014). For example, tPA activity gradually decreases during normal pregnancy. Moreover, plasminogen activator inhibitor type 1 (PAI-1) and type 2 (PAI-2), which inhibit tPA and regulate fibrin degradation by plasmin, increase during normal pregnancy (Hui, 2012; Robb, 2009). As reviewed by Holmes and Wallace (2005), these changes—which may indicate that the fibrinolytic system is impaired—are countered by increased levels of plasminogen and decreased levels of another plasmin inhibitor, α₂ antiplasmin. Such changes serve to ensure hemostatic balance during normal pregnancy.

**Platelets**

Normal pregnancy also involves platelet changes. In a study of almost 7000 healthy women at term, Boehlen and colleagues (2000) found that the average platelet count was decreased slightly.
Thrombocytopenia defined as below the 2.5th percentile corresponded to a platelet count of 116,000/μL. Decreased platelet concentrations are partially due to hemodilutional effects. There likely also is increased platelet consumption, leading to a greater proportion of younger and therefore larger platelets (Valera, 2010). Further supporting this concept, Hayashi and associates (2002) found that beginning in midpregnancy, production of thromboxane A₂, which induces platelet aggregation, progressively increases. Because of splenic enlargement, there may also be an element of “hypersplenism” (Kenny, 2014).

**Regulatory Proteins**

There are several natural inhibitors of coagulation, including proteins C and S and antithrombin. Inherited or acquired deficiencies of these and other natural regulatory proteins—collectively referred to as thrombophilies—account for many thromboembolic episodes during pregnancy. They are discussed in detail in Chapter 52 (p. 1029).

*Activated protein C*, along with the cofactors protein S and factor V, functions as an anticoagulant by neutralizing the procoagulants factor Va and factor VIIIa (Fig. 52–1, p. 1030). During pregnancy, resistance to activated protein C increases progressively and is related to a concomitant decrease in free protein S and increase in factor VIII levels. Between the first and third trimesters, activated protein C levels decrease from 2.4 to 1.9 U/mL, and free protein S concentrations decline from 0.4 to 0.16 U/mL (Walker, 1997). Oral contraceptives also decrease free protein S levels. Levels of *antithrombin* remain relatively constant throughout gestation and the early puerperium (Delorme, 1992).

**Spleen**

By the end of normal pregnancy, the spleen enlarges by up to 50 percent compared with that in the first trimester (Maymon, 2007). Moreover, in a study of 77 recently delivered gravidas, Gayer and coworkers (2012) found that splenic size was 68-percent larger compared with that of nonpregnant controls. The cause of this splenomegaly is unknown, but it might follow the increased blood volume and/or the hemodynamic changes of pregnancy, which are subsequently discussed. Sonographically, the echogenic appearance of the spleen remains homogeneous throughout gestation.

**CARDIOVASCULAR SYSTEM**

During pregnancy and the puerperium, the heart and circulation undergo remarkable physiological adaptations. Changes in cardiac function become apparent during the first 8 weeks of pregnancy (Hibbard, 2014). Cardiac output is increased as early as the fifth week and reflects a reduced systemic vascular resistance and an increased heart rate. Compared with prepregnancy measurements, brachial systolic blood pressure, diastolic blood pressure, and central systolic blood pressure are all significantly lower 6 to 7 weeks from the last menstrual period (Mahendru, 2012). The resting pulse rate increases approximately 10 beats/min during pregnancy. Between weeks 10 and 20, plasma volume expansion begins, and preload is increased.

Ventricular performance during pregnancy is influenced by both the decrease in systemic vascular resistance and changes in pulsatile arterial flow. Multiple factors contribute to this
overall altered hemodynamic function, which allows the physiological demands of the fetus to be met while maintaining maternal cardiovascular integrity (Hibbard, 2014). These changes during the last half of pregnancy are graphically summarized in Figure 4-7. The important effects of maternal posture on hemodynamics are also illustrated.

**FIGURE 4-7** Effect of maternal posture on hemodynamics. PP = postpartum. (Redrawn from Ueland, 1975.)

---

**Heart**

As the diaphragm becomes progressively elevated, the heart is displaced to the left and upward and is rotated on its long axis. As a result, the apex is moved somewhat laterally from its usual position and produces a larger cardiac silhouette in chest radiographs (Fig. 4-8). Furthermore, pregnant women normally have some degree of benign pericardial effusion, which may increase the cardiac silhouette (Enein, 1987). Variability of these factors makes it difficult to precisely identify moderate degrees of cardiomegaly by simple radiographic studies. Normal pregnancy induces no characteristic electrocardiographic changes other than slight left-axis deviation due to the altered heart position.
Many of the normal cardiac sounds are modified during pregnancy. Cutforth and MacDonald (1966) used phonocardiography and documented: (1) an exaggerated splitting of the first heart sound and increased loudness of both components, (2) no definite changes in the aortic and pulmonary elements of the second sound, and (3) a loud, easily heard third sound (Fig. 49-2, p. 975). In 90 percent of pregnant women, they also heard a systolic murmur that was intensified during inspiration in some or expiration in others and that disappeared shortly after delivery. A soft diastolic murmur was noted transiently in 20 percent, and continuous murmurs arising from the breast vasculature in 10 percent.

Structurally, the increasing plasma volume seen during normal pregnancy is reflected by enlarging cardiac end-systolic and end-diastolic dimensions. At the same time, however, there is no change in septal thickness or in ejection fraction. This is because the dimensional changes are accompanied by substantive ventricular remodeling, which is characterized by eccentric left-ventricular mass expansion averaging 30 to 35 percent near term. In the nonpregnant state, the heart is capable of remodeling in response to stimuli such as hypertension and exercise. Such cardiac plasticity likely is a continuum that encompasses physiological growth, such as that in exercise, as well as pathological hypertrophy—such as with hypertension (Hill, 2008).

And although it is widely held that there is physiological hypertrophy of cardiac myocytes as a result of pregnancy, this has never been absolutely proven. Hibbard and colleagues (2014) concluded that any increased mass does not meet criteria for hypertrophy.

Certainly for clinical purposes, ventricular function during pregnancy is normal, as estimated by
the Braunwald ventricular function graph depicted in Figure 4-9. For the given filling pressures, there is appropriate cardiac output so that cardiac function during pregnancy is eudynamic. Despite these findings, it remains controversial whether myocardial function per se is normal, enhanced, or depressed. In nonpregnant subjects with a normal heart who sustain a high-output state, the left ventricle undergoes longitudinal remodeling, and echocardiographic functional indices of its deformation provide normal values. In pregnancy, there instead appears to be spherical remodeling, and these calculated indices that measure longitudinal deformation are depressed (Savu, 2012). Thus, these normal indices are likely inaccurate when used to assess function in pregnant women because they do not account for the spherical eccentric hypertrophy characteristic of normal pregnancy.

**FIGURE 4-9** Relationship between left ventricular stroke work index (LVSWI), cardiac output, and pulmonary capillary wedge pressure (PCWP) in 10 normal pregnant women in the third trimester. (Data from Clark, 1989.)

### Cardiac Output

During normal pregnancy, mean arterial pressure and vascular resistance decrease, while blood volume and basal metabolic rate increase. As a result, cardiac output at rest, when measured in the lateral recumbent position, increases significantly beginning in early pregnancy (Duvekot, 1993; Mabie, 1994). It continues to increase and remains elevated during the remainder of pregnancy (Fig. 4-10).
During late pregnancy in a supine woman, the large uterus rather consistently compresses venous return from the lower body. It also may compress the aorta (Bieniarz, 1968). In response, cardiac filling may be reduced and cardiac output diminished. Specifically, Bamber and Dresner (2003) found cardiac output at term to increase 1.2 L/min—almost 20 percent—when a woman was moved from her back onto her left side. Moreover, in the supine pregnant woman, uterine blood flow estimated by Doppler velocimetry decreases by a third (Jeffreys, 2006). Of note, Simpson and James (2005) found that fetal oxygen saturation is approximately 10 percent higher if a laboring woman is in a lateral recumbent position compared with supine. Upon standing, cardiac output falls to the same degree as in the nonpregnant woman (Easterling, 1988).

In Multiple pregnancies, compared with singletons, maternal cardiac output is augmented further by almost another 20 percent because of a greater stroke volume (15 percent) and heart rate (3.5 percent). Left atrial diameter and left ventricular end-diastolic diameter are also increased due to augmented preload (Kametas, 2003b). The increased heart rate and inotropic contractility imply that cardiovascular reserve is reduced in Multiple gestations.

During the first stage of labor, cardiac output increases moderately. During the second stage,
with vigorous expulsive efforts, it is appreciably greater (see Fig. 4-10). The pregnancy-induced increase is lost after delivery, at times dependent on blood loss.

### Hemodynamic Function in Late Pregnancy

To further elucidate the net changes of normal pregnancy-induced cardiovascular changes, Clark and associates (1989) conducted invasive studies to measure hemodynamic function late in pregnancy (Table 4-4). Right heart catheterization was performed in 10 healthy nulliparous women at 35 to 38 weeks, and again at 11 to 13 weeks postpartum. Late pregnancy was associated with the expected increases in heart rate, stroke volume, and cardiac output. Systemic vascular and pulmonary vascular resistance both decreased significantly, as did colloid osmotic pressure. Pulmonary capillary wedge pressure and central venous pressure did not change appreciably between late pregnancy and the puerperium. Thus, as shown earlier in Figure 4-9, although cardiac output is increased, left ventricular function as measured by stroke work index remains similar to the nonpregnant normal range. Put another way, normal pregnancy is not a continuous “high-output” state.

### Circulation and Blood Pressure

Changes in posture affect arterial blood pressure. Brachial artery pressure when sitting is lower than that when in the lateral recumbent supine position (Bamber, 2003). Arterial pressure usually decreases to a nadir at 24 to 26 weeks and rises thereafter. Diastolic pressure decreases more than
Antecubital venous pressure remains unchanged during pregnancy. In the supine position, however, femoral venous pressure rises steadily, from approximately 8 mm Hg early in pregnancy to 24 mm Hg at term. Wright and coworkers (1950) demonstrated that venous blood flow in the legs is retarded during pregnancy except when the lateral recumbent position is assumed. This tendency toward blood stagnation in the lower extremities during latter pregnancy is attributable to occlusion of the pelvic veins and inferior vena cava by the enlarged uterus. The elevated venous pressure returns to normal when the pregnant woman lies on her side and immediately after delivery (McLennan, 1943). These alterations contribute to the dependent edema frequently experienced and to the development of varicose veins in the legs and vulva, as well as hemorrhoids. These changes also predispose to deep-vein thrombosis (Chap. 52, p. 1035).

**Supine Hypotension**

In approximately 10 percent of women, supine compression of the great vessels by the uterus causes significant arterial hypotension, sometimes referred to as the *supine hypotensive syndrome* (Kinsella, 1994). Also when supine, uterine arterial pressure—and thus blood flow—is significantly lower than that in the brachial artery. As discussed in Chapter 24 (p. 494), this may directly affect fetal heart rate patterns (Tamás, 2007). These changes are also seen with hemorrhage or with spinal analgesia (Chap. 25, p. 511).
Renin, Angiotensin II, and Plasma Volume

The renin-angiotensin-aldosterone axis is intimately involved in blood pressure control via sodium and water balance. All components of this system are increased in normal pregnancy (Bentley-Lewis, 2005). Renin is produced by both the maternal kidney and the placenta, and increased renin substrate (angiotensinogen) is produced by both maternal and fetal liver. Elevated angiotensinogen levels result, in part, from increased estrogen production during normal pregnancy and are important in first-trimester blood pressure maintenance (August, 1995).

Gant and associates (1973) studied vascular reactivity to angiotensin II throughout pregnancy. Nulliparas who remained normotensive became and stayed refractory to the pressor effects of infused angiotensin II. Conversely, those who ultimately became hypertensive developed, but then lost, this refractoriness. Follow-up studies by Gant (1974) and Cunningham (1975) and their colleagues indicated that increased refractoriness to angiotensin II stemmed from individual vessel refractoriness. Said another way, the abnormally increased sensitivity was an alteration in vessel wall refractoriness rather than the consequence of altered blood volume or renin-angiotensin secretion.

The vascular responsiveness to angiotensin II may be progesterone related. Normally, pregnant women lose their acquired vascular refractoriness to angiotensin II within 15 to 30 minutes after the placenta is delivered. Moreover, large amounts of intramuscular progesterone given during late labor delay this diminishing refractoriness. And although exogenous progesterone does not restore angiotensin II refractoriness to women with gestational hypertension, this can be done with infusion of its major metabolite, 5α-dihydroprogesterone.

Cardiac Natriuretic Peptides

At least two species of these—atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP)—are secreted by cardiomyocytes in response to chamber-wall stretching. These peptides regulate blood volume by provoking natriuresis, diuresis, and vascular smooth-muscle relaxation (Clerico, 2004). In nonpregnant and pregnant patients, levels of BNP and of amino-terminal pro-brain natriuretic peptide (Nt pro-BNP) may be useful in screening for depressed left ventricular systolic function and determining chronic heart failure prognosis (Jarolim, 2006; Tanous, 2010).

During normal pregnancy, plasma ANP and BNP levels are maintained in the nonpregnant range despite increased plasma volume (Lowe, 1992; Yurteri-Kaplan, 2012). In one study, Resnik and coworkers (2005) found median BNP levels to be stable across pregnancy with values < 20 pg/mL. BNP levels are increased in severe preeclampsia, and Tihtonen and colleagues (2007) concluded that this was caused by cardiac strain from increased afterload. It would appear that ANP-induced physiological adaptations participate in extracellular fluid volume expansion and in the increased plasma aldosterone concentrations characteristic of normal pregnancy.

A third species, C-type natriuretic peptide (CNP), is predominantly secreted by noncardiac tissues. Among its diverse biological functions, this peptide appears to be a major regulator of fetal bone growth. Walther and Stepan (2004) have provided a detailed review of its function during pregnancy.

Prostaglandins

Increased prostaglandin production during pregnancy is thought to have a central role in control of vascular tone, blood pressure, and sodium balance. Renal medullary prostaglandin E2 synthesis is
increased markedly during late pregnancy and is presumed to be natriuretic. Prostacyclin (PGI$_2$), the principal prostaglandin of endothelium, also is increased during late pregnancy and regulates blood pressure and platelet function. It also has been implicated in the angiotensin resistance characteristic of normal pregnancy (Friedman, 1988). The ratio of PGI$_2$ to thromboxane in maternal urine and blood has been considered important in preeclampsia pathogenesis (Chap. 40, p. 735). The molecular mechanisms regulating prostacyclin pathways during pregnancy have recently been reviewed by Majed and Khalil (2012).

**Endothelin**

There are several endothelins generated in pregnancy. Endothelin-1 is a potent vasoconstrictor produced in endothelial and vascular smooth muscle cells and regulates local vasomotor tone (Feletou, 2006; George, 2011). Its production is stimulated by angiotensin II, arginine vasopressin, and thrombin. Endothelins, in turn, stimulate secretion of ANP, aldosterone, and catecholamines. As discussed in Chapter 21 (p. 427), there are endothelin receptors in pregnant and nonpregnant myometrium. Endothelins also have been identified in the amnion, amnionic fluid, decidua, and placenta (Kubota, 1992; Margarit, 2005). Vascular sensitivity to endothelin-1 is not altered during normal pregnancy. Ajne and associates (2005) postulated that vasodilating factors counterbalance the endothelin-1 vasoconstrictor effects and reduce peripheral vascular resistance.

**Nitric Oxide**

This potent vasodilator is released by endothelial cells and may have important implications for modifying vascular resistance during pregnancy. Moreover, nitric oxide is one of the most important mediators of placental vascular tone and development (Krause, 2011; Kulandavelu, 2013). As discussed in Chapter 40 (p. 735), abnormal nitric oxide synthesis has been linked to preeclampsia development (Baksu, 2005; Teran, 2006).

**RESPIRATORY TRACT**

As shown in Figure 4-12, the diaphragm rises about 4 cm during pregnancy. The subcostal angle widens appreciably as the transverse diameter of the thoracic cage lengthens approximately 2 cm. The thoracic circumference increases about 6 cm, but not sufficiently to prevent reduced residual lung volumes created by the elevated diaphragm. Even so, diaphragmatic excursion is greater in pregnant than in nonpregnant women.
FIGURE 4-12 Chest wall measurements in nonpregnant (A) and pregnant women (B). With pregnancy, the subcostal angle increases, as does the anteroposterior and transverse diameters of the chest wall and chest wall circumference. These changes compensate for the 4-cm elevation of the diaphragm so that total lung capacity is not significantly reduced. (Redrawn from Hegewald, 2011, with permission.)

**Pulmonary Function**
The physiological changes in lung function during pregnancy are illustrated in Figure 4-13. Functional residual capacity (FRC) decreases by approximately 20 to 30 percent or 400 to 700 mL during pregnancy. This capacity is composed of expiratory reserve volume—which decreases 15 to 20 percent or 200 to 300 mL—and residual volume—which decreases 20 to 125 percent or 200 to 400 mL. FRC and residual volume decline due to diaphragm elevation, and significant reductions are observed by the sixth month with a progressive decline across pregnancy. Inspiratory capacity, the maximum volume that can be inhaled from FRC, increases by 5 to 10 percent or 200 to 250 mL during pregnancy. Total lung capacity—the combination of FRC and inspiratory capacity—is unchanged or decreases by less than 5 percent at term (Hegewald, 2011).

**FIGURE 4-13** Changes in lung volumes with pregnancy. The most significant changes are reduction in functional residual capacity (FRC) and its subcomponents, expiratory reserve volume (ERV) and residual volume (RV), as well as increases in inspiratory capacity (IC) and tidal volume (VT). (Redrawn from Hegewald, 2011, with permission.)

The respiratory rate is essentially unchanged, but tidal volume and resting minute ventilation increase significantly as pregnancy advances. In a study of 51 healthy pregnant women, Kolarzyk and coworkers (2005) reported significantly greater mean tidal volumes—0.66 to 0.8 L/min—and resting minute ventilations—10.7 to 14.1 L/min—compared with those of nonpregnant women. The increased minute ventilation is caused by several factors. These include enhanced respiratory drive primarily due to the stimulatory action of progesterone, low expiratory reserve volume, and compensated respiratory alkalosis, which is discussed in more detail subsequently (Wise, 2006).

Regarding pulmonary function, Grindheim and associates (2012) found in 75 healthy pregnant women that peak expiratory flow rates increase progressively as gestation advances. Lung compliance is unaffected by pregnancy. Airway conductance is increased and total pulmonary resistance reduced, possibly as a result of progesterone. The maximum breathing capacity and forced or timed vital capacity are not altered appreciably. It is unclear whether the critical
closing volume—the lung volume at which airways in the dependent parts of the lung begin to close during expiration—is higher in pregnancy (Hegewald, 2011). The increased oxygen requirements and perhaps the increased critical closing volume imposed by pregnancy make respiratory diseases more serious.

McAuliffe and associates (2002) compared pulmonary function in 140 women with a singleton pregnancy with that in 68 women with twins. They found no significant differences between the two groups.

### Oxygen Delivery

The amount of oxygen delivered into the lungs by the increased tidal volume clearly exceeds oxygen requirements imposed by pregnancy. Moreover, the total hemoglobin mass, and in turn, total oxygen-carrying capacity, increases appreciably during normal pregnancy, as does cardiac output. Consequently, the maternal arteriovenous oxygen difference is decreased. Oxygen consumption increases approximately 20 percent during pregnancy, and it is approximately 10 percent higher in multifetal gestations. During labor, oxygen consumption increases 40 to 60 percent (Bobrowski, 2010).

### Acid–Base Equilibrium

An increased awareness of a desire to breathe is common even early in pregnancy (Milne, 1978). This may be interpreted as dyspnea, which may suggest pulmonary or cardiac abnormalities when none exist. This physiological dyspnea, which should not interfere with normal physical activity, is thought to result from increased tidal volume that lowers the blood Pco₂ slightly and paradoxically causes dyspnea. The increased respiratory effort during pregnancy, and in turn the reduction in Pco₂, is likely induced in large part by progesterone and to a lesser degree by estrogen. Progesterone appears to act centrally, where it lowers the threshold and increases the sensitivity of the chemoreflex response to CO₂ (Jensen, 2005).

To compensate for the resulting respiratory alkalosis, plasma bicarbonate levels normally decrease from 26 to approximately 22 mmol/L. Although blood pH is increased only minimally, it does shift the oxygen dissociation curve to the left. This shift increases the affinity of maternal hemoglobin for oxygen—the Bohr effect—thereby decreasing the oxygen-releasing capacity of maternal blood. This is offset because the slight pH increase also stimulates an increase in 2,3-diphosphoglycerate in maternal erythrocytes. This shifts the curve back to the right (Tsai, 1982). Thus, reduced Pco₂ from maternal hyperventilation aids carbon dioxide (waste) transfer from the fetus to the mother while also aiding oxygen release to the fetus.

### URINARY SYSTEM

#### Kidney

Several remarkable changes are observed in the urinary system as a result of pregnancy (Table 4-5). Kidney size increases approximately 1.5 cm (Bailey, 1971). Both the glomerular filtration rate (GFR) and renal plasma flow increase early in pregnancy. The GFR increases as much as 25 percent by the second week after conception and 50 percent by the beginning of the second
trimester. This hyperfiltration appears to result from two principal factors. First, hypervolemia-induced hemodilution lowers the protein concentration and oncotic pressure of plasma entering the glomerular microcirculation. Second, renal plasma flow increases by approximately 80 percent before the end of the first trimester (Conrad, 2014; Cornelis, 2011). As shown in Figure 4-14, elevated GFR persists until term, even though renal plasma flow decreases during late pregnancy. Primarily as a consequence of this elevated GFR, approximately 60 percent of women report urinary frequency during pregnancy (Sandhu, 2009).

AVP = vasopressin; IVP = intravenous pyelography; Pco₂ = partial pressure carbon dioxide. Modified from Lindheimer, 2000.
During the puerperium, a marked GFR persists during the first postpartum day principally from the reduced glomerular capillary oncotic pressure. A reversal of the gestational hypervolemia and hemodilution, still evident on the first postpartum day, eventuates by the second week postpartum (Hladunewich, 2004).

Studies suggest that relaxin may be important for mediating both increased GFR and renal blood flow during pregnancy (Conrad, 2014; Helal, 2012). Relaxin increases endothelin and nitric oxide production in the renal circulation. This leads to renal vasodilation and decreased renal afferent and efferent arteriolar resistance, with a resultant increase in renal blood flow and GFR. Relaxin may also increase vascular gelatinase activity during pregnancy, which leads to renal vasodilation, glomerular hyperfiltration, and reduced myogenic reactivity of small renal arteries (Conrad, 2005).

As with blood pressure, maternal posture may have a considerable influence on several aspects of renal function. Late in pregnancy, for instance, urinary flow and sodium excretion average less than half the excretion rate in the supine position compared with that in the lateral recumbent position. The impact of posture on GFR and renal plasma flow is more variable.

One unusual feature of the pregnancy-induced changes in renal excretion is the remarkably increased amounts of various nutrients lost in the urine. Amino acids and water-soluble vitamins
are excreted in much greater amounts (Hytten, 1973; Powers, 2004).

Renal Function Tests

The physiological changes in renal hemodynamics induced during normal pregnancy have several implications for the interpretation of renal function tests (Appendix, p. 1292). Serum creatinine levels decrease during normal pregnancy from a mean of 0.7 to 0.5 mg/dL. Values of 0.9 mg/dL or greater suggest underlying renal disease and should prompt further evaluation.

Creatinine clearance in pregnancy averages 30 percent higher than the 100 to 115 mL/min in nonpregnant women (Lindheimer, 2000). This is a useful test to estimate renal function, provided that complete urine collection is made during an accurately timed period. If either is done incorrectly, results are misleading (Lindheimer, 2010). During the day, pregnant women tend to accumulate water as dependent edema, and at night, while recumbent, they mobilize this fluid with diuresis. This reversal of the usual nonpregnant diurnal pattern of urinary flow causes nocturia, and urine is more dilute than in nonpregnant women. Failure of a pregnant woman to excrete concentrated urine after withholding fluids for approximately 18 hours does not necessarily signify renal damage. In fact, the kidney in these circumstances functions perfectly normally by excreting mobilized extracellular fluid of relatively low osmolality.

Urinalysis

Glucosuria during pregnancy may not be abnormal. The appreciable increase in GFR, together with impaired tubular reabsorptive capacity for filtered glucose, accounts for most cases of glucosuria (Davison, 1974). For these reasons alone, Chesley (1963) calculated that about a sixth of pregnant women should spill glucose in the urine. That said, although common during pregnancy, when glucosuria is identified, the possibility of diabetes mellitus should not be ignored.

Hematuria is often the result of contamination during collection. If not, it most often suggests urinary tract disease. Hematuria is common after difficult labor and delivery because of trauma to the bladder and urethra.

Proteinuria is typically defined in nonpregnant patients as a protein excretion rate of more than 150 mg/day. Because of the aforementioned hyperfiltration and possible reduction of tubular reabsorption, significant proteinuria during pregnancy is usually defined as a protein excretion rate of at least 300 mg/day (Hladunewich, 2011). Higby and coworkers (1994) measured protein excretion in 270 normal women throughout pregnancy (Fig. 4-15). Their mean 24-hour excretion for all three trimesters was 115 mg, and the upper 95-percent confidence limit was 260 mg/day without significant differences by trimester. These investigators also showed that albumin excretion is minimal and ranges from 5 to 30 mg/day. Interestingly, however, Cornelis and colleagues (2011) noted that proteinuria is greater in the second half of pregnancy, which does not correspond precisely to the earlier peak in GFR (see Fig. 4-14). Alternative explanations might include alterations in tubular reabsorptive capacity or the presence of other proteinaceous material that might be detected in the urine of pregnant women. A recent study in normal gravidas also showed proteinuria levels greater than established thresholds (Phillips, 2014).
Measuring Urine Protein

The three most commonly employed approaches for assessing proteinuria are the qualitative classic dipstick, the quantitative 24-hour collection, and the albumin/creatinine or protein/creatinine ratio of a single voided urine specimen. The pitfalls of each approach have recently been reviewed by Conrad and colleagues (2014). The principal problem with dipstick assessment is that renal concentration or dilution of urine is not accounted for. For example, with polyuria and extremely dilute urine, a negative or trace dipstick could actually be associated with excessive protein excretion.

The 24-hour urine collection is affected by urinary tract dilatation, which is discussed subsequently. The dilated tract may lead to errors related both to retention—hundreds of milliliters of urine remaining in the dilated tract—and to timing—the remaining urine may have formed hours before the collection. To minimize these pitfalls, Lindheimer and Kanter (2010) recommend that the patient first be hydrated and positioned in lateral recumbency—the definitive nonobstructive posture—for 45 to 60 minutes. After this, she is asked to void, and this specimen is discarded. Immediately following this void, her 24-hour collection begins. During the final hour of collection, the patient is again placed in the lateral recumbent position. But, at the end of this hour, the final collected urine is incorporated into the total collected volume.

The protein/creatinine ratio is a promising approach because data can be obtained quickly and collection errors are avoided. Disadvantageously, the amount of protein per unit of creatinine excreted during a 24-hour period is not constant, and there are various thresholds that have been promulgated to define abnormal. Nomograms for urinary microalbumin and creatinine ratios during uncomplicated pregnancies have been developed by Waugh and coworkers (2003).

Ureters

After the uterus completely rises out of the pelvis, it rests on the ureters, which laterally displaces
and compresses them at the pelvic brim. Above this level, increased intraureteral tonus results (Rubi, 1968). Ureteral dilatation is impressive, and Schulman and Herlinger (1975) found it to be greater on the right side in 86 percent of women (Fig. 4-16). Unequal dilatation may result from cushioning provided the left ureter by the sigmoid colon and perhaps from greater right ureteral compression exerted by the dextrorotated uterus. The right ovarian vein complex, which is remarkably dilated during pregnancy, lies obliquely over the right ureter and may contribute significantly to right ureteral dilatation.
Progesterone likely also has some effect. Van Wagenen and Jenkins (1939) described continued ureteral dilatation after removal of the monkey fetus but with the placenta left in situ. The relatively abrupt onset of dilatation in women at midpregnancy, however, seems more consistent with ureteral compression.

Ureteral elongation accompanies distention, and the ureter is frequently thrown into curves of varying size, the smaller of which may be sharply angulated. These so-called kinks are poorly named, because the term connotes obstruction. They are usually single or double curves that, when viewed in a radiograph taken in the same plane as the curve, may appear as acute angulations. Another exposure at right angles nearly always identifies them to be more gentle curves. Despite these anatomical changes, Semins and associates (2009) concluded, based on their review, that complication rates associated with ureteroscopy in pregnant and nonpregnant patients do not differ significantly.

Bladder

There are few significant anatomical changes in the bladder before 12 weeks. From that time onward, however, increased uterine size, the hyperemia that affects all pelvic organs, and the hyperplasia of bladder muscle and connective tissues elevate the trigone and cause thickening of its posterior, or intraureteric, margin. Continuation of this process to the end of pregnancy produces marked deepening and widening of the trigone. There are no mucosal changes other than an increase in the size and tortuosity of its blood vessels.

Using urethrocystometry, Iosif and colleagues (1980) reported that bladder pressure in primigravidas increased from 8 cm H₂O early in pregnancy to 20 cm H₂O at term. To compensate for reduced bladder capacity, absolute and functional urethral lengths increased by 6.7 and 4.8 mm, respectively. At the same time, maximal intraurethral pressure increased from 70 to 93 cm H₂O, and thus continence is maintained. Still, at least half of women experience some degree of urinary incontinence by the third trimester (van Brummen, 2006; Wesnes, 2009). Indeed, this is always considered in the differential diagnosis of ruptured membranes.

Toward the end of pregnancy, particularly in nulliparas in whom the presenting part often engages before labor, the entire base of the bladder is pushed forward and upward, converting the normal convex surface into a concavity. As a result, difficulties in diagnostic and therapeutic procedures are greatly increased. In addition, pressure from the presenting part impairs blood and lymph drainage from the bladder base, often rendering the area edematous, easily traumatized, and possibly more susceptible to infection.

GASTROINTESTINAL TRACT

During pregnancy, the gums may become hyperemic and softened and may bleed when mildly traumatized, as with a toothbrush. This pregnancy gingivitis typically subsides postpartum. A
focal, highly vascular swelling of the gums, a so-called epulis gravidarum, is a pyogenic granuloma that occasionally develops but typically regresses spontaneously after delivery. Most evidence indicates that pregnancy does not incite tooth decay.

As pregnancy progresses, the stomach and intestines are displaced by the enlarging uterus. Consequently, the physical findings in certain diseases are altered. The appendix, for instance, is usually displaced upward and somewhat laterally as the uterus enlarges. At times, it may reach the right flank.

*Pyrosis (heartburn)* is common during pregnancy and is most likely caused by reflux of acidic secretions into the lower esophagus (Chap. 54, p. 1072). Although the altered stomach position probably contributes to its frequency, lower esophageal sphincter tone also is decreased. In addition, intraesophageal pressures are lower and intragastric pressures higher in pregnant women. At the same time, esophageal peristalsis has lower wave speed and lower amplitude (Ulmsten, 1978).

*Gastric emptying time* appears to be unchanged during each trimester and compared with nonpregnant women (Macfie, 1991; Wong, 2002, 2007). During labor, however, and especially after administration of analgesic agents, gastric emptying time may be appreciably prolonged. As a result, one danger of general anesthesia for delivery is regurgitation and aspiration of either food-laden or highly acidic gastric contents (Chap. 25, p. 519).

*Hemorrhoids* are common during pregnancy (Avsar, 2010). They are caused in large measure by constipation and elevated pressure in veins below the level of the enlarged uterus.

### Liver

Unlike in some animals, there is no increase in liver size during human pregnancy (Combes, 1971). Hepatic arterial and portal venous blood flow, however, increase substantively (Clapp, 2000). Histological evaluation of liver biopsies, including examination with the electron microscope, has shown no distinct morphological changes in normal pregnant women (Ingerslev, 1946).

Some laboratory test results of hepatic function are altered during normal pregnancy, and some would be considered abnormal for nonpregnant patients (Appendix, p. 1289). Total alkaline phosphatase activity almost doubles, but much of the increase is attributable to heat-stable placental alkaline phosphatase isozymes. Serum aspartate transaminase (AST), alanine transaminase (ALT), γ-glutamyl transpeptidase (GGT), and bilirubin levels are slightly lower compared with nonpregnant values (Girling, 1997; Ruiz-Extremera, 2005).

The serum albumin concentration decreases during pregnancy. By late pregnancy, albumin concentrations may be near 3.0 g/dL compared with approximately 4.3 g/dL in nonpregnant women (Mendenhall, 1970). Total body albumin levels are increased, however, because of pregnancy-associated increased plasma volume. Serum globulin levels are also slightly higher.

Leucine aminopeptidase is a proteolytic liver enzyme whose serum levels may be increased with liver disease. Its activity is markedly elevated in pregnant women. The increase, however, results from a pregnancy-specific enzyme(s) with distinct substrate specificities (Song, 1968). Pregnancy-induced aminopeptidase has oxytocinase and vasopressinase activity that occasionally causes transient diabetes insipidus (Chap. 58, p. 1162).

### Gallbladder

During normal pregnancy, gallbladder contractility is reduced and leads to increased residual
volume (Braverman, 1980). Progesterone potentially impairs gallbladder contraction by inhibiting cholecystokinin-mediated smooth muscle stimulation, which is the primary regulator of gallbladder contraction. Impaired emptying, subsequent stasis, and an increased bile cholesterol saturation of pregnancy contribute to the increased prevalence of cholesterol gallstones in multiparas.

The pregnancy effects on maternal serum bile acid concentrations have been incompletely characterized. This is despite the long-acknowledged propensity for pregnancy to cause intrahepatic cholestasis and pruritus gravidarum from retained bile salts. Intrahepatic cholestasis has been linked to high circulating levels of estrogen, which inhibit intraductal bile acid transport (Simon, 1996). In addition, increased progesterone levels and genetic factors have been implicated in the pathogenesis (Lammert, 2000). Cholestasis of pregnancy is described further in Chapter 55 (p. 1084).

ENDOCRINE SYSTEM

Some of the most important endocrine changes of pregnancy are discussed elsewhere, especially in Chapters 57 and 58.

Pituitary Gland

During normal pregnancy, the pituitary gland enlarges by approximately 135 percent (Gonzalez, 1988). Although it has been suggested that this size increase may sufficiently compress the optic chiasma to reduce visual fields, impaired vision from this is rare (Inoue, 2007). Pituitary enlargement is primarily caused by estrogen-stimulated hypertrophy and hyperplasia of the lactotrophs (Feldt-Rasmussen, 2011). And, as discussed subsequently, maternal serum prolactin levels parallel the increasing size. Gonadotrophs decline in number, and corticotrophs and thyrotrophs remain constant. Somatotrophs are generally suppressed due to negative feedback by the placental production of growth hormone. Peak pituitary size may reach 12 mm on magnetic resonance (MR) imaging in the first days postpartum, but the gland involutes rapidly thereafter and reaches normal size by 6 months postpartum (Feldt-Rasmussen, 2011). According to Scheithauer and coworkers (1990), the incidence of pituitary prolactinomas is not increased during pregnancy. When these tumors are large before pregnancy—a macroadenoma measuring ≥ 10 mm—then growth during pregnancy is more likely (Chap. 58, p. 1162).

The maternal pituitary gland is not essential for pregnancy maintenance. Many women have undergone hypophysectomy, completed pregnancy successfully, and entered spontaneous labor while receiving compensatory glucocorticoids, thyroid hormone, and vasopressin.

Growth Hormone

During the first trimester, growth hormone is secreted predominantly from the maternal pituitary gland, and concentrations in serum and amniotic fluid are within nonpregnant values of 0.5 to 7.5 ng/mL (Kletzky, 1985). As early as 8 weeks’ gestation, growth hormone secreted from the placenta becomes detectable (Lonberg, 2003). By approximately 17 weeks, the placenta is the principal source of growth hormone secretion (Obuobie, 2001). Maternal serum values increase slowly from approximately 3.5 ng/mL at 10 weeks to plateau after 28 weeks at approximately 14 ng/mL. Growth hormone in amniotic fluid peaks at 14 to 15 weeks and slowly declines thereafter to reach baseline values after 36 weeks.
Placental growth hormone—which differs from pituitary growth hormone by 13 amino acid residues—is secreted by syncytiotrophoblast in a nonpulsatile fashion (Fuglsang, 2006). Its regulation and physiological effects are incompletely understood, but it appears to have some influence on fetal growth as well as preeclampsia development (Mittal, 2007; Pedersen, 2010). Placental growth hormone is a major determinant of maternal insulin resistance after midpregnancy. And, maternal serum levels correlate positively with birthweight but negatively with fetal-growth restriction and uterine artery resistance (Chellakooty, 2004; Schiessl, 2007). That said, fetal growth still progresses in the complete absence of this hormone. Freemark (2006) concluded that, although not absolutely essential, the hormone may act in concert with placental lactogen and other somatolactogens to regulate fetal growth.

Prolactin

Maternal plasma prolactin levels increase markedly during normal pregnancy, and concentrations are usually tenfold greater at term—about 150 ng/mL—compared with those of nonpregnant women. Paradoxically, plasma concentrations decrease after delivery even in women who are breast feeding. During early lactation, there are pulsatile bursts of prolactin secretion in response to suckling.

The physiological basis of the marked prolactin level increase before parturition is still unclear. As mentioned earlier, it is known is that estrogen increases the number of anterior pituitary lactotrophs and may stimulate their release of prolactin (Andersen, 1982). Thyroid-releasing hormone also acts to increased prolactin levels in pregnant compared with nonpregnant women, but this response decreases as pregnancy advances (Miyamoto, 1984). Serotonin also is believed to increase prolactin levels. In contrast, dopamine—previously known as prolactin-inhibiting factor—inhibits its secretion.

The principal function of maternal prolactin is to ensure lactation. Early in pregnancy, prolactin acts to initiate DNA synthesis and mitosis of glandular epithelial cells and presecretory alveolar cells of the breast. Prolactin also increases the number of estrogen and prolactin receptors in these cells. Finally, prolactin promotes mammary alveolar cell RNA synthesis, galactopoiesis, and production of casein, lactalbumin, lactose, and lipids (Andersen, 1982). A woman with isolated prolactin deficiency described by Kauppila and colleagues (1987) failed to lactate after two pregnancies. This established prolactin as a requisite for lactation but not for pregnancy.

Prolactin is present in amnionic fluid in high concentrations. Levels of up to 10,000 ng/mL are found at 20 to 26 weeks’ gestation. Thereafter, levels decrease and reach a nadir after 34 weeks. There is convincing evidence that the uterine decidua is the synthesis site of prolactin found in amnionic fluid (Chap. 5, p. 88). Although the exact function of amnionic fluid prolactin is unknown, suggestions are that this prolactin impairs water transfer from the fetus into the maternal compartment, thus preventing fetal dehydration.

A possible pathological role has been proposed for a prolactin fragment in the genesis of peripartum cardiomyopathy (Chap. 49, p. 988) (Cunningham, 2012).

Oxytocin and Antidiuretic Hormone

These two hormones are secreted from the posterior pituitary. The role of oxytocin in parturition and lactation is discussed in Chapters 21 (p. 426) and 36 (p. 672), respectively. Brunton and Russell (2010) have reviewed the complex mechanisms that promote quiescence of oxytocin systems during pregnancy. Levels of antidiuretic hormone, also called vasopressin, do not change during pregnancy. As discussed in Chapter 58 (p. 1162), vasopressin deficiency is associated with
Thyroid Gland

Physiological changes of pregnancy cause the thyroid gland to increase production of thyroid hormones by 40 to 100 percent to meet maternal and fetal needs (Smallridge, 2005). To accomplish this, there are several pregnancy-induced changes. Anatomically, the thyroid gland undergoes moderate enlargement during pregnancy caused by glandular hyperplasia and increased vascularity. Glinoer and colleagues (1990) reported that mean thyroid volume increased from 12 mL in the first trimester to 15 mL at delivery. Total volume was inversely proportional to serum thyrotropin concentrations. Such enlargement is not pathological, but normal pregnancy does not typically cause significant thyromegaly. Thus, any goiter should be investigated.

Several alterations in thyroid physiology and function during pregnancy are outlined in Figure 4-17. Early in the first trimester, levels of the principal carrier protein—thyroxine-binding globulin (TBG)—increase, reach their zenith at about 20 weeks, and stabilize at approximately double baseline values for the remainder of pregnancy. The increased TBG concentrations result from both higher hepatic synthesis rates—due to estrogen stimulation—and lower metabolism rates due to increased TBG sialylation and glycosylation. These elevated TBG levels increase total serum thyroxine (T4) and triiodothyronine (T3) concentrations, but do not affect the physiologically important serum free T4 and T3 levels. Specifically, total serum T4 increases sharply beginning between 6 and 9 weeks and reaches a plateau at 18 weeks. Free serum T4 levels rise slightly and peak along with hCG levels, and then they return to normal. The rise in total T4 is more pronounced up to 18 weeks, and thereafter, it plateaus. As detailed in Chapter 58 (p. 1147), the fetus is reliant on maternal thyroxine, which crosses the placenta in small quantities to maintain normal fetal thyroid function. Recall that the fetal thyroid does not begin to concentrate iodine until 10 to 12 weeks’ gestation. The synthesis and secretion of thyroid hormone by fetal pituitary thyroid-stimulating hormone ensues at approximately 20 weeks. At birth, approximately 30 percent of the T4 in umbilical cord blood is of maternal origin (Leung, 2012).
FIGURE 4-17 Relative changes in maternal and fetal thyroid-associated analytes across pregnancy. Maternal changes include a marked and early increase in hepatic production of
thyroxine-binding globulin (TBG) and placental production of human chorionic gonadotropin (hCG). Increased thyroxine-binding globulin increases serum thyroxine (T₄) concentrations. hCG has thyrotropin-like activity and stimulates maternal free T₄ secretion. This transient hCG-induced increase in serum T₄ levels inhibits maternal secretion of thyrotropin. Except for minimally increased free T₄ levels when hCG peaks, these levels are essentially unchanged. Fetal levels of all serum thyroid analytes increase incrementally across pregnancy. Fetal triiodothyronine (T₃) does not increase until late pregnancy. (Modified from Burrow, 1994.)

**Thyrotropin-releasing hormone (TRH)** is secreted by the hypothalamus and stimulates thyrotrpoe cells of the anterior pituitary to release thyroid-stimulating hormone (TSH) or thyrotropin. TRH levels are not increased during normal pregnancy. However, this neurotransmitter does cross the placenta and may serve to stimulate the fetal pituitary to secrete thyrotropin (Thorpe-Beeston, 1991).

Interestingly, T₄ and T₃ secretion is not similar for all pregnant women (Glinoer, 1990). Approximately a third of women experience relative hypothyroxinemia, preferential T₃ secretion, and higher, albeit normal, serum thyrotropin levels. Thus, there may be considerable variability in thyroidal adjustments during normal pregnancy.

The modifications in serum TSH and hCG levels as a function of gestational age are shown in Figure 4-17. As discussed in Chapter 5 (p. 101), the α-subunits of the two glycoproteins are identical, whereas the β-subunits, although similar, differ in their amino acid sequence. As a result of this structural similarity, hCG has intrinsic thyrotropic activity, and thus, high serum hCG levels cause thyroid stimulation. Indeed, thyrotropin levels decrease in more than 80 percent of pregnant women, whereas they remain in the normal range for nonpregnant women.

As shown in Figure 4-18, normal suppression of TSH during pregnancy may lead to a misdiagnosis of subclinical hyperthyroidism. Of greater concern is the potential failure to identify women with early hypothyroidism because of suppressed TSH concentrations. To mitigate the likelihood of such misdiagnoses, Dashe and coworkers (2005) conducted a population-based study at Parkland Hospital to develop gestational-age-specific TSH normal curves for both singleton and twin pregnancies (Chap. 58, p. 1148). Similarly, Ashoor and associates (2010) have established normal ranges for maternal TSH, free T₄, and free T₃ at 11 to 13 weeks.
These complex alterations of thyroid regulation do not appear to alter maternal thyroid status as measured by metabolic studies. Although basal metabolic rate increases progressively by as much as 25 percent during normal pregnancy, most of this increase in oxygen consumption can be attributed to fetal metabolic activity. If fetal body surface area is considered along with that of the mother, the predicted and observed basal metabolic rates are similar to those in nonpregnant women.

Iodine Status

Iodine requirements increase during normal pregnancy. In women with low or marginal intake, deficiency may manifest as low thyroxine and increased TSH levels. Importantly, more than a third of the world population lives in areas where iodine intake is only marginal. For the fetus, early exposure to thyroid hormone is essential for the nervous system, and iodine deficiency is the most common preventable cause of impaired neurological development after famine (Kennedy, 2010). Severe deficiency leads to cretinism.

Parathyroid Glands
The regulation of calcium concentration is closely interrelated with magnesium, phosphate, parathyroid hormone, vitamin D, and calcitonin physiology. Any altered levels of one of these likely changes the others. In a longitudinal investigation of 20 women, More and associates (2003) found that all markers of bone turnover increased during normal pregnancy and failed to reach baseline level by 12 months postpartum. They concluded that the calcium needed for fetal growth and lactation may be drawn at least in part from the maternal skeleton.

**Parathyroid Hormone**

Acute or chronic decreases in plasma calcium or acute decreases in magnesium stimulate parathyroid hormone (PTH) release. Conversely, increased calcium and magnesium levels suppress PTH levels. The action of this hormone on bone resorption, intestinal absorption, and kidney reabsorption is to increase extracellular fluid calcium concentrations and decrease phosphate levels.

As reviewed by Cooper (2011), fetal skeleton mineralization requires approximately 30 g of calcium, primarily during the third trimester. Although this amounts to only 3 percent of the total calcium held within the maternal skeleton, the provision of calcium is still a challenge for the mother. In most circumstances, increased maternal calcium absorption provides the additional calcium. During pregnancy, the amount of calcium absorbed rises gradually and reaches approximately 400 mg/day in the third trimester. Increased calcium absorption appears to be mediated by elevated maternal 1,25-dihydroxyvitamin D concentrations. This occurs despite decreased levels during early pregnancy of PTH, which is the normal stimulus for active vitamin D production within the kidney. Indeed, PTH plasma concentrations decrease during the first trimester and then increase progressively throughout the remainder of pregnancy (Pitkin, 1979).

The increased production of active vitamin D is likely due to placental production of either PTH or a PTH-related protein (PTH-rP). Outside pregnancy and lactation, PTH-rP is usually only detectable in serum of women with hypercalcemia due to malignancy. During pregnancy, however, PTH-rP concentrations increase significantly. This protein is synthesized in both fetal tissues and maternal breasts.

**Calcitonin**

The known actions of calcitonin generally are considered to oppose those of PTH and vitamin D to protect maternal skeletal calcification during times of calcium stress. Pregnancy and lactation cause profound calcium stress, and during these times, calcitonin levels are appreciably higher than those in nonpregnant women (Weiss, 1998).

The C cells that secrete calcitonin are derived embryologically from the neural crest and are located predominantly in the perifollicular areas of the thyroid gland. Calcium and magnesium increase the biosynthesis and secretion of calcitonin. Various gastric hormones—gastrin, pentagastrin, glucagon, and pancreozymin—and food ingestion also increase calcitonin plasma levels.

**Adrenal Glands**

**Cortisol**

In normal pregnancy, unlike their fetal counterparts, the maternal adrenal glands undergo little, if any, morphological change. The serum concentration of circulating cortisol is increased, but much of it is bound by transcortin, the cortisol-binding globulin. The adrenal secretion rate of this
The principal glucocorticoid is not increased, and probably it is decreased compared with that of the nonpregnant state. The metabolic clearance rate of cortisol, however, is lower during pregnancy because its half-life is nearly doubled compared with that for nonpregnant women (Migeon, 1957). Administration of estrogen, including most oral contraceptives, causes changes in serum cortisol levels and transcortin similar to those of pregnancy (Jung, 2011).

During early pregnancy, the levels of circulating *adrenocorticotropic hormone* (*ACTH*), also known as *corticotropin*, are reduced strikingly. As pregnancy progresses, ACTH and free cortisol levels rise equally and strikingly (Fig. 4-19). This apparent paradox is not understood completely. Nolten and Rueckert (1981) suggest that the higher free cortisol levels observed in pregnancy result from a “resetting” of the maternal feedback mechanism to higher levels. They further propose that this might result from tissue refractoriness to cortisol. Keller-Wood and Wood (2001) later asserted that these incongruities may result from an antagonistic action of progesterone on mineralocorticoids. Thus, in response to elevated progesterone levels during pregnancy, an elevated free cortisol is needed to maintain homeostasis. Indeed, experiments in pregnant ewes demonstrate that elevated maternal cortisol and aldosterone secretion are necessary to maintain the normal increase in plasma volume during late pregnancy (Jensen, 2002).

![Graph showing the increase in serum cortisol and ACTH levels during pregnancy](image)

**FIGURE 4-19** Serial increases in serum cortisol (*blue line*) and adrenocorticotropic hormone (*ACTH*) (*red line*) across normal pregnancy. (Redrawn from Carr, 1981, with permission.)

**Aldosterone**

As early as 15 weeks’ gestation, the maternal adrenal glands secrete considerably increased
amounts of aldosterone, the principal mineralocorticoid. By the third trimester, approximately 1 mg/day is secreted. If sodium intake is restricted, aldosterone secretion is elevated even further (Watanabe, 1963). At the same time, levels of renin and angiotensin II substrate normally are increased, especially during the latter half of pregnancy. This scenario gives rise to increased plasma levels of angiotensin II, which acts on the zona glomerulosa of the maternal adrenal glands and accounts for the markedly elevated aldosterone secretion. It has been suggested that the increased aldosterone secretion during normal pregnancy affords protection against the natriuretic effect of progesterone and atrial natriuretic peptide. More recently, Gennari-Moser and colleagues (2011) provided evidence that aldosterone may play a role in modulating trophoblast growth and placental size.

**Deoxycorticosterone**

Maternal plasma levels of this potent mineralocorticosteroid progressively increase during pregnancy. Indeed, plasma levels of deoxycorticosterone rise to near 1500 pg/mL by term, a more than 15-fold increase (Parker, 1980). This marked elevation is not derived from adrenal secretion but instead represents increased kidney production resulting from estrogen stimulation. The levels of deoxycorticosterone and its sulfate in fetal blood are appreciably higher than those in maternal blood, which suggests transfer of fetal deoxycorticosterone into the maternal compartment.

**Androgens**

In balance, there is increased androgenic activity during pregnancy. Maternal plasma levels of both androstenedione and testosterone are increased during pregnancy. This finding is not totally explained by alterations in their metabolic clearance. Both androgens are converted to estradiol in the placenta, which increases their clearance rates. Conversely, increased plasma sex hormone-binding globulin in pregnant women retards testosterone clearance. Thus, the production rates of maternal testosterone and androstenedione during human pregnancy are increased. The source of this increased C_{19}-steroid production is unknown, but it likely originates in the ovary. Interestingly, little or no testosterone in maternal plasma enters the fetal circulation as testosterone. Even when massive testosterone levels are found in the circulation of pregnant women, as with androgen-secreting tumors, testosterone concentrations in umbilical cord blood are likely to be undetectable. This results from the near complete trophoblastic conversion of testosterone to 17\beta-estradiol (Edman, 1979).

Maternal serum and urine levels of dehydroepiandrosterone sulfate are decreased during normal pregnancy. As discussed in Chapter 5 (p. 107), this is a consequence of increased metabolic clearance through extensive maternal hepatic 16\beta-hydroxylation and placental conversion to estrogen.

**MUSCULOSKELETAL SYSTEM**

Progressive lordosis is a characteristic feature of normal pregnancy. Compensating for the anterior position of the enlarging uterus, lordosis shifts the center of gravity back over the lower extremities.

The sacroiliac, sacrococcygeal, and pubic joints have increased mobility during pregnancy. However, as discussed earlier (p. 49), increased joint laxity during pregnancy does not correlate...
with increased maternal serum levels of estradiol, progesterone, or relaxin (Marnach, 2003). Most relaxation takes place in the first half of pregnancy. It may contribute to maternal posture alterations and in turn create lower back discomfort. Although some symphyseal separation likely accompanies many deliveries, those greater than 1 cm may cause significant pain (Fig. 4-20) (Jain, 2005). Aching, numbness, and weakness also occasionally are experienced in the upper extremities. This may result from the marked lordosis and associated anterior neck flexion and shoulder girdle slumping, which produce traction on the ulnar and median nerves (Crisp, 1964).

**FIGURE 4-20 A.** Symphyseal diastasis. Marked widening of the pubic symphysis (arrows) after vaginal delivery. **B.** Sacroiliac (SI) joint widening; left (arrow) greater than right (arrowhead). (Images contributed by Dr. Daniel Moore.)

Joint strengthening begins immediately following delivery and is usually complete within 3 to 5 months. Pelvic dimensions measured up to 3 months after delivery by MR imaging are not significantly different from prepregnancy measurements (Huerta-Enochian, 2006).

### CENTRAL NERVOUS SYSTEM

#### Memory

Changes in the central nervous center are relatively few and mostly subtle. Women often report problems with attention, concentration, and memory throughout pregnancy and the early puerperium. Systematic studies of memory in pregnancy, however, are limited and often anecdotal. Keenan and associates (1998) longitudinally investigated memory in pregnant women and a matched control group. They found pregnancy-related memory decline, which was limited to the third trimester. This decline was not attributable to depression, anxiety, sleep deprivation, or other
physical changes associated with pregnancy. It was transient and quickly resolved following delivery. Henry and Sherwin (2012) also reported that pregnant women in late pregnancy performed significantly worse on tests of verbal recall and processing speed compared with matched nonpregnant controls. Interestingly, Rana and colleagues (2006) found that attention and memory were improved in women with preeclampsia receiving magnesium sulfate compared with normal pregnant women.

Zeeman and coworkers (2003) used magnetic resonance imaging to measure cerebral blood flow across pregnancy in 10 healthy women. They found that mean blood flow in the middle and posterior cerebral arteries decreased progressively from 147 and 56 mL/min when nonpregnant to 118 and 44 mL/min late in pregnancy, respectively. The mechanism and clinical significance of this decline is unknown. Pregnancy does not appear to affect cerebrovascular autoregulation (Bergersen, 2006; Cipolla, 2014).

Eyes

Intraocular pressure decreases during pregnancy and is attributed in part to increased vitreous outflow (Sunnness, 1988). Corneal sensitivity is decreased, and the greatest changes are late in gestation. Most pregnant women demonstrate a measurable but slight increase in corneal thickness, thought to be due to edema. Consequently, they may have difficulty with previously comfortable contact lenses. Brownish-red opacities on the posterior surface of the cornea—Krukenberg spindles—have also been observed with a higher than expected frequency during pregnancy. Hormonal effects similar to those observed for skin lesions are postulated to cause this increased pigmentation. Other than transient loss of accommodation reported with both pregnancy and lactation, visual function is unaffected by pregnancy. These changes during pregnancy, as well as pathological eye aberrations, were recently reviewed by Grant and Chung (2013).

Sleep

Beginning as early as approximately 12 weeks’ gestation and extending through the first 2 months postpartum, women have difficulty with going to sleep, frequent awakenings, fewer hours of night sleep, and reduced sleep efficiency (Pavlova, 2011). The frequency and duration of sleep apnea episodes were reported to be decreased significantly in pregnant women compared with those postpartum (Trakada, 2003). In the supine position, however, average Pao₂ levels were lower. The greatest disruption of sleep is encountered postpartum and may contribute to postpartum blues or to frank depression (Chap. 61, p. 1205).

SECTION 3
PLACENTATION, EMBRYOGENESIS, AND FETAL DEVELOPMENT
All obstetricians should be aware of the basic reproductive biological processes required for women to successfully achieve pregnancy. Several abnormalities can affect each of these and lead to infertility or pregnancy loss. In most women, spontaneous, cyclical ovulation at 25- to 35-day intervals continues during almost 40 years between menarche and menopause. Without contraception, there are approximately 400 opportunities for pregnancy, which may occur with intercourse on any of 1200 days—the day of ovulation and its two preceding days. This narrow window for fertilization is controlled by tightly regulated production of ovarian steroids. Moreover, these hormones promote optimal endometrial regeneration after menstruation in preparation for the next implantation window.

Should fertilization occur, events that begin after initial blastocyst implantation onto the endometrium and continue through to parturition result from a unique interaction between fetal trophoblasts and maternal endometrium-decidua. The ability of mother and fetus to coexist as two distinct immunological systems results from endocrine, paracrine, and immunological modification of fetal and maternal tissues in a manner not seen elsewhere. The placenta mediates a unique fetal–maternal communication system, which creates a hormonal environment that initially maintains pregnancy and eventually initiates events leading to parturition. The following sections address the physiology of the ovarian-endometrial cycle, implantation, placenta, and fetal membranes, as well as specialized endocrine arrangements between fetus and mother.
Predictable, regular, cyclical, and spontaneous ovulatory menstrual cycles are regulated by complex interactions of the hypothalamic-pituitary axis, ovaries, and genital tract (Fig. 5-1). The average cycle duration is approximately 28 days, with a range of 25 to 32 days. The hormonal sequence leading to ovulation directs this cycle. Concurrently, cyclical changes in endometrial histology are faithfully reproduced. Rock and Bartlett (1937) first suggested that endometrial histological features were sufficiently characteristic to permit cycle “dating.” In this scheme, the follicular-proliferative phase and the postovulatory luteal-secretory phase are customarily divided into early and late stages. These changes are detailed in Chapter 15 of Williams Gynecology, 2nd edition (Halvorson, 2012).

FIGURE 5-1 Gonadotropin control of the ovarian and endometrial cycles. The ovarian-endometrial cycle has been structured as a 28-day cycle. The follicular phase (days 1 to 14) is characterized by rising estrogen levels, endometrial thickening, and selection of the dominant
“ovulatory” follicle. During the luteal phase (days 14 to 21), the corpus luteum (CL) produces estrogen and progesterone, which prepare the endometrium for implantation. If implantation occurs, the developing blastocyst begins to produce human chorionic gonadotropin (hCG) and rescues the corpus luteum, thus maintaining progesterone production. FSH = follicle-stimulating hormone; LH = luteinizing hormone.

# The Ovarian Cycle

## Follicular or Preovulatory Ovarian Phase

The human ovary contains 2 million oocytes at birth, and approximately 400,000 follicles are present at puberty onset (Baker, 1963). The remaining follicles are depleted at a rate of approximately 1000 follicles per month until age 35, when this rate accelerates (Faddy, 1992). Only 400 follicles are normally released during female reproductive life. Therefore, more than 99.9 percent of follicles undergo atresia through a process of cell death termed apoptosis (Gougeon, 1996; Kaipia, 1997).

Follicular development consists of several stages, which include the gonadotropin-independent recruitment of primordial follicles from the resting pool and their growth to the antral stage. This appears to be controlled by locally produced growth factors. Two members of the transforming growth factor-β family—growth differentiation factor 9 (GDF9) and bone morphogenetic protein 15 (BMP-15)—regulate granulosa cell proliferation and differentiation as primary follicles grow (Trombly, 2009; Yan, 2001). They also stabilize and expand the cumulus oocyte complex in the oviduct (Hreinsson, 2002). These factors are produced by oocytes, suggesting that the early steps in follicular development are, in part, oocyte controlled. As antral follicles develop, surrounding stromal cells are recruited, by a yet-to-be-defined mechanism, to become thecal cells.

Although not required for early follicular maturation, follicle-stimulating hormone (FSH) is required for further development of large antral follicles (Hillier, 2001). During each ovarian cycle, a group of antral follicles, known as a cohort, begins a phase of semisynchronous growth based on their maturation state during the FSH rise in the late luteal phase of the previous cycle. This FSH rise leading to follicle development is called the selection window of the ovarian cycle (Macklon, 2001). Only the follicles progressing to this stage develop the capacity to produce estrogen.

During the follicular phase, estrogen levels rise in parallel to growth of a dominant follicle and to the increase in its number of granulosa cells (see Fig. 5-1). These cells are the exclusive site of FSH receptor expression. The rise of circulating FSH levels during the late luteal phase of the previous cycle stimulates an increase in FSH receptors and subsequently, the ability of cytochrome P450 aromatase within granulosa cells to convert androstenedione into estradiol. The requirement for thecal cells, which respond to luteinizing hormone (LH), and granulosa cells, which respond to FSH, represents the two-gonadotropin, two-cell hypothesis for estrogen biosynthesis (Short, 1962). As shown in Figure 5-2, FSH induces aromatase and expansion of the antrum of growing follicles. The follicle within the cohort that is most responsive to FSH is likely to be the first to produce estradiol and initiate expression of LH receptors.
FIGURE 5-2 The two-cell, two-gonadotropin principle of ovarian steroid hormone production. During the follicular phase (left panel), luteinizing hormone (LH) controls theca cell production of androstenedione, which diffuses into the adjacent granulosa cells and acts as precursor for estradiol biosynthesis. The granulosa cell capacity to convert androstenedione to estradiol is controlled by follicle-stimulating hormone (FSH). After ovulation (right panel), the corpus luteum forms and both theca-lutein and granulosa-lutein cells respond to LH. The theca-lutein cells continue to produce androstenedione, whereas granulosa-lutein cells greatly increase their capacity to produce progesterone and to convert androstenedione to estradiol. LH and hCG bind to the same LH-hCG receptor. If pregnancy occurs (right panel), human chorionic gonadotropin (hCG) rescues the corpus luteum through their shared LH-hCG receptor. Low-density lipoprotein (LDL) is an important source of cholesterol for steroidogenesis. cAMP = cyclic adenosine monophosphate.

After the appearance of LH receptors, the preovulatory granulosa cells begin to secrete small quantities of progesterone. The preovulatory progesterone secretion, although somewhat limited, is believed to exert positive feedback on the estrogen-primed pituitary to either cause or augment LH release. In addition, during the late follicular phase, LH stimulates thecal cell production of androgens, particularly androstenedione, which are then transferred to the adjacent follicles where they are aromatized to estradiol (see Fig. 5-2). During the early follicular phase, granulosa cells also produce inhibin B, which can feed back on the pituitary to inhibit FSH release (Groome 1996). As the dominant follicle begins to grow, production of estradiol and the inhibins increases and results in a decline of follicular-phase FSH. This drop in FSH levels is responsible for the
failure of other follicles to reach preovulatory status—the Graafian follicle stage—during any one cycle. Thus, 95 percent of plasma estradiol produced at this time is secreted by the dominant follicle—the one destined to ovulate. Concurrently, the contralateral ovary is relatively inactive.

Ovulation

The onset of the gonadotropin surge resulting from increasing estrogen secretion by preovulatory follicles is a relatively precise predictor of ovulation. It occurs 34 to 36 hours before ovum release from the follicle (see Fig. 5-1). LH secretion peaks 10 to 12 hours before ovulation and stimulates resumption of meiosis in the ovum and release of the first polar body. Current studies suggest that in response to LH, increased progesterone and prostaglandin production by the cumulus cells, as well as GDF9 and BMP-15 by the oocyte, activates expression of genes critical to formation of a hyaluronan-rich extracellular matrix by the cumulus complex (Richards, 2007). As seen in Figure 5-3, during synthesis of this matrix, cumulus cells lose contact with one another and move outward from the oocyte along the hyaluronan polymer—this process is called expansion. This results in a 20-fold increase in the complex volume along with an LH-induced remodeling of the ovarian extracellular matrix to allow release of the mature oocyte and its surrounding cumulus cells through the surface epithelium. Activation of proteases likely plays a pivotal role in weakening of the follicular basement membrane and ovulation (Curry, 2006; Ny, 2002).

FIGURE 5-3 An ovulated cumulus-oocyte complex. An oocyte is at the center of the complex. Cumulus cells are widely separated from each other in the cumulus layer by the hyaluronan-rich extracellular matrix. (Photograph contributed by Dr. Kevin J. Doody.)

Luteal or Postovulatory Ovarian Phase

Following ovulation, the corpus luteum develops from the dominant or Graafian follicle remains in
a process referred to as luteinization. The basement membrane separating the granulosa-lutein and theca-lutein cells breaks down, and by day 2 postovulation, blood vessels and capillaries invade the granulosa cell layer. The rapid neovascularization of the once-avascular granulosa may be due to angiogenic factors that include vascular endothelial growth factor (VEGF) and others produced in response to LH by theca-lutein and granulosa-lutein cells (Albrecht, 2003; Fraser, 2001). During luteinization, these cells undergo hypertrophy and increase their capacity to synthesize hormones.

LH is the primary luteotropic factor responsible for corpus luteum maintenance (Vande Wiele, 1970). Indeed, LH injections can extend the corpus luteum life span in normal women by 2 weeks (Segaloff, 1951). In normal cycling women, the corpus luteum is maintained by low-frequency, high-amplitude LH pulses secreted by gonadotropes in the anterior pituitary (Filicori, 1986).

The hormone secretion pattern of the corpus luteum differs from that of the follicle (see Fig. 5-1). The increased capacity of granulosa-lutein cells to produce progesterone is the result of increased access to considerably more steroidogenic precursors through blood-borne low-density lipoprotein (LDL)-derived cholesterol as depicted in Figure 5-2 (Carr, 1981a). The important role for LDL in progesterone biosynthesis is supported by the observation that women with extremely low LDL cholesterol levels exhibit minimal progesterone secretion during the luteal phase (Illingworth, 1982). In addition, high-density lipoprotein (HDL) may contribute to progesterone production in granulosa-lutein cells (Ragoobir, 2002).

Estrogen levels follow a more complex pattern of secretion. Specifically, just after ovulation, estrogen levels decrease followed by a secondary rise that reaches a peak production of 0.25 mg/day of 17β-estradiol at the midluteal phase. Toward the end of the luteal phase, there is a secondary decline in estradiol production.

Ovarian progesterone production peaks at 25 to 50 mg/day during the midluteal phase. With pregnancy, the corpus luteum continues progesterone production in response to embryonic human chorionic gonadotropin (hCG), which binds to the same receptor as LH (see Fig. 5-2).

The human corpus luteum is a transient endocrine organ that, in the absence of pregnancy, will rapidly regress 9 to 11 days after ovulation via apoptotic cell death (Vaskivuo, 2002). The mechanisms that control luteolysis remain unclear. However, in part, it results from decreased levels of circulating LH in the late luteal phase and decreased LH sensitivity of luteal cells (Duncan, 1996; Filicori, 1986). The role of other factors is less clear, however, prostaglandin F2α (PGF2α) appears to be luteolytic in nonhuman primates (Auletta, 1987; Wentz, 1973). The endocrine effects, consisting of a dramatic drop in circulating estradiol and progesterone levels, are critical for follicular development and ovulation during the next ovarian cycle. In addition, corpus luteum regression and decline in circulating steroid concentrations signal the endometrium to initiate molecular events that lead to menstruation.

**Estrogen and Progesterone Action**

The fluctuating levels of ovarian steroids are the direct cause of the endometrial cycle. Recent advances in the molecular biology of estrogen and progesterone receptors have greatly improved understanding of their function. The most biologically potent naturally occurring estrogen—17β-estradiol—is secreted by granulosa cells of the dominant follicle and luteinized granulosa cells of the corpus luteum (see Fig. 5-2). Estrogen is the essential hormonal signal on which most events in the normal menstrual cycle depend. Estradiol action is complex and appears to involve two classic nuclear hormone receptors designated estrogen receptor α (ERα) and β (ERβ) (Katzenellenbogen 2001). These isoforms are the products of separate genes and can exhibit distinct tissue
expression. Both estradiol-receptor complexes act as transcriptional factors that become associated with the estrogen response element of specific genes. They share a robust activation by estradiol. However, differences in their binding affinities to other estrogens and their cell-specific expression patterns suggest that ERα and ERβ receptors may have both distinct and overlapping function (Saunders, 2005). Both receptors are expressed in the uterine endometrium (Bombail, 2008; Lecce, 2001). Estrogens function in many cell types to regulate follicular development, uterine receptivity, or blood flow.

Most progesterone actions on the female reproductive tract are mediated through the nuclear hormone receptors, progesterone receptor type A (PR-A) and B (PR-B). Progesterone enters cell by diffusion and in responsive tissues becomes associated with progesterone receptors (Conneely, 2002). Both progesterone receptor isoforms arise from a single gene, are members of the steroid receptor superfamily of transcription factors, and regulate transcription of target genes. These receptors have unique actions. When PR-A and PR-B receptors are coexpressed, it appears that PR-A can inhibit PR-B gene regulation. The endometrial glands and stroma appear to have different expression patterns for progesterone receptors that vary during the menstrual cycle (Mote, 1999). In addition, progesterone can evoke rapid responses such as changes in intracellular free calcium levels that cannot be explained by genomic mechanisms. G-protein-coupled membrane receptors for progesterone have been identified, but their role in the ovarian-endometrium cycle remains to be elucidated (Peluso, 2007).

The Endometrial Cycle

Proliferative or Preovulatory Endometrial Phase
Fluctuations in estrogen and progesterone levels produce striking effects on the reproductive tract, particularly the endometrium. Epithelial—glandular cells; stromal—mesenchymal cells; and blood vessels of the endometrium replicate cyclically in reproductive-aged women at a rapid rate. The endometrium is regenerated during each ovarian–endometrial cycle. The superficial endometrium, termed the functionalis layer, is shed and regenerated from the deeper basalis layer almost 400 times during the reproductive lifetime of most women (Fig. 5-4). There is no other example in humans of such cyclical shedding and regrowth of an entire tissue.
The endometrium consists of two layers, the functionalis layer and basalis layer. These layers are supplied by the spiral and basal arteries, respectively. Numerous glands also span these layers. As the menstrual cycle progresses, greater coiling of the spiral arteries and increased gland folding can be seen. Near the end of the menstrual cycle (day 27), the coiled arteries constrict, depriving the functionalis layer of its blood supply and leading to necrosis and sloughing of this layer.

Follicular-phase estradiol production is the most important factor in endometrial recovery following menstruation. Although up to two thirds of the functionalis endometrium is fragmented and shed during menstruation, reepithelialization begins even before menstrual bleeding has ceased. By the fifth day of the endometrial cycle—fifth day of menses, the epithelial surface of the endometrium has been restored, and revascularization is in progress. The preovulatory endometrium is characterized by proliferation of glandular, stromal, and vascular endothelial cells. During the early part of the proliferative phase, the endometrium is usually less than 2 mm thick. The glands are narrow, tubular structures that pursue almost a straight and parallel course from the basalis layer toward the endometrial cavity. Mitotic figures, especially in the glandular epithelium, are identified by the fifth cycle day. Mitotic activity in both epithelium and stroma persists until day 16 to 17, or 2 to 3 days after ovulation. Although blood vessels are numerous and prominent, there is no extravascular blood or leukocyte infiltration in the endometrium at this stage.

Clearly, reepithelialization and angiogenesis are important to endometrial bleeding cessation (Chennazhi, 2009; Rogers, 2009). These are dependent on tissue regrowth, which is estrogen-
regulated. Epithelial cell growth also is regulated in part by epidermal growth factor (EGF) and transforming growth factor α (TGFα). Stromal cell proliferation appears to increase through paracrine and autocrine actions of estrogen and increased local levels of fibroblast growth factor-9 (Tsai, 2002). Estrogens also increase local production of VEGF, which causes angiogenesis through vessel elongation in the basalis (Gargett, 2001; Sugino, 2002).

By the late proliferative phase, the endometrium thickens from both glandular hyperplasia and increased stromal ground substance, which is edema and proteinaceous material. The loose stroma is especially prominent, and the glands in the functionalis layer are widely separated. This is compared with those of the basalis layer, in which the glands are more crowded and the stroma is denser. At midcycle, as ovulation nears, glandular epithelium becomes taller and pseudostratified. The surface epithelial cells acquire numerous microvilli, which increase epithelial surface area, and cilia, which aid in the movement of endometrial secretions during the secretory phase (Ferenczy, 1976).

Dating the menstrual cycle day by endometrial histological criteria is difficult during the proliferative phase because of considerable phase-length variation among women. Specifically, the follicular phase normally may be as short as 5 to 7 days or as long as 21 to 30 days. In contrast, the luteal or secretory postovulatory phase of the cycle is remarkably constant at 12 to 14 days.

**Secretory or Postovulatory Endometrial Phase**

During the early secretory phase, endometrial dating is based on glandular epithelium histology. After ovulation, the estrogen-primed endometrium responds to rising progesterone levels in a highly predictable manner. By day 17, glycogen accumulates in the basal portion of glandular epithelium, creating subnuclear vacuoles and pseudostratification. This is the first sign of ovulation that is histologically evident. It is likely the result of direct progesterone action through receptors expressed in glandular cells (Mote, 2000). On day 18, vacuoles move to the apical portion of the secretory nonciliated cells. By day 19, these cells begin to secrete glycoprotein and mucopolysaccharide contents into the lumen (Hafez, 1975). Glandular cell mitosis ceases with secretory activity on day 19 due to rising progesterone levels, which antagonize the mitotic effects of estrogen. Estradiol action is also decreased because of glandular expression of the type 2 isoform of 17β-hydroxysteroid dehydrogenase. This converts estradiol to the less active estrone (Casey, 1996).

Dating in the mid- to late-secretory phase relies on endometrial stromal changes. On days 21 to 24, the stroma becomes edematous. On days 22 to 25, stromal cells surrounding the spiral arterioles begin to enlarge, and stromal mitosis becomes apparent. Days 23 to 28 are characterized by predecidual cells, which surround spiral arterioles.

An important feature of secretory-phase endometrium between days 22 and 25 is striking changes associated with predecidual transformation of the upper two thirds of the functionalis layer. The glands exhibit extensive coiling, and luminal secretions become visible. Changes within the endometrium also can mark the so-called window of implantation seen on days 20 to 24. Epithelial surface cells show decreased microvilli and cilia but appearance of luminal protrusions on the apical cell surface (Nikas, 2003). These pinopodes are important in preparation for blastocyst implantation. They also coincide with changes in the surface glycocalyx that allow acceptance of a blastocyst (Aplin, 2003).

The secretory phase is also highlighted by the continuing growth and development of the spiral arteries. Boyd and Hamilton (1970) emphasized the extraordinary importance of the endometrial spiral or coiled arteries. They arise from the radial arteries, which are myometrial branches of the arcuate and ultimately, uterine vessels (see Fig. 5-4). The morphological and functional properties
of spiral arteries are unique and essential for establishing blood flow changes to permit either menstruation or implantation. During endometrial growth, spiral arteries lengthen at a rate appreciably greater than the rate of endometrial tissue thickening (Fig. 5-5). This growth discordance obliges even greater coiling of the already spiraling vessels. Spiral artery development reflects a marked induction of angiogenesis, consisting of widespread vessel sprouting and extension. Perrot-Appplanat and associates (1988) described progesterone and estrogen receptors in the smooth muscle cells of the uterus and spiral arteries. Such rapid angiogenesis is regulated, in part, through estrogen- and progesterone-regulated synthesis of VEGF (Ancelin, 2002; Chennazhi, 2009).

FIGURE 5-5 The spiral arteries of human endometrium are modified during the ovulatory cycle. Initially, blood flow changes through these vessels aid endometrial growth. Excessive coiling and blood flow stasis coincide with regression of corpus luteum function and lead to a decline in endometrial tissue volume. Finally, spiral artery coiling leads to endometrial hypoxia and necrosis. Before endometrial bleeding, intense spiral artery vasospasm serves to limit blood loss during menses.

Menstruation

The midluteal–secretory phase of the endometrial cycle is a critical branch point in endometrial development and differentiation. With corpus luteum rescue and continued progesterone secretion, the decidualization process continues. If luteal progesterone production decreases with luteolysis, events leading to menstruation are initiated (Critchley, 2006; Thiruchelvam, 2013).

A notable histological characteristic of late premenstrual-phase endometrium is stromal infiltration by neutrophils, giving a pseudoinflammatory appearance to the tissue. These cells infiltrate primarily on the day or two immediately preceding menses onset. The endometrial stromal and epithelial cells produce interleukin-8 (IL-8), a chemotactic–activating factor for
Leukocyte infiltration is considered key to both endometrial extracellular matrix breakdown and repair of the functionalis layer. The term “inflammatory tightrope” refers to the ability of macrophages to assume phenotypes that vary from proinflammatory and phagocytic to immunosuppressive and reparative. These are likely relevant to menstruation, in which tissue breakdown and restoration occur simultaneously (Evans, 2012). Invading leukocytes secrete enzymes that are members of the matrix metalloprotease (MMP) family. These add to the proteases already produced by endometrial stromal cells and effectively initiate matrix degradation. This phenomenon has been proposed to initiate the events leading to menstruation (Dong, 2002). As tissue shedding is completed, microenvironment-regulated changes in macrophage phenotype promote repair and resolution (Evans, 2012; Thiruchelvam, 2013).

**Anatomical Events During Menstruation.** The classic study by Markee (1940) described tissue and vascular changes in endometrium before menstruation. First, there are marked changes in endometrial blood flow essential for menstruation. With endometrial regression, spiral artery coiling becomes sufficiently severe that resistance to blood flow increases strikingly, causing endometrial hypoxia. Resultant stasis is the primary cause of endometrial ischemia and tissue degeneration (see Fig. 5-5). Vasoconstriction precedes menstruation and is the most striking and constant event observed in the cycle. Intense spiral artery vasoconstriction also serves to limit menstrual blood loss. Blood flow appears to be regulated in an endocrine manner by sex steroid hormone–induced modifications of a paracrine-mediated vasoactive peptide system as described subsequently.

**Prostaglandins and Menstruation.** Progesterone withdrawal increases expression of cyclooxygenase 2 (COX-2), also called prostaglandin synthase 2, to synthesize prostaglandins. Withdrawal also decreases expression of 15-hydroxyprostaglandin dehydrogenase (PGDH), which degrades prostaglandins (Casey, 1980, 1989). The net result is increased prostaglandin production by endometrial stromal cells and increased prostaglandin-receptor density on blood vessels and surrounding cells.

A role for prostaglandins—especially vasoconstricting PGF$_{2\alpha}$—in menstruation initiation has been suggested (Abel, 2002). Large amounts of prostaglandins are present in menstrual blood. PGF$_{2\alpha}$ administration to nonpregnant women prompts menstruation and symptoms that mimic dysmenorrhea. Painful menstruation is common and likely caused by myometrial contractions and uterine ischemia. This response is believed to be mediated by PGF$_{2\alpha}$-induced spiral artery vasoconstriction that causes the uppermost endometrial zones to become hypoxic. The hypoxic environment is a potent inducer of angiogenesis and vascular permeability factors such as VEGF. Prostaglandins serve an important function in the event cascade leading to menstruation that includes vasoconstriction, myometrial contractions, and upregulation of proinflammatory responses.

**Activation of Lytic Mechanisms.** Following vasoconstriction and endometrial cytokine changes, protease activation within stromal cells and leukocyte invasion is required to degrade the endometrial interstitial matrix. Matrix metalloproteases—MMP-1 and MMP-3—are released from stromal cells and may activate other neutrophilic proteases such as MMP-8 and MMP-9.

**Origin of Menstrual Blood.** Menstrual bleeding is appreciably arterial rather than venous
Endometrial bleeding appears to follow rupture of a spiral arteriole and consequent hematoma formation. With a hematoma, the superficial endometrium is distended and ruptures. Subsequently, fissures develop in the adjacent functionalis layer, and blood and tissue fragments are sloughed. Hemorrhage stops with arteriolar constriction. Changes that accompany partial tissue necrosis also serve to seal vessel tips.

The endometrial surface is restored by growth of flanges, or collars, that form the everted free ends of the endometrial glands (Markee, 1940). These flanges increase in diameter very rapidly, and epithelial continuity is reestablished by fusion of the edges of these sheets of migrating cells.

Interval between Menses. The modal interval of menstruation is considered to be 28 days, but variation is considerable among women, as well as in the cycle lengths of a given woman. Marked differences in the intervals between menstrual cycles are not necessarily indicative of infertility. Arey (1939) analyzed 12 studies comprising approximately 20,000 calendar records from 1500 women. He concluded that there is no evidence of perfect menstrual cycle regularity. Among average adult women, a third of cycles departed by more than 2 days from the mean of all cycle lengths. In his analysis of 5322 cycles in 485 normal women, an average interval of 28.4 days was estimated.

THE DECIDUA

This is a specialized, highly modified endometrium of pregnancy. It is essential for hemochorial placentation, that is, one in which maternal blood contacts trophoblast. This relationship requires trophoblast invasion, and considerable research has focused on the interaction between decidual cells and invading trophoblasts. Decidualization, that is, transformation of secretory endometrium to decidua, is dependent on estrogen and progesterone and factors secreted by the implanting blastocyst. The special relationship that exists between the decidua and the invading trophoblast seemingly defies the laws of transplantation immunology. The success of this unique semiallograft not only is of great scientific interest but may involve processes that harbor insights leading to more successful transplantation surgery and perhaps even immunological treatment of neoplasia (Billingham, 1986; Lala, 2002).

Decidual Structure

The decidua is classified into three parts based on anatomical location. Decidua directly beneath blastocyst implantation is modified by trophoblast invasion and becomes the decidua basalis. The decidua capsularis overlies the enlarging blastocyst and initially separates the conceptus from the rest of the uterine cavity (Fig. 5-6). This portion is most prominent during the second month of pregnancy and consists of decidual cells covered by a single layer of flattened epithelial cells. Internally, it contacts the avascular, extraembryonic fetal membrane—the chorion laeve. The remainder of the uterus is lined by decidua parietalis. During early pregnancy, there is a space between the decidua capsularis and parietalis because the gestational sac does not fill the entire uterine cavity. By 14 to 16 weeks’ gestation, the expanding sac has enlarged to completely fill the uterine cavity. The resulting apposition of the decidua capsularis and parietalis creates the decidua vera, and the uterine cavity is functionally obliterated.
The decidua begins to thicken, eventually attaining a depth of 5 to 10 mm. With magnification, furrows and numerous small openings, representing the mouths of uterine glands, can be detected. Later in pregnancy, the decidua becomes thinner, presumably because of pressure exerted by the expanding uterine contents.

The decidua parietalis and basalis are composed of three layers. There is a surface or compact zone—zona compacta; a middle portion or spongy zone—zona spongiosa—with remnants of glands and numerous small blood vessels; and a basal zone—zona basalis. The zona compacta and spongiosa together form the zona functionalis. The basal zone remains after delivery and gives rise to new endometrium.

**Decidual Reaction**

In human pregnancy, the decidual reaction is completed only with blastocyst implantation. Predecidual changes, however, commence first during the midluteal phase in endometrial stromal cells adjacent to the spiral arteries and arterioles. Thereafter, they spread in waves throughout the uterine endometrium and then from the implantation site. The endometrial stromal cells enlarge to form polygonal or round decidual cells. The nuclei become round and vesicular, and the cytoplasm becomes clear, slightly basophilic, and surrounded by a translucent membrane. Each mature decidual cell becomes surrounded by a pericellular membrane. Thus, the human decidual cells clearly build walls around themselves and possibly around the fetus. The pericellular matrix surrounding the decidual cells may allow attachment of cytotrophoblasts through cellular adhesion molecules. The cell membrane also may provide decidual cell protection against selected cytotrophoblastic proteases.
Decidual Blood Supply

As a consequence of implantation, the blood supply to the decidua capsularis is lost as the embryo-fetus grows. Blood supply to the decidua parietalis through spiral arteries persists. These arteries retain a smooth-muscle wall and endothelium and thereby remain responsive to vasoactive agents.

In contrast, the spiral arterial system supplying the decidua basalis directly beneath the implanting blastocyst, and ultimately the intervillous space, is altered remarkably. These spiral arterioles and arteries are invaded by cytotrophoblasts. During this process, the vessel walls in the basalis are destroyed. Only a shell without smooth muscle or endothelial cells remains. Importantly, as a result, these vascular conduits of maternal blood—which become the uteroplacental vessels—are not responsive to vasoactive agents. Conversely, the fetal chorionic vessels, which transport blood between the placenta and the fetus, contain smooth muscle and thus do respond to vasoactive agents.

Decidual Histology

Early in pregnancy, the zona spongiosa of the decidua consists of large distended glands, often exhibiting marked hyperplasia and separated by minimal stroma. At first, the glands are lined by typical cylindrical uterine epithelium with abundant secretory activity that contributes to blastocyst nourishment. As pregnancy progresses, the epithelium gradually becomes cuboidal or even flattened and later degenerates and sloughs to a greater extent into the gland lumens. With advanced pregnancy, the glandular elements largely disappear. In comparing the decidua parietalis at 16 weeks’ gestation with the early proliferative endometrium of a nonpregnant woman, there is marked hypertrophy but only slight hyperplasia of the endometrial stroma during decidual transformation.

The decidua basalis contributes to formation of the placental basal plate (Fig. 5-7). It differs histologically from the decidua parietalis in two important respects. First, the spongy zone of the decidua basalis consists mainly of arteries and widely dilated veins, and by term, glands have virtually disappeared. Second, the decidua basalis is invaded by many interstitial trophoblast cells and trophoblastic giant cells. Although most abundant in the decidua, the giant cells commonly penetrate the upper myometrium. Their number and invasiveness can be so extensive as to resemble choriocarcinoma.
The Nitabuch layer is a zone of fibrinoid degeneration in which invading trophoblasts meet the decidua basalis. If the decidua is defective, as in placenta accreta, the Nitabuch layer is usually absent (Chap. 41, p. 804). There is also a more superficial, but inconsistent, deposition of fibrin—Rohr stria—at the bottom of the intervillous space and surrounding the anchoring villi. McCombs and Craig (1964) found that decidual necrosis is a normal phenomenon in the first and probably second trimesters. Thus, necrotic decidua obtained through curettage after spontaneous abortion in the first trimester should not necessarily be interpreted as either a cause or an effect of the pregnancy loss.

Both deciduas contain numerous cell types whose composition varies with gestational stage (Loke, 1995). The primary cellular components are the true decidual cells, which differentiated from the endometrial stromal cells, and numerous maternal bone marrow–derived cells.
Early in pregnancy, a striking abundance of large, granular lymphocytes termed decidual natural killer (NK) cells are present in the decidua. In peripheral blood, there are two subsets of NK cells. Approximately 90 percent are highly cytolytic. Ten percent show less cytolytic ability but increased cytokine secretion. In contrast to peripheral blood, 95 percent of NK cells in decidua secrete cytokines, and about half of these unique cells also express angiogenic factors. These decidua NK cells likely play an important role in trophoblast invasion and vasculogenesis.

Decidual Prolactin

In addition to placental development, the decidua potentially provides other functions. The decidua is the source of prolactin that is present in enormous amounts in amnionic fluid (Golander, 1978; Riddick, 1979). Decidual prolactin is not to be confused with placental lactogen (hPL), which is produced only by syncytiotrophoblast. Rather, decidual prolactin is a product of the same gene that encodes for anterior pituitary prolactin. And although the amino-acid sequence of prolactin in both tissues is identical, an alternative promoter is used within the prolactin gene to initiate transcription in decidua (Telgmann, 1998). This may explain the different mechanisms that regulate expression in the decidua versus pituitary (Christian, 2002a,b).

Prolactin preferentially enters amnionic fluid, and little enters maternal blood. Consequently, prolactin levels in amnionic fluid are extraordinarily high and may reach 10,000 ng/mL at 20 to 24 weeks’ gestation (Tyson, 1972). This compares with fetal serum levels of 350 ng/mL and maternal serum levels of 150 to 200 ng/mL. As a result, decidual prolactin is a classic example of paracrine function between maternal and fetal tissues.

The exact physiological roles of decidual prolactin are still unknown. Its action is mediated by the relative expression of two unique prolactin receptors and by the amount of intact or full-length prolactin protein compared with the truncated 16-kDa form (Jabbour, 2001). Receptor expression has been demonstrated in decidua, chorionic cytotrophoblasts, amnionic epithelium, and syncytiotrophoblast (Maaskant, 1996). There are several possible roles for decidual prolactin. First, most or all of this protein hormone enters amnionic fluid. Thus, it may serve in transmembrane solute and water transport and in amnionic fluid volume maintenance. Second, there are prolactin receptors in several bone marrow-derived immune cells, and prolactin may stimulate T cells in an autocrine or paracrine manner (Pellegrini, 1992). This raises the possibility that decidual prolactin may act in regulating immunological functions during pregnancy. Prolactin may play a role in angiogenesis regulation during implantation. Last, decidual prolactin has been shown in the mouse to have a protective function by repressing expression of genes detrimental to pregnancy maintenance (Bao, 2007).

Regulation of decidual prolactin is not clearly defined. Most agents known to inhibit or stimulate pituitary prolactin secretion—including dopamine, dopamine agonists, and thyrotropin-releasing hormone—do not alter decidual prolactin secretion either in vivo or in vitro. Brosens and colleagues (2000) demonstrated that progestins act synergistically with cyclic adenosine monophosphate on endometrial stromal cells in culture to increase prolactin expression. This suggests that the level of progesterone receptor expression may determine the decidualization process, at least as marked by prolactin production. Conversely, various cytokines and growth factors—endothelin-1, IL-1, IL-2, and epidermal growth factor—decrease decidual prolactin secretion (Chao, 1994; Frank, 1995). Studies in decidualized human endometrial cells in culture have led to identification of several transcription factors that regulate decidual prolactin (Jiang, 2011; Lynch, 2009).
Implantation and Early Trophoblast Formation

The fetus is dependent on the placenta for pulmonary, hepatic, and renal functions. These are accomplished through the unique anatomical relationship of the placenta and its uterine interface. Maternal blood spurts from uteroplacental vessels into the placental intervillous space and bathes the outer syncytiotrophoblast. This allows exchange of gases, nutrients, and other substances with fetal capillary blood within the villous core. Thus, fetal and maternal blood are not normally mixed in this hemochorial placenta. There is also a paracrine system that links mother and fetus through the anatomical and biochemical juxtaposition of the maternal decidua parietalis and the extraembryonic chorion laeve, which is fetal. This is an extraordinarily important arrangement for communication between fetus and mother and for maternal immunological acceptance of the conceptus (Guzeloglu-Kayisli, 2009).

Fertilization and Implantation

With ovulation, the secondary oocyte and adhered cells of the cumulus-oocyte complex are freed from the ovary. Although technically this mass of cells is released into the peritoneal cavity, the oocyte is quickly engulfed by the fallopian tube infundibulum. Further transport through the tube is accomplished by directional movement of cilia and tubal peristalsis. Fertilization, which normally occurs in the oviduct, must take place within a few hours, and no more than a day after ovulation. Because of this narrow opportunity window, spermatozoa must be present in the fallopian tube at the time of oocyte arrival. Almost all pregnancies result when intercourse occurs during the 2 days preceding or on the day of ovulation. Thus, postovulatory and postfertilization developmental ages are similar.

Steps of fertilization are highly complex. Molecular mechanisms allow spermatozoa to pass between follicular cells; through the zona pellucida, which is a thick glycoprotein layer surrounding the oocyte cell membrane; and into the oocyte cytoplasm. Fusion of the two nuclei and intermingling of maternal and paternal chromosomes creates the zygote. These steps are reviewed by Primakoff and Myles (2002).

Early human development is described by days or weeks postfertilization, that is, post-conceptional. By contrast, in most chapters of this book, clinical pregnancy dating is calculated from the start of the last menses. As discussed earlier, the follicular phase length is more variable than the luteal phase. Thus, 1 week postfertilization corresponds to approximately 3 weeks from the last menstrual period in women with regular 28-day cycles.

The Zygote

After fertilization, the zygote—a diploid cell with 46 chromosomes—undergoes cleavage, and zygote cells produced by this division are called blastomeres (Fig. 5-8). In the two-cell zygote, the blastomeres and polar body continue to be surrounded by the zona pellucida. The zygote undergoes slow cleavage for 3 days while still within the fallopian tube. As the blastomeres continue to divide, a solid mulberry-like ball of cells—the morula—is produced. The morula enters the uterine cavity about 3 days after fertilization. Gradual accumulation of fluid between the morula cells leads to formation of the early blastocyst.
FIGURE 5-8 Zygote cleavage and blastocyst formation. The morula period begins at the 12- to 16-cell stage and ends when the blastocyst forms, which occurs when there are 50 to 60 blastomeres present. The polar bodies, shown in the 2-cell stage, are small nonfunctional cells that soon degenerate.

The Blastocyst

As early as 4 to 5 days after fertilization, the 58-cell blastula differentiates into five embryo-producing cells—the inner cell mass, and 53 cells destined to form trophoblast (Hertig, 1962). In a 58-cell blastocyst, the outer cells, called the trophectoderm, can be distinguished from the inner cell mass that forms the embryo (see Fig. 5-8).

Interestingly, the 107-cell blastocyst is found to be no larger than the earlier cleavage stages, despite the accumulated fluid. It measures approximately 0.155 mm in diameter, which is similar to the size of the initial postfertilization zygote. At this stage, the eight formative, embryo-producing cells are surrounded by 99 trophoblastic cells. And, the blastocyst is released from the zona pellucida secondary to secretion of specific proteases from the secretory-phase endometrial glands (O’Sullivan, 2002).

Release from the zona pellucida allows blastocyst-produced cytokines and hormones to directly influence endometrial receptivity (Lindhard, 2002). IL-1α and IL-1β are secreted by the blastocyst and these cytokines likely directly influence the endometrium. Embryos also have been shown to secrete hCG, which may influence endometrial receptivity (Licht, 2001; Lobo, 2001). The receptive endometrium is thought to respond by producing leukemia inhibitory factor (LIF) and colony-stimulating factor-1 (CSF-1). These serve to increase trophoblast protease production. This degrades selected endometrial extracellular matrix proteins and allows trophoblast invasion. Thus, embryo “hatching” is a critical step toward successful pregnancy as it allows association of
trophoblasts with endometrial epithelial cells and permits release of trophoblast-produced hormones into the uterine cavity.

**Blastocyst Implantation**

Six or 7 days after fertilization, the embryo implants the uterine wall. This process can be divided into three phases: (1) apposition—initial contact of the blastocyst to the uterine wall; (2) adhesion—increased physical contact between the blastocyst and uterine epithelium; and (3) invasion—penetration and invasion of syncytiotrophoblast and cytotrophoblasts into the endometrium, inner third of the myometrium, and uterine vasculature.

Successful implantation requires a receptive endometrium appropriately primed with estrogen and progesterone by the corpus luteum. Such uterine receptivity is limited to days 20 to 24 of the cycle. Adherence is mediated by cell-surface receptors at the implantation site that interact with blastocyst receptors (Carson, 2002; Lessey, 2002; Lindhard, 2002; Paria, 2002). If the blastocyst approaches the endometrium after cycle day 24, the potential for adhesion is diminished because antiadhesive glycoprotein synthesis prevents receptor interactions (Navot, 1991).

At the time of its interaction with the endometrium, the blastocyst is composed of 100 to 250 cells. The blastocyst loosely adheres to the endometrial epithelium by apposition. This most commonly occurs on the upper posterior uterine wall. Attachment of the blastocyst trophectoderm to the endometrial surface by apposition and adherence appears to be closely regulated by paracrine interactions between these two tissues.

Successful endometrial blastocyst adhesion involves modification in expression of cellular adhesion molecules (CAMs). The integrins—one of four families of CAMs—are cell-surface receptors that mediate cell adhesion to extracellular matrix proteins (Lessey, 2002). Great diversity of cell binding to several different extracellular matrix proteins is possible by differential regulation of the integrin receptors. Endometrial integrins are hormonally regulated, and a specific set of integrins is expressed at implantation (Lessey, 1996). Specifically, αVβ3 and α4β1 integrins expressed on endometrial epithelium are considered a receptivity marker for blastocyst attachment. Aberrant expression of αVβ3 has been associated with infertility (Lessey, 1995). Recognition-site blockade on integrins for binding to extracellular matrix molecules such as fibronectin will prevent blastocyst attachment (Kaneko, 2013).

**The Trophoblast**

Human placental formation begins with the trophectoderm, which appears at the morula stage. It gives rise to a trophoblast cell layer encircling the blastocyst. From then until term, the trophoblast plays a critical part at the fetal-maternal interface. Trophoblast exhibits the most variable structure, function, and developmental pattern of all placental components. Its invasiveness promotes implantation, its nutritional role for the conceptus is reflected in its name, and its endocrine organ function is essential to maternal physiological adaptations and to pregnancy maintenance.

**Trophoblast Differentiation**

By the eighth day postfertilization, after initial implantation, the trophoblast has differentiated into an outer multinucleated syncytium—primitive syncytiotrophoblast, and an inner layer of primitive mononuclear cells—cytotrophoblasts (Fig. 5-9). The latter are germinal cells for the syncytium. Each cytotrophoblast has a well-demarcated cell border, a single nucleus, and ability to undergo
DNA synthesis and mitosis (Arnholdt, 1991). These are lacking in the syncytiotrophoblast. It is so named because instead of individual cells, it has an amorphous cytoplasm without cell borders, nuclei that are multiple and diverse in size and shape, and a continuous syncytial lining. This configuration aids transport.

**FIGURE 5-9** Drawing of sections through implanted blastocysts. **A.** At 10 days. **B.** At 12 days after fertilization. This stage is characterized by the intercommunication of the lacunae filled with maternal blood. Note in (B) that large cavities have appeared in the extraembryonic mesoderm, forming the beginning of the extraembryonic coelom. Also note that extraembryonic endodermal cells have begun to form on the inside of the primitive yolk sac. (Adapted from Moore, 1988.)

After implantation is complete, trophoblast further differentiate along two main pathways, giving rise to villous and extravillous trophoblast. As shown in **Figure 5-10**, both pathways create populations of trophoblast cells that have distinct functions (Loke, 1995). The **villous trophoblast** gives rise to the chorionic villi, which primarily transport oxygen, nutrients, and other compounds between the fetus and mother. Extravillous trophoblasts migrate into the decidua and myometrium and also penetrate maternal vasculature, thus coming into contact with various maternal cell types (Pijnenborg, 1994). Extravillous trophoblasts are thus further classified as **interstitial trophoblasts** and **endovascular trophoblasts**. The interstitial trophoblasts invade the decidua and eventually penetrate the myometrium to form placental bed giant cells. These trophoblasts also surround spiral arteries. The endovascular trophoblasts penetrate the spiral artery lumens (Pijnenborg, 1983). These are both discussed in greater detail in subsequent sections.
Extravillous trophoblasts are found outside the villus and can be subdivided into endovascular and interstitial categories. Endovascular trophoblasts invade and transform spiral arteries during pregnancy to create low-resistance blood flow that is characteristic of the placenta. Interstitial trophoblasts invade the decidua and surround spiral arteries.

**Early Trophoblast Invasion**

After gentle erosion between epithelial cells of the surface endometrium, invading trophoblasts burrow deeper. By the 10th day, the blastocyst becomes totally encased within the endometrium. The mechanisms leading to trophoblast invasion are similar to those of metastasizing malignant cells and are discussed further on page 93.

At 9 days of development, the blastocyst wall facing the uterine lumen is a single layer of flattened cells (see Fig. 5-9A). The opposite, thicker wall comprises two zones—the trophoblasts and the embryo-forming inner cell mass. As early as 7½ days after fertilization, the inner cell mass or embryonic disc is differentiated into a thick plate of primitive ectoderm and an underlying layer of endoderm. Some small cells appear between the embryonic disc and the trophoblast and enclose a space that will become the amnionic cavity.

Embryonic mesenchyme first appears as isolated cells within the blastocyst cavity. When the cavity is completely lined with this mesoderm, it is termed the chorionic vesicle, and its membrane, now called the chorion, is composed of trophoblasts and mesenchyme. Some mesenchymal cells eventually will condense to form the body stalk. This stalk joins the embryo to the nutrient chorion and later develops into the umbilical cord. The body stalk can be recognized at an early stage at the caudal end of the embryonic disc (Fig. 7-4, 129).

**Lacunae Formation within the Syncytiotrophoblast**
As the embryo enlarges, more maternal decidua basalis is invaded by syncytiotrophoblast. Beginning approximately 12 days after conception, the syncytiotrophoblast is permeated by a system of intercommunicating channels called trophoblastic lacunae. After invasion of superficial decidual capillary walls, lacunae become filled with maternal blood (see Figs. 5-9B and 5-11). At the same time, the decidual reaction intensifies in the surrounding stroma. This is characterized by decidual stromal cell enlargement and glycogen storage.

**Placental Organization**

**Chorionic Villi**

With deeper blastocyst invasion into the decidua, the extravillous cytotrophoblasts give rise to solid primary villi composed of a cytotrophoblast core covered by syncytiotrophoblast. These arise from buds of cytotrophoblast that protrude into the primitive syncytium before 12 days postfertilization. As the lacunae join, a complicated labyrinth is formed that is partitioned by these solid cytotrophoblastic columns. The trophoblast-lined labyrinthine channels form the intervillus space, and the solid cellular columns form the *primary villous stalks*. The villi initially are
located over the entire blastocyst surface. They later disappear except over the most deeply implanted portion, which is destined to form the placenta.

Beginning on approximately the 12th day after fertilization, mesenchymal cords derived from extraembryonic mesoderm invade the solid trophoblast columns. These form secondary villi. Once angiogenesis begins in the mesenchymal cores, tertiary villi are formed. Although maternal venous sinuses are tapped early in implantation, maternal arterial blood does not enter the intervillous space until around day 15. By approximately the 17th day, however, fetal blood vessels are functional, and a placental circulation is established. The fetal–placental circulation is completed when the blood vessels of the embryo are connected with chorionic vessels. In some villi, angiogenesis fails from lack of circulation. They can be seen normally, but the most striking exaggeration of this process is seen with hydatidiform mole (Fig. 20-1, p. 397).

Villi are covered by an outer layer of syncytiotrophoblasts, which are also known as Langhans cells. Cytotrophoblast proliferation at the villous tips produces the trophoblastic cell columns that form anchoring villi. They are not invaded by fetal mesenchyme, and they are anchored to the decidua at the basal plate. Thus, the base of the intervillous space faces the maternal side and consists of cytotrophoblasts from cell columns, the covering shell of syncytiotrophoblast, and maternal decidua of the basal plate. The base of the chorionic plate forms the roof of the intervillous space. It consists of two layers of trophoblasts externally and fibrous mesoderm internally. The “definitive” chorionic plate is formed by 8 to 10 weeks as the amnionic and primary chorionic plate mesenchyme fuse together. This formation is accomplished by expansion of the amnionic sac, which also surrounds the connective stalk and the allantois and joins these structures to form the umbilical cord (Kaufmann, 1992).

**Villus Ultrastructure**

Interpretation of the fine structure of the placenta came from electron microscopic studies of Wislocki and Dempsey (1955). There are prominent microvilli on the syncytial surface that correspond to the so-called brush border described by light microscopy. Associated pinocytotic vacuoles and vesicles are related to absorptive and secretory placental functions. Microvilli act to increase surface area in direct contact with maternal blood. This contact between the trophoblast and maternal blood is the defining characteristic of a hemochorial placenta.

The human hemochorial placenta can be subdivided into hemodichorial or hemomonochorial (Enders, 1965). The dichorial type is more prominent during the first trimester of gestation. It consists of the inner layer of the cytotrophoblasts and associated basal lamina, covered by a syncytiotrophoblast layer. Later in gestation the inner layer of cytotrophoblasts is no longer continuous, and by term, there are only scattered cells present (Fig. 5-12). These create a narrower hemomonochorial barrier that aids nutrient and oxygen transport to the fetus.
FIGURE 5-12 Electron micrograph of term human placenta villus. A villus capillary filled with red blood cells (asterisks) is seen in close proximity to the microvilli border. (From Boyd, 1970, with permission.)

PLACENTA AND CHORION DEVELOPMENT

Chorion and Decidua Development

In early pregnancy, the villi are distributed over the entire periphery of the chorionic membrane (Fig. 5-13). As the blastocyst with its surrounding trophoblasts grows and expands into the decidua, one pole faces the endometrial cavity. The opposite pole will form the placenta from villous trophoblasts and anchoring cytotrophoblasts. Chorionic villi in contact with the decidua basalis proliferate to form the chorion frondosum—or leafy chorion—which is the fetal component of the placenta. As growth of embryonic and extraembryonic tissues continues, the blood supply to the chorion facing the endometrial cavity is restricted. Because of this, villi in contact with the
decidua capsularis cease to grow and then degenerate. This portion of the chorion becomes the avascular fetal membrane that abuts the decidua parietalis, that is, the chorion laeve—or smooth chorion. This smooth chorion is composed of cytotrophoblasts and fetal mesodermal mesenchyme that survives in a relatively low-oxygen atmosphere.

FIGURE 5-13 Photograph of an opened chorionic sac. An early embryo and yolk sac are seen. Note the prominent fringe of chorionic villi. (From Boyd, 1970, with permission.)

Until near the end of the third month, the chorion laeve is separated from the amnion by the exocoelomic cavity. Thereafter, they are in intimate contact to form an avascular amniochorion. The chorion laeve is generally more translucent than the amnion and rarely exceeds 1-mm thickness. These two structures are important sites of molecular transfer and metabolic activity. Moreover, they constitute an important paracrine arm of the fetal–maternal communication system.

**Maternal Regulation of Trophoblast Invasion and Vascular Growth**
During the first half of pregnancy, decidual natural killer cells (dNK) accumulate in the decidua
and are found in direct contact with trophoblasts. As described on page 88, these cells lack cytotoxic functions and are able to dampen inflammatory T(H)17 cells. These along with other unique properties distinguish dNK cells from circulating natural killer cells and from natural killer cells in the endometrium before pregnancy (Fu, 2013; Winger, 2013). Recent studies suggest that decidual macrophages play a regulatory role in inhibiting NK cell killing during pregnancy (Co, 2013). This importantly prevents them from recognizing and destroying fetal cells as “foreign.” Hanna and colleagues (2006) have elucidated the ability of dNK cells to attract and promote trophoblast invasion into the decidua and promote vascular growth. Decidual NK cells express both IL-8 and interferon-inducible protein-10, which bind to receptors on invasive trophoblast cells to promote their decidual invasion toward the spiral arteries. Decidual NK cells also produce proangiogenic factors, including VEGF and placental growth factor (PIGF), which promote vascular growth in the decidua. In addition, trophoblasts secrete specific chemokines that attract the dNK cells to the maternal-fetal interface. Thus, both cell types simultaneously attract each other.

**Trophoblast Invasion of the Endometrium**

Extravillous trophoblasts of the first-trimester placenta are highly invasive. They form cell columns that extend from the endometrium to the inner third of the myometrium. Recall that hemochorial placental development requires invasion of endometrium and spiral arteries. This process occurs under low-oxygen conditions, and regulatory factors that are induced under hypoxic conditions contribute in part to invasive trophoblast activation (Soares, 2012). Invasive trophoblasts secrete numerous proteolytic enzymes that digest extracellular matrix and activate proteinases already present in the endometrium. Trophoblasts produce urokinase-type plasminogen activator, which converts plasminogen into the broadly acting serine protease, plasmin. This in turn both degrades matrix proteins and activates matrix metalloproteases. One member of the MMP family, MMP-9, appears to be critical for human trophoblast invasion. The timing and extent of trophoblast invasion is regulated by a balanced interplay between pro- and antiinvasive factors.

The relative ability to invade maternal tissue in early pregnancy compared with limited invasiveness in late pregnancy is controlled by autocrine and paracrine trophoblastic and endometrial factors. Trophoblasts secrete insulin-like growth factor II, which acts in an autocrine manner. It promotes invasion into the endometrium, whereas decidual cells secrete insulin-like growth factor binding-protein type 4, which blocks this autocrine loop. Thus, the degree of trophoblast invasion is controlled by matrix degradation regulation and by factors that cause trophoblast migration.

Low estradiol levels in the first trimester are critical for trophoblast invasion and remodeling of the spiral arteries. Recent studies in nonhuman primates suggest that the increase in second-trimester estradiol levels suppresses and limits vessel remodeling by reducing trophoblast expression of VEGF and specific integrin receptors (Bonagura, 2012). As the extravillous trophoblast differentiates, it gains expression of integrin receptors that recognize the extracellular matrix proteins collagen IV, laminin, and fibronectin. Binding of these extracellular matrix proteins to specific integrin receptors initiates signals that promote trophoblast cell migration and differentiation. As pregnancy advances, increasing estradiol levels repress and thus control the extent of uterine vessel transformation via downregulation of VEGF and integrin receptors expression.
One of the most remarkable features of human placental development is the extensive modification of maternal vasculature by trophoblasts, which are by definition of fetal origin. These events occur in the first half of pregnancy and are considered in detail because of their importance to uteroplacental blood flow. They are also integral to some pathological conditions such as preeclampsia, fetal-growth restriction, and preterm birth. Spiral artery modifications are carried out by two populations of extravillous trophoblast—interstitial trophoblasts, which surround the arteries, and endovascular trophoblasts, which penetrate the spiral artery lumen (see Fig. 5-10). Although earlier work has focused on the role of the endovascular trophoblast, interstitial trophoblast function has more recently been investigated (Benirschke, 2012; Pijnenborg, 1983). These interstitial cells constitute a major portion of the placental bed and penetrate the decidua and adjacent myometrium. They aggregate around spiral arteries, and their functions may include vessel preparation for endovascular trophoblast invasion.

Hamilton and Boyd (1966) report that Friedlander in 1870 first described structural changes in spiral arteries. Endovascular trophoblasts first enter the spiral-artery lumens and initially form cellular plugs. They then destroy vascular endothelium via an apoptosis mechanism and invade and modify the vascular media. Thus, fibrinoid material replaces smooth muscle and connective tissue of the vessel media. Spiral arteries later regenerate endothelium. Invading endovascular trophoblasts can extend several centimeters along the vessel lumen, and they must migrate against arterial flow. These vascular changes are not observed in the decidua parietalis, that is, in decidual sites removed from the invading cytotrophoblasts. Of note, invasion by trophoblasts involves only the decidual spiral arteries and not decidual veins.

In their summary of uteroplacental vasculature, Ramsey and Donner (1980) describe uteroplacental vessel development as proceeding in two waves or stages. The first wave occurs before 12 weeks’ postfertilization and consists of invasion and modification of spiral arteries up to the border between the decidua and myometrium. The second wave is between 12 and 16 weeks and involves some invasion of the intramyometrial segments of spiral arteries. Remodeling converts narrow-lumen, muscular spiral arteries into dilated, low-resistance uteroplacental vessels. Molecular mechanisms of these crucial events, and their significance in the pathogenesis of preeclampsia and fetal-growth restriction, have been reviewed by Kaufmann (2003) and Red-Horse (2006).

**Establishment of Maternal Blood Flow**

Approximately 1 month after conception, maternal blood enters the intervillous space in fountain-like bursts from the spiral arteries. Blood is propelled outside of the maternal vessels and sweeps over and directly bathes the syncytiotrophoblast. The apical surface of the syncytiotrophoblast consists of a complex microvillous structure that undergoes continual shedding and reformation during pregnancy.

**Villus Branching**

Although certain villi of the chorion frondosum extend from the chorionic plate to the decidua to serve as anchoring villi, most villi arborize and end freely within the intervillous space. As gestation proceeds, the short, thick, early stem villi branch to form progressively finer subdivisions and greater numbers of increasingly smaller villi (Fig. 5-14). Each of the truncal or main stem villi and their ramifications (rami) constitutes a placental lobule, or cotyledon. Each lobule is supplied with a single truncal branch of the chorionic artery. And each lobule has a single vein so that lobules constitute functional units of placental architecture.
Placental Growth and Maturation

Placental Growth

In the first trimester, placental growth is more rapid than that of the fetus. But by approximately 17 postmenstrual weeks, placental and fetal weights are approximately equal. By term, placental weight is approximately one sixth of fetal weight.

The mature placenta and its variant forms are discussed in detail in Chapter 6 (p. 116). Briefly, viewed from the maternal surface, the number of slightly elevated convex areas, called lobes, varies from 10 to 38 (Fig. 5-15). Lobes are incompletely separated by grooves of variable depth that overlie placental septa, which arise from folding of the basal plate. The total number of placental lobes remains the same throughout gestation, and individual lobes continue to grow—
although less actively in the final weeks (Crawford, 1959). Although grossly visible lobes are commonly referred to as cotyledons, this is not accurate. Correctly used, lobules or cotyledons are the functional units supplied by each main stem villus.

**FIGURE 5-15** Photograph of the maternal surface of a placenta. Placental lobes are formed by clefs on the surface that originate from placental septa. (Photograph contributed by Dr. Judith J. Head.)

**Placental Maturation**

As villi continue to branch and the terminal ramifications become more numerous and smaller, the volume and prominence of cytotrophoblasts decrease. As the syncytium thins, the fetal vessels become more prominent and lie closer to the surface. The villous stroma also exhibits changes as gestation progresses. In early pregnancy, the branching connective-tissue cells are separated by an abundant loose intercellular matrix. Later, the villous stroma becomes denser, and the cells more spindly and more closely packed.

Another change in the stroma involves the infiltration of Hofbauer cells, which are fetal macrophages. These are nearly round with vesicular, often eccentric nuclei and very granular or vacuolated cytoplasm. Hofbauer cells are characterized histochemically by intracytoplasmic lipid and by phenotypic markers specific for macrophages. They increase in numbers and maturational state throughout pregnancy and appear to be important mediators of protection at the maternal-fetal interface (Johnson, 2012). These macrophages are phagocytic, have an immunosuppressive phenotype, can produce various cytokines, and are capable of paracrine regulation of trophoblast functions (Cervar, 1999; Vince, 1996).

Some of the histological changes that accompany placental growth and maturation provide an
increased efficiency of transport and exchange to meet increasing fetal metabolic requirements. Among these changes are decreased syncytiotrophoblast thickness, significantly reduced cytotrophoblast number, decreased stroma, and increased number of capillaries with close approximation to the syncytial surface. By 16 weeks, the apparent continuity of the cytotrophoblasts is lost. At term, villi may be focally reduced to a thin layer of syncytium covering minimal villous connective tissue in which thin-walled fetal capillaries abut the trophoblast and dominate the villi (see Fig. 5-14D).

There are some changes in placental architecture that can cause decreased placental exchange efficiency if they are substantive. As described in Chapter 6 (p. 119), these include thickening of the basal lamina of trophoblast or capillaries, obliteration of certain fetal vessels, increased villous stroma, and fibrin deposition on the villous surface.

**Fetal and Maternal Blood Circulation in the Mature Placenta**

Because the placenta is functionally an intimate approximation of the fetal capillary bed to maternal blood, its gross anatomy primarily concerns vascular relations. The fetal surface is covered by the transparent amnion, beneath which chorionic vessels course. A section through the placenta includes amnion, chorion, chorionic villi and intervillous space, decidual (basal) plate, and myometrium (Figs. 5-16 and 5-17).

![FIGURE 5-16](image-url) Uterus of pregnant woman showing a normal placenta in situ. A. Photomicrograph of a histologic section through amnion, chorion, and decidua vera that is depicted in (B) (green slice). (Photograph contributed by Dr. Kurt Benirschke.)
Fetal Circulation

Deoxygenated venous-like fetal blood flows to the placenta through the two umbilical arteries. As the cord joins the placenta, these umbilical vessels branch repeatedly beneath the amnion and again within the villi, finally forming capillary networks in the terminal villous branches. Blood with significantly higher oxygen content returns from the placenta via a single umbilical vein to the fetus.

The branches of the umbilical vessels that traverse along the fetal surface of the placenta in the chorionic plate are referred to as the placental surface or chorionic vessels. These vessels are responsive to vasoactive substances, but anatomically, morphologically, histologically, and functionally, they are unique. Chorionic arteries always cross over chorionic veins. Vessels are most readily recognized by this interesting relationship, but they are difficult to distinguish by histological criteria. In 65 percent of placentas, chorionic arteries form a fine network supplying the cotyledons—a pattern of disperse-type branching. In the remaining 35 percent, the arteries radiate to the edge of the placenta without narrowing. Both types are end arteries that supply one cotyledon as each branch turns downward to pierce the chorionic plate.

Truncal arteries are perforating branches of the surface arteries that pass through the chorionic plate. Each truncal artery supplies one main stem villus and thus one cotyledon. The amount of vessel wall smooth muscle decreases, and the vessel caliber increases as it penetrates the
chorionic plate. The loss in muscle continues as the truncal arteries and veins branch into their smaller rami.

Before 10 weeks, there is no end-diastolic flow pattern within the umbilical artery at the end of the fetal cardiac cycle (Cole, 1991; Fisk, 1988; Loquet, 1988). After 10 weeks, end-diastolic flow appears and is maintained throughout normal pregnancy (Maulik, 1997). Clinically, these are studied with Doppler sonography to assess fetal well-being (Chap. 10, p. 219).

Maternal Circulation

Because an efficient maternal–placental circulation is requisite, many investigators have sought to define factors that regulate blood flow into and from the intervillous space. An adequate mechanism must explain how blood can: (1) leave maternal circulation; (2) flow into an amorphous space lined by syncytiotrophoblast, rather than endothelium; and (3) return through maternal veins without producing arteriovenous-like shunts that would prevent maternal blood from remaining in contact with villi long enough for adequate exchange. Early studies of Ramsey and Davis (1963) and Ramsey and Harris (1966) provide a physiological explanation of placental circulation. These researchers demonstrated, by careful, low-pressure injections of radiocontrast material, that arterial entrances and venous exits are scattered randomly over the entire placental base.

The physiology of maternal-placental circulation is depicted in Figure 5-18. Maternal blood enters through the basal plate and is driven high up toward the chorionic plate by arterial pressure before laterally dispersing. After bathing the external microvillous surface of chorionic villi, maternal blood drains back through venous orifices in the basal plate and enters uterine veins. Thus, maternal blood traverses the placenta randomly without preformed channels. The previously described trophoblast invasion of the spiral arteries creates low-resistance vessels that can accommodate massive increase in uterine perfusion during gestation. Generally, spiral arteries are perpendicular to, but veins are parallel to, the uterine wall. This arrangement aids closure of veins during a uterine contraction and prevents the exit of maternal blood from the intervillous space. The number of arterial openings into the intervillous space becomes gradually reduced by cytotrophoblast invasion. According to Brosens and Dixon (1963), there are about 120 spiral arterial entries into the intervillous space at term. These discharge blood in spurts that bathes the adjacent villi (Borell, 1958). After the 30th week, a prominent venous plexus separates the decidua basalis from the myometrium and thus participates in providing a cleavage plane for placental separation.
FIGURE 5-18 Schematic drawing of a section through a full-term placenta. Maternal blood flows into the intervillous spaces in funnel-shaped spurts. Exchanges occur with fetal blood as maternal blood flows around the villi. In-flowing arterial blood pushes venous blood into the endometrial veins, which are scattered over the entire surface of the decidua basalis. Note also that the umbilical arteries carry deoxygenated fetal blood to the placenta and that the umbilical vein carries oxygenated blood to the fetus. Placental lobes are separated from each other by placental (decidual) septa.

As discussed, both inflow and outflow are curtailed during uterine contractions. Bleker and associates (1975) used serial sonography during normal labor and found that placental length, thickness, and surface area increased during contractions. They attributed this to distention of the intervillous space by impairment of venous outflow compared with arterial inflow. During contractions, therefore, a somewhat larger volume of blood is available for exchange even though the rate of flow is decreased. Similarly, Doppler velocimetry has shown that diastolic flow velocity in spiral arteries is diminished during uterine contractions. Thus, principal factors regulating intervillous space blood flow are arterial blood pressure, intrauterine pressure, uterine contraction pattern, and factors that act specifically on arterial walls.

**Breaks in the Placental “Barrier”**

The placenta does not maintain absolute integrity of the fetal and maternal circulations. There are numerous examples of trafficking cells between mother and fetus in both directions. This situation
is best exemplified clinically by erythrocyte D-antigen alloimmunization and resulting erythroblastosis fetalis (Chap. 15, p. 307). Although fetal cell admixtures likely are small in most cases, occasionally the fetus exsanguinates into the maternal circulation (Silver, 2007).

It is indisputable that fetal cells can become engrafted in the mother during pregnancy and can be identified decades later. Fetal lymphocytes, CD34+ mesenchymal stem cells, and endothelial colony-forming cells reside in maternal blood, bone marrow, or uterine vasculature (Nguyen, 2006; Piper, 2007; Sipos, 2013). Termed microchimerism, such residual stem cells may participate in maternal tissue regeneration and have been implicated in the disparate female:male ratio of autoimmune disorders (Gleicher, 2007; Greer, 2011; Stevens, 2006). As discussed in Chapter 59 (p. 1168), they are associated with the pathogenesis of lymphocytic thyroiditis, scleroderma, and systemic lupus erythematosus.

## Immunological Considerations of the Fetal–Maternal Interface

The lack of uterine transplantation immunity is unique compared with that of other tissues, and there have been many attempts to explain survival of the semiallogenic fetal graft. Some note the immunological peculiarity of cells involved in implantation and fetal-placental development. These include decidual natural killer cells with their inefficient cytotoxic abilities, decidual stromal cells, and invasive trophoblasts that populate the decidua (Hanna, 2006; Santoni, 2007; Staun-Ram, 2005). The trophoblasts are the only fetal-derived cells in direct contact with maternal tissues. Previous studies have suggested that maternal natural killer cells act to control the invasion of trophoblast, which have adapted to survive in an immunologically hostile environment (Thellin, 2000). Subsequently, Hanna and coworkers (2006) reported a “peaceful” model of trophoblast invasion and maternal vascular remodeling. In this scheme, decidual natural killer cells work in concert with stromal cells. They mediate angiogenesis through production of proangiogenic factors such as VEGF and control trophoblast chemoattraction toward spiral arteries by production of IL-8 and interferon inducible protein-10.

### Immunogenicity of the Trophoblasts

More than 50 years ago, Sir Peter Medawar (1953) suggested that fetal semiallograft survival might be explained by immunological neutrality. The placenta was considered immunologically inert and therefore unable to create a maternal immune response. Subsequently, research was focused on defining expression of the major histocompatibility complex (MHC) antigens on trophoblasts. Human leukocyte antigens (HLAs) are the human analogue of the MHC. And indeed, MHC class I and II antigens are absent from villous trophoblasts, which appear to be immunologically inert at all gestational stages (Weetman, 1999). But invasive extravillous cytotrophoblasts do express MHC class I molecules, which have been the focus of considerable study.

### Trophoblast HLA Class I Expression

The HLA genes are the products of multiple genetic loci of the major histocompatibility complex located within the short arm of chromosome 6 (Hunt, 1992). There are 17 HLA class I genes, including three classic genes, HLA-A, -B, and -C, that encode the major class I (class Ia) transplantation antigens. Three other class I genes, designated HLA-E, -F, and -G, encode class Ib HLA antigens.

Moffett-King (2002) reasoned that normal implantation depends on controlled trophoblastic invasion of maternal endometrium–decidua and spiral arteries. Such invasion must proceed far enough to provide for normal fetal growth and development, but there must be a mechanism for
regulating its depth. She suggests that uterine decidual natural killer (uNK) cells combined with unique expression of three specific HLA class I genes in extravillous cytotrophoblasts act in concert to permit and subsequently limit trophoblast invasion.

Class I antigens in extravillous cytotrophoblasts are accounted for by the expression of classic HLA-C and nonclassic class Ib molecules of HLA-E and HLA-G. HLA-G antigen is expressed only in humans, with expression restricted to extravillous cytotrophoblasts contiguous with maternal tissues, that is, decidual and uNK cells. Indeed, HLA-G antigen expression is identified only in extravillous cytotrophoblasts in the decidua basalis and in the chorion laeve (McMaster, 1995). During pregnancy, a soluble major isoform—HLA-G2—has increased levels (Hunt 2000a,b). Embryos used for in vitro fertilization do not implant if they do not express this soluble HLA-G isoform (Fuzzi, 2002). Thus, HLA-G may be immunologically permissive of the maternal-fetal antigen mismatch (LeBouteiller, 1999). HLA-G has a proposed role in protecting extravillous trophoblasts from immune rejection via modulation of uNK functions (Apps, 2011; Rajagopalan, 2012). Finally, Goldman-Wohl and associates (2000) have provided evidence for abnormal HLA-G expression in extravillous trophoblasts from women with preeclampsia.

Uterine Natural Killer Cells

These distinctive lymphocytes are believed to originate in bone marrow and belong to the natural killer cell lineage. They are the predominant population of leukocytes present in midluteal phase endometrium at the expected time of implantation (Johnson, 1999). These uNKs have a distinctive phenotype characterized by a high surface density of CD56 or neural cell adhesion molecule (Manaster, 2008; Moffett-King, 2002). Their infiltration is increased by progesterone and by stromal cell production of IL-15 and decidual prolactin (Dunn, 2002; Gubbay, 2002).

Near the end of the luteal phase of nonfertile ovulatory cycles, uterine NK cell nuclei begin to disintegrate. But if implantation proceeds, they persist in large numbers in the decidua during early pregnancy. By term, however, there are relatively few uNK cells in the decidua. In first-trimester decidua, there are many uNK cells in close proximity to extravillous trophoblast, where it is speculated that they serve to regulate trophoblast invasion. These uNK cells secrete large amounts of granulocyte-macrophage–colony-stimulating factor (GM-CSF), which suggests that they are in an activated state. Jokhi and coworkers (1999) speculate that GM-CSF may function primarily to forestall trophoblast apoptosis and not to promote trophoblast replication. Expression of angiogenic factors by uNK cells also suggests a function in decidual vascular remodeling (Li, 2001). In this case, it is uNKs, rather than the T lymphocytes, that are primarily responsible for decidual immunosurveillance.

THE AMNION

At term, the amnion is a tough and tenacious but pliable membrane. This innermost avascular fetal membrane is contiguous with amnionic fluid and occupies a role of incredible importance in human pregnancy. The amnion provides almost all tensile strength of the fetal membranes. Thus, its resilience to rupture is vitally important to successful pregnancy outcome. Indeed, preterm rupture of fetal membranes is a major cause of preterm delivery (Chap. 42, p. 839).

Bourne (1962) described five separate amnion layers. The inner surface, which is bathed by amnionic fluid, is an uninterrupted, single layer of cuboidal epithelium (Fig. 5-19). This epithelium is attached firmly to a distinct basement membrane that is connected to an acellular compact layer.
composed primarily of interstitial collagens. On the outer side of the compact layer, there is a row of fibroblast-like mesenchymal cells, which are widely dispersed at term. There also are a few fetal macrophages in the amnion. The outermost amnion layer is the relatively acellular zona spongiosa, which is contiguous with the second fetal membrane, the chorion laeve. The human amnion lacks smooth muscle cells, nerves, lymphatics, and importantly, blood vessels.

### Amnion Development

Early during implantation, a space develops between the embryonic cell mass and adjacent trophoblasts (see Fig. 5-9). Small cells that line this inner surface of trophoblasts have been called amniogenic cells—precursors of amnionic epithelium. The amnion is first identifiable the 7th or 8th day of embryo development. It is initially a minute vesicle, which then develops into a small sac that covers the dorsal embryo surface. As the amnion enlarges, it gradually engulfs the growing embryo, which prolapses into its cavity (Benirschke, 2012).

Distention of the amnionic sac eventually brings it into contact with the interior surface of the chorion laeve. Apposition of the chorion laeve and amnion near the end of the first trimester then causes an obliteration of the extraembryonic coelom. The amnion and chorion laeve, although slightly adhered, are never intimately connected and can be separated easily. Placental amnion covers the placenta surface and thereby is in contact with the adventitial surface of chorionic vessels. Umbilical amnion covers the umbilical cord. With diamnionic-monochorionic placentas, there is no intervening tissue between the fused amnions. In the conjoined portion of membranes of diaminonic-dichorionic twin placentas, fused amnions are separated by fused chorion laeve.
Amnion Cell Histogenesis

Epithelial cells of the amnion are thought to be derived from fetal ectoderm of the embryonic disc. They do not arise by delamination from trophoblasts. This is an important consideration from both embryological and functional perspectives. For example, HLA class I gene expression in amnion is more akin to that in embryonic cells than that in trophoblasts.

In contrast, the fibroblast-like mesenchymal cell layer previously described is likely derived from embryonic mesoderm. Early in human embryogenesis, the amnionic mesenchymal cells lie immediately adjacent to the basal surface of the amnion epithelium. At this time, the amnion surface is a two-cell layer with approximately equal numbers of epithelial and mesenchymal cells. Simultaneously with growth and development, interstitial collagens are deposited between these two cell layers. This marks formation of the amnion compact layer, which separates the two layers of amnion cells.

As the amnionic sac expands to line the placenta and then the chorion frondosum at 10 to 14 weeks, the compactness of the mesenchymal cells is progressively reduced and become sparsely distributed. Early in pregnancy, amnionic epithelium replicates at a rate appreciably faster than mesenchymal cells. At term, these cells form a continuous uninterrupted epithelium on the fetal amnionic surface. Conversely, mesenchymal cells are widely dispersed, being connected by a fine lattice network of extracellular matrix with the appearance of long slender fibrils.

Amnion Epithelial Cells.

The apical surface of the amnionic epithelium is replete with highly developed microvilli. This structure reflects its function as a major site of transfer between amnionic fluid and amnion. This epithelium is metabolically active, and its cells synthesize tissue inhibitor of MMP-1, prostaglandin E\(_2\) (PGE\(_2\)), and fetal fibronectin (fFN) (Rowe, 1997). In term pregnancies, amnionic expression of prostaglandin endoperoxide H synthase correlates with elevated fFN levels (Mijovic, 2000). Although epithelia produce fFN, recent studies suggest that fibronectin functions in the underlying mesenchymal cells. Here, fFN promotes synthesis of MMPs that break down the strength-bearing collagens and increases prostaglandin synthesis to prompt uterine contractions and cervical ripening (Mogami, 2013). This pathway is upregulated in premature rupture of membranes induced by infection.

Epithelial cells may respond to signals derived from the fetus or the mother, and they are responsive to various endocrine or paracrine modulators. Examples include oxytocin and vasopressin, both of which increase PGE\(_2\) production in vitro (Moore, 1988). They may also produce cytokines such as IL-8 during labor initiation (Elliott, 2001).

Amnionic epithelium also synthesizes vasoactive peptides, including endothelin and parathyroid hormone-related protein (Economos, 1992; Germain, 1992). The tissue produces brain natriuretic peptide (BNP) and corticotropin-releasing hormone (CRH), which are peptides that invoke smooth-muscle relaxation (Riley, 1991; Warren, 1995). BNP production is positively regulated by mechanical stretch in fetal membranes and is proposed to function in uterine quiescence. Epidermal growth factor, a negative regulator of BNP, is upregulated in the membranes at term and leads to a decline in BNP-regulated uterine quiescence (Carvajal, 2013). It seems reasonable that vasoactive peptides produced in amnion gain access to the adventitial surface of chorionic vessels. Thus, the amnion may be involved in modulating chorionic vessel tone and blood flow. Amnion-derived vasoactive peptides function in both maternal and fetal tissues in diverse physiological processes. After their secretion, these bioactive agents enter amnionic fluid and thereby are available to the fetus by swallowing and inhalation.

Amnion Mesenchymal Cells.

Mesenchymal cells of the amnionic fibroblast layer are responsible
for other major functions. Synthesis of interstitial collagens that compose the compact layer of the amnion—the major source of its tensile strength—takes place in mesenchymal cells (Casey, 1996). These cells also synthesize cytokines that include IL-6, IL-8, and monocyte chemoattractant protein-1. Cytokine synthesis increases in response to bacterial toxins and IL-1. This functional capacity of amnion mesenchymal cells is an important consideration in amnionic fluid study of labor-associated accumulation of inflammatory mediators (Garcia-Velasco, 1999). Finally, mesenchymal cells may be a greater source of PGE$_2$ than epithelial cells, in particular in the case of premature membrane rupture (Mogami, 2013; Whittle, 2000).

### Amnion Tensile Strength

During tests of tensile strength, the decidua and then the chorion laeve give way long before the amnion ruptures. Indeed, the membranes are elastic and can expand to twice normal size during pregnancy (Benirschke, 2012). The amnion tensile strength resides almost exclusively in the compact layer, which is composed of cross-linked interstitial collagens I and III and lesser amounts of collagens V and VI.

Collagens are the primary macromolecules of most connective tissues and are the most abundant proteins in the body. Collagen I is the major interstitial collagen in tissues characterized by great tensile strength, such as bone and tendon. In other tissues, collagen III is believed to contribute to tissue integrity and provides both tissue extensibility and tensile strength. For example, the ratio of collagen III to collagen I in the walls of a number of highly extensible tissues—amnionic sac, blood vessels, urinary bladder, bile ducts, intestine, and gravid uterus—is greater than that in nonelastic tissues (Jeffrey, 1991). Although collagen III provides some of the amnion extensibility, elastin microfibrils have also been identified (Bryant-Greenwood, 1998).

Amnion tensile strength is regulated in part by fibrillar collagen interacting with proteoglycans such as decorin, which promote tissue strength. Compositional changes at the time of labor include a decline in decorin and increase in hyaluronan. This leads to a loss of tensile strength and is further discussed in Chapter 42 (p. 840) (Meinert, 2007). Fetal membranes overlying the cervix have a reported regional decline in expression of matrix proteins such as fibulins. This change may contribute to tissue remodeling and tensile strength loss (Moore, 2009).

### Amnion Metabolic Functions

From the foregoing, it is apparent that the amnion is more than a simple avascular membrane that contains amnionic fluid. It is metabolically active, is involved in solute and water transport for amnionic fluid homeostasis, and produces an impressive array of bioactive compounds. The amnion is responsive both acutely and chronically to mechanical stretch, which alters amnionic gene expression (Carvajal, 2013; Nemeth, 2000). This in turn may trigger both autocrine and paracrine responses to include production of MMPs, IL-8, and collagenase (Bryant-Greenwood 1998; Maradny, 1996; Mogami, 2013). Such factors may modulate changes in membrane properties during labor.

### Amnionic Fluid

Until about 34 weeks’ gestation, the normally clear fluid that collects within the amnionic cavity increases as pregnancy progresses. After this, the volume declines. At term, the average volume is approximately 1000 mL, although this may vary widely in normal and especially abnormal...
conditions. The origin, composition, circulation, and function of amnionic fluid are discussed further in Chapter 11 (p. 231).

THE UMBILICAL CORD

Cord Development

The yolk sac and the umbilical vesicle into which it develops are prominent early in pregnancy. At first, the embryo is a flattened disc interposed between amnion and yolk sac. Its dorsal surface grows faster than the ventral surface, in association with the elongation of its neural tube. Thus, the embryo bulges into the amnionic sac, and the dorsal part of the yolk sac is incorporated into the embryo body to form the gut. The allantois projects into the base of the body stalk from the caudal wall of the yolk sac and later, from the anterior wall of the hindgut.

As pregnancy advances, the yolk sac becomes smaller and its pedicle relatively longer. By the middle of the third month, the expanding amnion obliterates the exocoelom, fuses with the chorion laeve, and covers the bulging placental disc and the lateral surface of the body stalk. The latter is then called the umbilical cord—or funis. A greater description of this cord and potential abnormalities is found in Chapter 6 (p. 121).

The cord at term normally has two arteries and one vein (Fig. 5-20). The right umbilical vein usually disappears early during fetal development, leaving only the original left vein. In sections of any portion of the cord near the center, the small duct of the umbilical vesicle can usually be seen. The vesicle is lined by a single layer of flattened or cuboidal epithelium. In sections just beyond the umbilicus, another duct representing the allantoic remnant is occasionally found. The intraabdominal portion of the duct of the umbilical vesicle, which extends from umbilicus to intestine, usually atrophies and disappears, but occasionally it remains patent, forming the Meckel diverticulum. The most common vascular anomaly is the absence of one umbilical artery, which may be associated with fetal anomalies (Chap. 6, p. 122).
Cord Function

The umbilical cord extends from the fetal umbilicus to the fetal surface of the placenta, that is, the chorionic plate. Blood flows from the umbilical vein and takes a path of least resistance via two routes within the fetus. One is the ductus venosus, which empties directly into the inferior vena cava (Fig. 7–8, p. 136). The other route consists of numerous smaller openings into the hepatic circulation. Blood from the liver flows into the inferior vena cava via the hepatic vein. Resistance in the ductus venosus is controlled by a sphincter that is situated at the origin of the ductus at the umbilical recess and is innervated by a vagus nerve branch.

Blood exits the fetus via the two umbilical arteries. These are anterior branches of the internal iliac artery and become obliterated after birth. Remnants can be seen as the medial umbilical ligaments.

PLACENTAL HORMONES

The production of steroid and protein hormones by human trophoblasts is greater in amount and diversity than that of any single endocrine tissue in all of mammalian physiology. A compendium of average production rates for various steroid hormones in nonpregnant and in near-term pregnant women is given in Table 5-1. It is apparent that alterations in steroid hormone production that
accompany normal human pregnancy are incredible. The human placenta also synthesizes an enormous amount of protein and peptide hormones as summarized in Table 5-2. It is understandable, therefore, that yet another remarkable feature of human pregnancy is the successful physiological adaptations of pregnant women to the unique endocrine milieu as discussed throughout Chapter 4 (p. 46).

\(^a\) Estrogens and progesterone are produced by placenta. Aldosterone is produced by the maternal adrenal in response to the stimulus of angiotensin II. Deoxycorticosterone is produced in extraglandular tissue sites by way of the 21-hydroxylation of plasma progesterone. Cortisol production during pregnancy is not increased, even though the blood levels are elevated because of decreased clearance caused by increased cortisol-binding globulin.

### TABLE 5-2. Protein Hormones Produced by the Human Placenta
**Human Chorionic Gonadotropin**

This so-called pregnancy hormone is a glycoprotein with biological activity similar to luteinizing hormone. Both act via the same plasma membrane LH-hCG receptor. Although hCG is produced almost exclusively in the placenta, low levels are synthesized in the fetal kidney. Other fetal tissues produce either the β-subunit or intact hCG molecule (McGregor, 1981, 1983).

Various malignant tumors also produce hCG, sometimes in large amounts—especially
trophoblastic neoplasms (Chap. 20, p. 396). Chorionic gonadotropin is produced in very small amounts in tissues of men and nonpregnant women, perhaps primarily in the anterior pituitary gland. Nonetheless, the detection of hCG in blood or urine almost always indicates pregnancy (Chap. 9, p. 169).

**Chemical Characteristics**

Chorionic gonadotropin is a glycoprotein with a molecular weight of 36,000 to 40,000 Da. It has the highest carbohydrate content of any human hormone—30 percent. The carbohydrate component, and especially the terminal sialic acid, protects the molecule from catabolism. The 36-hour plasma half-life of intact hCG is much longer than the 2 hours for LH. The hCG molecule is composed of two dissimilar subunits termed α and β subunits. These are noncovalently linked and are held together by electrostatic and hydrophobic forces. Isolated subunits are unable to bind the LH-hCG receptor and thus lack biological activity.

This hormone is structurally related to three other glycoprotein hormones—LH, FSH, and TSH. All four glycoproteins share a common α-subunit. The β-subunits, although sharing certain similarities, are characterized by distinctly different amino-acid sequences. Recombination of an α- and a β-subunit of the four glycoprotein hormones gives a molecule with biological activity characteristic of the hormone from which the β-subunit was derived.

**Biosynthesis**

Syntheses of the α- and β-chains of hCG are regulated separately. A single gene located on chromosome 6 encodes the α-subunit common to hCG, LH, FSH, and TSH. Seven genes on chromosome 19 encode for the β-hCG–β-LH family of subunits. Six genes code for β-hCG and one for β-LH (Miller-Lindholm, 1997). Both subunits are synthesized as larger precursors, which are then cleaved by endopeptidases. Intact hCG is then assembled and rapidly released by secretory granule exocytosis (Morrish, 1987). There are multiple forms of hCG in maternal plasma and urine that vary enormously in bioactivity and immunoreactivity. Some result from enzymatic degradation, and others from modifications during molecular synthesis and processing.

Before 5 weeks, hCG is expressed in both syncytiotrophoblast and cytotrophoblast (Maruo, 1992). Later, in the first trimester when maternal serum levels peak, hCG is produced almost solely in the syncytiotrophoblast (Beck, 1986; Kurman, 1984). At this time, mRNA concentrations of both α- and β-subunits in the syncytiotrophoblast are greater than at term (Hoshina, 1982). This may be an important consideration when hCG is used as a screening procedure to identify abnormal fetuses.

Circulating free β-subunit levels are low to undetectable throughout pregnancy. In part, this is the result of its rate-limiting synthesis. Free α-subunits that do not combine with the β-subunit are found in placental tissue and maternal plasma. These levels increase gradually and steadily until they plateau at about 36 weeks’ gestation. At this time, they account for 30 to 50 percent of hormone (Cole, 1997). Thus, α-hCG secretion roughly corresponds to placental mass, whereas secretion of complete hCG molecules is maximal at 8 to 10 weeks.

**Concentrations of hCG in Serum and Urine**

The combined hCG molecule is detectable in plasma of pregnant women 7 to 9 days after the midcycle surge of LH that precedes ovulation. Thus, hCG likely enters maternal blood at the time of blastocyst implantation. Plasma levels increase rapidly, doubling every 2 days in the first trimester (Fig. 5-21). Appreciable fluctuations in levels for a given patient are observed on the
same day—evidence that trophoblast secretion of protein hormones is episodic.

FIGURE 5-21 Distinct profiles for the concentrations of human chorionic gonadotropin (hCG), human placental lactogen (hPL), and corticotropin-releasing hormone (CRH) in serum of women throughout normal pregnancy.

Intact hCG circulates as multiple highly related isoforms with variable cross-reactivity between commercial assays. Thus, there is considerable variation in calculated serum hCG levels among the more than a hundred available assays. Peak maternal plasma levels reach approximately 100,000 mIU/mL between the 60th and 80th days after menses. At 10 to 12 weeks, plasma levels begin to decline, and a nadir is reached by approximately 16 weeks. Plasma levels are maintained at this lower level for the remainder of pregnancy (see Fig. 5-21).

The pattern of hCG appearance in fetal blood is similar to that in the mother. Fetal plasma levels, however, are only about 3 percent of those in maternal plasma. Amnionic fluid hCG concentration early in pregnancy is similar to that in maternal plasma. As pregnancy progresses, hCG concentration in amnionic fluid declines, and near term the levels are approximately 20 percent of those in maternal plasma.

Maternal urine contains the same variety of hCG degradation products as maternal plasma. The principal urinary form is the terminal degradation hCG product—the \( \beta \)-core fragment. Its concentrations follow the same general pattern as that in maternal plasma, peaking at about 10 weeks. It is important to recognize that the so-called \( \beta \)-subunit antibody used in most pregnancy tests reacts with both intact hCG—the major form in the plasma, and with fragments of hCG—the major forms found in urine.

**Regulation of hCG Synthesis and Clearance**

Placental gonadotropin-releasing hormone (GnRH) is likely involved in the regulation of hCG formation. Both GnRH and its receptor are expressed by cytotrophoblasts and syncytiotrophoblas (Wolfgangt, 1998). GnRH administration elevates circulating hCG levels, and cultured trophoblasts cells respond to GnRH treatment with increased hCG secretion (Iwashita, 1993; Siler-Khodr 1981). Pituitary GnRH production also is regulated by inhibin and activin. In cultured placenta
cells, activin stimulates and inhibin inhibits GnRH and hCG production (Petraglia, 1989; Steele, 1993).

Renal clearance of hCG accounts for 30 percent of its metabolic clearance. The remainder is likely cleared by metabolism in the liver (Wehmann, 1980). Clearances of β- and α-subunits are approximately 10-fold and 30-fold, respectively, greater than that of intact hCG.

Biological Functions of hCG

Both hCG subunits are required for binding to the LH-hCG receptor in the corpus luteum and the fetal testis. LH-hCG receptors are present in various other tissues, but their role there is less defined. The best-known biological function of hCG is the so-called rescue and maintenance of corpus luteum function—that is, continued progesterone production. Bradbury and colleagues (1950) found that the progesterone-producing life span of a corpus luteum of menstruation could be prolonged perhaps for 2 weeks by hCG administration. This is only an incomplete explanation for the physiological function of hCG in pregnancy. For example, maximum plasma hCG concentrations are attained well after hCG-stimulated corpus luteum secretion of progesterone has ceased. Specifically, progesterone luteal synthesis begins to decline at about 6 weeks despite continued and increasing hCG production.

A second hCG role is stimulation of fetal testicular testosterone secretion, which is maximum approximately when hCG levels peak. Thus, at a critical time in male sexual differentiation, hCG enters fetal plasma from the syncytiotrophoblast. In the fetus, it acts as an LH surrogate to stimulate Leydig cell replication and testosterone synthesis to promote male sexual differentiation (Chap. 7, p. 148). Before approximately 110 days, there is no vascularization of the fetal anterior pituitary from the hypothalamus. Thus, pituitary LH secretion is minimal, and hCG acts as LH before this time. Thereafter, as hCG levels fall, pituitary LH maintains modest testicular stimulation.

The maternal thyroid gland is also stimulated by large quantities of hCG. In some women with gestational trophoblastic disease, biochemical and clinical evidence of hyperthyroidism sometimes develops (Chap. 20, p. 399). This once was attributed to formation of chorionic thyrotropins by neoplastic trophoblasts. It was subsequently shown, however, that some forms of hCG bind to TSH receptors on thyrocytes (Hershman, 1999). And treatment of men with exogenous hCG increases thyroid activity. The thyroid-stimulatory activity in plasma of first-trimester pregnant women varies appreciably from sample to sample. Modifications of hCG oligosaccharides likely are important in the capacity of hCG to stimulate thyroid function. For example, acidic isoforms stimulate thyroid activity, and some more basic isoforms stimulate iodine uptake (Kraiem, 1994; Tsuruta, 1995; Yoshimura, 1994). Finally, the LH-hCG receptor is expressed by thyrocytes, which suggests that hCG stimulates thyroid activity via the LH-hCG receptor as well as by the TSH receptor (Tomer, 1992).

Other hCG functions include promotion of relaxin secretion by the corpus luteum (Duffy, 1996). LH-hCG receptors are found in myometrium and in uterine vascular tissue. It has been hypothesized that hCG may promote uterine vascular vasodilation and myometrial smooth-muscle relaxation (Kurtzman, 2001). Chorionic gonadotropin also regulates expansion of uterine natural killer cell numbers during early stages of placentation, thus ensuring appropriate establishment of pregnancy (Kane, 2009).

Abnormally High or Low hCG Levels

There are several clinical circumstances in which substantially higher maternal plasma hCG levels are found. Some examples are multifetal pregnancy, erythroblastosis fetalis associated with
fetal hemolytic anemia, and gestational trophoblastic disease. Relatively higher hCG levels may be found at midtrimester in women carrying a fetus with Down syndrome—an observation used in biochemical screening tests (Chap. 14, p. 290). The reason for this is not clear, but reduced placental maturity has been speculated. Relatively lower hCG plasma levels are found in women with early pregnancy wastage, including ectopic pregnancy (Chap. 19, p. 381).

**Human Placental Lactogen**

Prolactin-like activity in the human placenta was first described by Ehrhardt (1936). Because of its potent lactogenic and growth hormone-like bioactivity, as well as an immunochemical resemblance to human growth hormone (hGH), it was called human placental lactogen or chorionic growth hormone. Currently, human placental lactogen is used by most.

Grumbach and Kaplan (1964) showed that this hormone, like hCG, was concentrated in syncytiotrophoblast. It is detected as early as the second or third week after fertilization. Also similar to hCG, hPL is demonstrated in cytotrophoblasts before 6 weeks (Maruo, 1992).

**Chemical Characteristics and Synthesis**

Human placental lactogen is a single, nonglycosylated polypeptide chain with a molecular weight of 22,279 Da. It is derived from a 25,000-Da precursor. The sequence of hPL and hGH is strikingly similar, with 96-percent homology. Also, hPL is structurally similar to human prolactin (hPRL), with a 67-percent amino-acid sequence similarity. For these reasons, it has been suggested that the genes for hPL, hPRL, and hGH evolved from a common ancestral gene—probably that for prolactin—by repeated gene duplication (Ogren, 1994).

There are five genes in the growth hormone–placental lactogen gene cluster that are linked and located on chromosome 17. Two of these—hPL2 and hPL3—encode hPL, and the amount of mRNA in the term placenta is similar for each.

Within 5 to 10 days after conception, hPL is demonstrable in the placenta and can be detected in maternal serum as early as 3 weeks. Maternal plasma concentrations are linked to placental mass, and they rise steadily until 34 to 36 weeks’ gestation. The hPL production rate near term—approximately 1 g/day—is by far the greatest of any known hormone in humans. The half-life of hPL in maternal plasma is between 10 and 30 minutes (Walker, 1991). In late pregnancy, maternal serum concentrations reach levels of 5 to 15 μg/mL (see Fig. 5-21).

Very little hPL is detected in fetal blood or in the urine of the mother or newborn. Amnionic fluid levels are somewhat lower than in maternal plasma. Because hPL is secreted primarily into the maternal circulation, with only very small amounts in cord blood, it appears that its role in pregnancy is mediated through actions in maternal rather than in fetal tissues. Nonetheless, there is continuing interest in the possibility that hPL serves select functions in fetal growth.

**Regulation of hPL Biosynthesis**

Levels of mRNA for hPL in syncytiotrophoblast remain relatively constant throughout pregnancy. This finding supports the idea that the hPL secretion rate is proportional to placental mass. There are very high plasma levels of hCG in women with trophoblastic neoplasms, but only low levels of hPL in these same women.

Prolonged maternal starvation in the first half of pregnancy leads to increased hPL plasma concentrations. Short-term changes in plasma glucose or insulin, however, have relatively little effect on plasma hPL levels. In vitro studies of syncytiotrophoblast suggest that hPL synthesis is
stimulated by insulin and insulin-like growth factor-1 and inhibited by PGE\textsubscript{2} and PGF\textsubscript{2α} (Bhaumick, 1987; Genbacev, 1977).

**Metabolic Actions**

Placental lactogen has putative actions in several important metabolic processes. First, hPL promotes maternal lipolysis with increased circulating free fatty acid levels. This provides an energy source for maternal metabolism and fetal nutrition. In vitro studies suggest that hPL inhibits leptin secretion by term trophoblast (Coya, 2005).

Second, hPL may aid maternal adaptation to fetal energy requirements. For example, increased maternal insulin resistance ensures nutrient flow to the fetus. It also favors protein synthesis and provides a readily available amino-acid source to the fetus. To counterbalance the increased insulin resistance and prevent maternal hyperglycemia, maternal insulin levels are increased. Both hPL and prolactin signal through the prolactin receptor to increase maternal beta cell proliferation to augment insulin secretion (Georgia, 2010). Recent animal studies provide insight into the mechanism by which lactogenic hormones drive beta cell expansion. Specifically, prolactin and hPL upregulate serotonin synthesis via regulation of the rate-limiting enzyme, tryptophan hydroxylase-1, which in turn increases beta cell proliferation (Kim, 2010).

Last, hPL is a potent angiogenic hormone. It may serve an important function in fetal vasculature formation (Corbacho, 2002).

**Other Placental Protein Hormones**

The placenta has a remarkable capacity to synthesize numerous peptide hormones, including some that are analogous or related to hypothalamic and pituitary hormones. In contrast to their counterparts, the placental peptide/protein hormones are not subject to feedback inhibition. Examples include pro-opiomelanocortin-derived peptides, growth hormone variant V, and gonadotropin-releasing hormone.

**Chorionic Adrenocorticotropin**

Adrenocorticotropic hormone (ACTH), lipotropin, and β-endorphin—all proteolytic products of pro-opiomelanocortin—are recovered from placental extracts (Genazzani, 1975; Odagiri, 1979). The physiological action of placental ACTH is unclear. Placental corticotropin-releasing hormone stimulates synthesis and release of chorionic ACTH. Placental CRH production is positively regulated by cortisol, producing a novel positive feedback loop. As discussed later, this system may be important for controlling fetal lung maturation and parturition timing.

**Growth Hormone Variant**

The placenta expresses a growth hormone variant (hGH-V) that is not expressed in the pituitary. The gene encoding hGH-V is located in the hGH–hPL gene cluster on chromosome 17. Sometimes referred to as placental growth hormone, hGH-V is a 191 amino-acid protein that differs in 15 amino-acid positions from the sequence for hGH. Although hGH-V retains growth-promoting and antilipogenic functions similar to hGH, it has reduced diabetogenic and lactogenic functions relative to hGH (Vickers, 2009). Placental hGH-V presumably is synthesized in the syncytiotrophoblast. However, its pattern of synthesis and secretion during gestation is not precisely known because antibodies against hGH-V cross-react with hGH. It is believed that hGH-V is present in maternal plasma by 21 to 26 weeks’ gestation, increases in concentration until approximately 36 weeks, and
remains relatively constant thereafter. There is a correlation between the levels of hGH-V in maternal plasma and those of insulin-like growth factor-1. Also, hGH-V secretion by trophoblasts in vitro is inhibited by glucose in a dose-dependent manner (Patel, 1995). Overexpression of hGH-V in mice causes severe insulin resistance, and thus it is a likely candidate to mediate insulin resistance of pregnancy (Barbour, 2002).

**Hypothalamic-Like Releasing Hormones**

The known hypothalamic-releasing or -inhibiting hormones include GnRH, CRH, thyroid-releasing hormone (TRH), growth hormone-releasing hormone (GHRH), and somatostatin. For each, there is an analogous hormone produced in the human placenta (Petraglia, 1992; Siler-Khodr, 1988). Many investigators suggest this indicates a hierarchy of control in chorionic trophic-agent synthesis.

**Gonadotropin-Releasing Hormone.** There is a reasonably large amount of immunoreactive GnRH in the placenta (Siler-Khodr, 1978, 1988). Interestingly, it is found in cytotrophoblasts, but not syncytiotrophoblast. Gibbons and coworkers (1975) and Khodr and Siler-Khodr (1980) demonstrated that the human placenta could synthesize both GnRH and TRH in vitro. Placental-derived GnRH functions to regulate trophoblast hCG production, hence the observation that GnRH levels are higher early in pregnancy. Placental-derived GnRH is also the likely cause of elevated maternal GnRH levels in pregnancy (Siler-Khodr, 1984).

**Corticotropin-Releasing Hormone.** This hormone is a member of a larger family of CRH-related peptides that includes CRH, urocortin, urocortin II, and urocortin III (Dautzenberg, 2002). Maternal serum CRH levels increase from 5 to 10 pmol/L in the nonpregnant woman to approximately 100 pmol/L in the early third trimester of pregnancy and to almost 500 pmol/L abruptly during the last 5 to 6 weeks (see Fig. 5-21). Urocortin also is produced by the placenta and secreted into the maternal circulation, but at much lower levels than seen for CRH (Florio, 2002). After labor begins, maternal plasma CRH levels increase further by two- to threefold (Petraglia, 1989, 1990). The biological function of CRH synthesized in the placenta, membranes, and decidua has been somewhat defined. CRH receptors are present in many tissues: placenta, adrenal gland, sympathetic ganglia, lymphocytes, gastrointestinal tract, pancreas, gonads, and myometrium. Some findings suggest that CRH can act through two major families—the type 1 and type 2 CRF receptors (CRH-R1 and CRH-R2). Trophoblast, amniochorion, and decidua express both CRH-R and CRH-R2 receptors and several variant receptors (Florio, 2000). Both CRH and urocortins increase trophoblast ACTH secretion, supporting an autocrine-paracrine role (Petraglia, 1999). Large amounts of trophoblast CRH enter maternal blood. That said, there also is a large concentration of a specific CRH-binding protein in maternal plasma, and the bound CRH seems to be biologically inactive.

Other proposed biological roles include induction of smooth-muscle relaxation in vascular and myometrial tissue and immunosuppression. The physiological reverse, however, induction of myometrial contractions, has been proposed for the rising CRH levels seen near term. One hypothesis suggests that CRH may be involved with parturition initiation (Wadhwa, 1998). Prostaglandin formation in the placenta, amnion, chorion laeve, and decidua is increased with CRH treatment (Jones, 1989b). This latter observation further supports a potential action in parturition timing.

Glucocorticoids act in the hypothalamus to inhibit CRH release, but in the trophoblast glucocorticoids stimulate CRH gene expression (Jones, 1989a; Robinson, 1988). Thus, there ma
be a novel positive feedback loop in the placenta by which placental CRH stimulates placental ACTH to stimulate fetal and maternal adrenal glucocorticoid production with subsequent stimulation of placental CRH expression (Nicholson, 2001; Riley, 1991).

### Growth Hormone-Releasing Hormone

The role of placental GHRH is not known (Berry, 1992). Ghrelin is another regulator of hGH secretion that is produced by placental tissue (Horvath, 2001). Trophoblast ghrelin expression peaks at midpregnancy and is a potential regulator of hGH-V production or a paracrine regulator of differentiation (Fuglsang, 2005; Gualillo, 2001).

### Other Placental Protein Hormones

#### Relaxin

Expression of relaxin has been demonstrated in human corpus luteum, decidua, and placenta (Bogic, 1995). This peptide is synthesized as a single, 105 amino-acid preprorelaxin molecule that is cleaved to A and B molecules. Relaxin is structurally similar to insulin and insulin-like growth factor. Two of the three relaxin genes—H2 and H3—are transcribed in the corpus luteum (Bathgate, 2002; Hudson, 1983, 1984). Other tissues, including decidua, placenta, and membranes express H1 and H2 (Hansell, 1991).

The rise in maternal circulating relaxin levels seen in early pregnancy is attributed to corpus luteum secretion, and levels parallel those of hCG. Relaxin, along with rising progesterone levels, may act on myometrium to promote relaxation and the quiescence of early pregnancy (Chap. 21, p. 421). In addition, the production of relaxin and relaxin-like factors within the placenta and fetal membranes may play an autocrine-paracrine role in postpartum regulation of extracellular matrix degradation (Qin, 1997a,b). One important relaxin function is enhancement of the glomerular filtration rate (Chap. 4, p. 64).

#### Parathyroid Hormone–Related Protein

In pregnancy, circulating parathyroid hormone-related protein (PTH-rP) levels are significantly elevated within maternal but not fetal circulation (Bertelloni, 1994; Saxe, 1997). Many potential functions of this hormone have been proposed. PTH-rP synthesis is found in several normal adult tissues, especially in reproductive organs that include myometrium, endometrium, corpus luteum, and lactating mammary tissue. PTH-rP is not produced in the parathyroid glands of normal adults. Based on insights from parathyroid hormone-related protein null mice, placental-derived PTH-rP may have an important function to regulate genes involved in transfer of calcium and other solutes. It also contributes to fetal mineral homeostasis in bone, amnionic fluid, and the fetal circulation (Simmonds, 2010).

#### Leptin

This hormone is normally secreted by adipocytes. It functions as an antiobesity hormone that decreases food intake through its hypothalamic receptor. It also regulates bone growth and immune function (Cock, 2003; La Cava, 2004). In the placenta, leptin also is synthesized by both cytotrophoblast and syncytiotrophoblast (Henson, 2002). Relative contributions of leptin from maternal adipose tissue versus placenta are currently not well defined. Maternal serum levels are significantly higher than those in nonpregnant women. Fetal leptin levels correlate positively with birthweight and likely play an important function in fetal development and growth. Studies suggest that leptin inhibits apoptosis and promotes trophoblast proliferation (Magarinos, 2007).
Neuropeptide Y
This 36 amino-acid peptide is widely distributed in brain. It also is found in sympathetic neurons innervating the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. Neuropeptide Y has been isolated from the placenta and localized in cytotrophoblasts (Petraglia, 1989). There are receptors for neuropeptide Y on trophoblast, and treatment of placental cells with neuropeptide Y causes CRH release (Robidoux, 2000).

Inhibin and Activin
Inhibin is a glycoprotein hormone that acts preferentially to inhibit pituitary FSH release. It is produced by human testis and by ovarian granulosa cells, including the corpus luteum. Inhibin is a heterodimer made up of an α-subunit and one of two distinct β-subunits, βA or βB. All three are produced by trophoblast, and maternal serum levels peak at term (Petraglia, 1991). One function may be to act in concert with the large amounts of sex steroid hormones to inhibit FSH secretion and thereby inhibit ovulation during pregnancy. Inhibin may act via GnRH to regulate placental hCG synthesis (Petraglia, 1987).

Activin is closely related to inhibin and is formed by the combination of the two β-subunits. Its receptor is expressed in the placenta and amnion. Activin A is not detectable in fetal blood before labor but is present in umbilical cord blood after labor begins. Petraglia (1994) found that serum activin A levels decline rapidly after delivery. It is not clear if chorionic activin and inhibin are involved in placental metabolic processes other than GnRH synthesis.

Placental Progesterone Production
After 6 to 7 weeks’ gestation, little progesterone is produced in the ovary (Diczfalussy, 1961). Surgical removal of the corpus luteum or even bilateral oophorectomy during the 7th to 10th week does not decrease excretion rates of urinary pregnanediol, the principal urinary metabolite of progesterone. Before this time, however, corpus luteum removal will result in spontaneous abortion unless an exogenous progestin is given (Chap. 63, p. 1227). After approximately 8 weeks, the placenta assumes progesterone secretion, resulting in a gradual increase in maternal serum levels throughout pregnancy (Fig. 5-22). By term, these levels are 10 to 5000 times those found in nonpregnant women, depending on the stage of the ovarian cycle.
**FIGURE 5-22** Plasma levels of progesterone, estradiol, estrone, estetrol, and estriol in women during the course of gestation. (Modified from Mesiano, 2009, with permission.)

**Progesterone Production Rates**

The daily production rate of progesterone in late, normal, singleton pregnancies is approximately 250 mg. In multifetal pregnancies, the daily production rate may exceed 600 mg/day. Progesterone is synthesized from cholesterol in a two-step enzymatic reaction. First, cholesterol is converted to pregnenolone within the mitochondria, in a reaction catalyzed by cytochrome P<sub>450</sub> cholesterol side-chain cleavage enzyme. Pregnenolone leaves the mitochondria and is converted to progesterone in the endoplasmic reticulum by 3β-hydroxysteroid dehydrogenase. Progesterone is released immediately through a process of diffusion.

Although the placenta produces a prodigious amount of progesterone, there is limited capacity for trophoblast cholesterol biosynthesis. Radiolabeled acetate is incorporated into cholesterol by placental tissue at a slow rate. The rate-limiting enzyme in cholesterol biosynthesis is 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase. Because of this, the placenta must rely on
exogenous cholesterol for progesterone formation. Bloch (1945) and Werbin and colleagues (1957) found that after intravenous administration of radiolabeled cholesterol to pregnant women, the amount of radioactivity of urinary pregnanediol was similar to that of plasma cholesterol. Hellig and associates (1970) also found that maternal plasma cholesterol was the principal precursor—as much as 90 percent—of progesterone biosynthesis. The trophoblast preferentially uses LDL cholesterol for progesterone biosynthesis (Simpson, 1979, 1980). In studies of pregnant baboons, when maternal serum LDL levels were reduced, there was a significant drop in placental progesterone production (Henson, 1997). Thus, placental progesterone is formed through the uptake and use of a maternal circulating precursor. This mechanism is unlike the placental production of estrogens, which relies principally on fetal adrenal precursors.

**Progesterone Synthesis and Fetal Relationships**

Although there is a relationship between fetal well-being and placental estrogen production, this is not the case for placental progesterone. Fetal demise, ligation of the umbilical cord with the fetus and placenta remaining in situ, and anencephaly are all conditions associated with very low maternal plasma levels and low urinary excretion of estrogens. In these circumstances, there is not a concomitant decrease in progesterone levels until some indeterminate time after fetal death. Thus, placental endocrine function, including the formation of protein hormones such as hCG and progesterone biosynthesis, may persist for long periods (weeks) after fetal demise.

**Progesterone Metabolism During Pregnancy**

The metabolic clearance rate of progesterone in pregnant women is similar to that found in men and nonpregnant women. During pregnancy, the plasma concentration of 5α-dihydroprogesterone disproportionately increases due to synthesis in syncytiotrophoblast from both placenta-produced progesterone and fetal-derived precursor (Dombroski, 1997). Thus, the concentration ratio of this progesterone metabolite to progesterone is increased in pregnancy. The mechanisms for this are not defined completely. Progesterone also is converted to the potent mineralocorticoid deoxycorticosterone in pregnant women and in the fetus. The concentration of deoxycorticosterone is increased strikingly in both maternal and fetal compartments (see Table 5-1). The extraadrenal formation of deoxycorticosterone from circulating progesterone accounts for most of its production in pregnancy (Casey, 1982a,b).

**Placental Estrogen Production**

The placenta produces huge amounts of estrogens using blood-borne steroidal precursors from the maternal and fetal adrenal glands. Near term, normal human pregnancy is a hyperestrogenic state. The amount of estrogen produced each day by syncytiotrophoblast during the last few weeks of pregnancy is equivalent to that produced in 1 day by the ovaries of no fewer than 1000 ovulatory women. The hyperestrogenic state of human pregnancy is one of continually increasing magnitude as pregnancy progresses, terminating abruptly after delivery.

During the first 2 to 4 weeks of pregnancy, rising hCG levels maintain production of estradiol in the maternal corpus luteum. Production of both progesterone and estrogens in the maternal ovaries decreases significantly by the 7th week of pregnancy. At this time, there is a luteal-placental transition. By the 7th week, more than half of estrogen entering maternal circulation is produced in the placenta (MacDonald, 1965a; Siiteri, 1963, 1966). These studies support the transition of a steroid milieu dependent on the maternal corpus luteum to one dependent on the developing placenta.
Placental Estrogen Biosynthesis

The estrogen synthesis pathways in the placenta differ from those in the ovary of nonpregnant women. Estrogen is produced during the follicular and luteal phases through the interaction of theca and granulosa cells that surround the follicles. Specifically, androstenedione is synthesized in ovarian theca cells and then is transferred to adjacent granulosa cells for estradiol synthesis. Estradiol production within the corpus luteum of nonpregnant women and in early pregnancy continues to require interaction between the luteinized theca and granulosa cells. However, in human trophoblast, neither cholesterol nor progesterone can serve as precursor for estrogen biosynthesis. A crucial enzyme necessary for sex steroid synthesis—steroid 17α-hydroxylase/17,20-lyase (CYP17)—is not expressed in the human placenta. Consequently, the conversion of C_{21}-steroids to C_{19}-steroids—the latter being the immediate and obligatory precursors of estrogens—is not possible.

Dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S) are C_{19}-steroids. Although these are often called adrenal androgens, these steroids can also serve as estrogen precursors (Fig. 5-23). Ryan (1959a) found that the placenta had an exceptionally high capacity to convert appropriate C_{19}-steroids to estrone and estradiol. The conversion of DHEA-S to estradiol requires placental expression of four key enzymes that are located principally in syncytiotrophoblast (Bonenfant, 2000; Salido, 1990). First, the placenta expresses high levels of steroid sulfatase (STS), which converts the conjugated DHEA-S to DHEA. DHEA is then acted upon by 3β-hydroxysteroid dehydrogenase type 1 (3βHSD) to produce androstenedione. Cytochrome P_{450} aromatase (CYP19) then converts androstenedione to estrone, which is then converted to estradiol by 17β-hydroxysteroid dehydrogenase type 1 (17βHSD1).
FIGURE 5-23 Schematic presentation of estrogen biosynthesis in the human placenta. Dehydroepiandrosterone sulfate (DHEA-S), secreted in prodigious amounts by the fetal adrenal glands, is converted to 16α-hydroxydehydroepiandrosterone sulfate (16αOHDHEA-S) in the fetal liver. These steroids, DHEA-S and 16αOHDHEA-S, are converted in the placenta to estrogens, that is, 17β-estradiol (E_2) and estriol (E_3). Near term, half of E_2 is derived from fetal adrenal DHEA-S and half from maternal DHEA-S. On the other hand, 90 percent of E_3 in the placenta arises from fetal 16αOHDHEA-S and only 10 percent from all other sources.

Plasma C_{19}-Steroids as Estrogen Precursors
Frandsen and Stakemann (1961) found that urinary estrogens levels in women pregnant with ar
Anencephalic fetuses were only about 10 percent of that found in normal pregnancy. The adrenal glands of anencephalic fetuses are atrophic because of absent hypothalamic-pituitary function, which precludes ACTH stimulation. Thus, it seemed reasonable that fetal adrenal glands might provide substance(s) used for placental estrogen formation.

In subsequent studies, DHEA-S was found to be a major precursor of estrogens in pregnancy (Baulieu, 1963; Siiteri, 1963). The large amounts of DHEA-S in plasma and its much longer half life uniquely qualify it as the principal precursor for placental estradiol synthesis. There is a 10- to 20-fold increased metabolic clearance rate of plasma DHEA-S in women at term compared with that in men and nonpregnant women (Gant, 1971). This rapid use results in a progressive decrease in plasma DHEA-S concentration as pregnancy progresses (Milewich, 1978). However, maternal adrenal glands do not produce sufficient amounts of DHEA-S to account for more than a fraction of total placental estrogen biosynthesis. The fetal adrenal glands are quantitatively the most important source of placental estrogen precursors in human pregnancy. A schematic representation of the estrogen formation pathways in the placenta is presented in Figure 5-23. As shown, the estrogen products released from the placenta are dependent on the substrate available. Thus, estrogen production during pregnancy reflects the unique interactions among fetal adrenal glands, fetal liver, placenta, and maternal adrenal glands.

**Directional Secretion of Steroids from Syncytiotrophoblast**

More than 90 percent of estradiol and estriol formed in syncytiotrophoblast as shown in Table 5-1 enters maternal plasma (Gurpide, 1966). And 85 percent or more of placental progesterone enters maternal plasma, with little maternal progesterone crossing the placenta to the fetus (Gurpide, 1972).

The major reason for directional movement of newly formed steroid into the maternal circulation is the nature of hemochorioendothelial placentation. In this system, steroids secreted from syncytiotrophoblast can enter maternal blood directly. Steroids that leave the syncytiotrophoblast do not enter fetal blood directly. They must first traverse the cytotrophoblasts and then enter the stroma of the villous core and then fetal capillaries. From either of these spaces, steroids can reenter the syncytiotrophoblast. The net result of this hemochorial arrangement is that there is substantially greater entry of steroids into the maternal circulation compared with the amount that enters fetal blood.

**FETAL ADRENAL GLAND–PLACENTAL INTERACTIONS**

Morphologically, functionally, and physiologically, the fetal adrenal glands are remarkable organs. At term, the fetal adrenal glands weigh the same as those of the adult. More than 85 percent of the fetal gland is composed of a unique fetal zone, which has a great capacity for steroid biosynthesis. Daily steroid production of fetal adrenal glands near term is 100 to 200 mg/day. This compares with resting adult steroid secretion of 30 to 40 mg/day.

The fetal zone is lost in the first year of life and is not present in the adult. In addition to ACTH fetal adrenal gland growth is influenced by factors secreted by the placenta. This is exemplified by the continued growth of the fetal glands throughout gestation, but rapid involution immediately after birth when placenta-derived factors dissipate. A discussion of the fetal adrenal and liver is warranted in this chapter, given the dependence of normal placental function on the unique fetal adrenal and vice versa.
Placental Estriol Synthesis

The estrogen products released from the placenta are dependent on the substrate available from the developing fetus. Estradiol is the primary placental estrogen secretory product at term. In addition, significant levels of estriol and estetrol are found in the maternal circulation, and they increase, particularly late in gestation (see Fig. 5-22). These hydroxylated forms of estrogen are produced in the placenta using substrates formed by the combined efforts of the fetal adrenal gland and liver.

There are important fetal-maternal interactions through the fetal liver (see Fig. 5-23). High levels of fetal hepatic 16α-hydroxylase act on adrenal-derived steroids. Ryan (1959b) and MacDonald and Siiteri (1965b) found that 16α-hydroxylated C_{19}-steroids, particularly 16α-hydroxydehydroepiandrosterone (16-OHDHEA), were converted to estriol by placental tissue. Thus, the disproportionate increase in estriol formation during pregnancy is accounted for by placental synthesis of estriol primarily from plasma-borne 16-OHDHEA-sulfate. Near term, the fetus is the source of 90 percent of placental estriol and estetrol precursor in normal human pregnancy.

Thus, the placenta secretes several estrogens, including estradiol, estrone, estriol, and estetrol. Because of its hemochorial nature, most placental estrogens are released into the maternal circulation. Maternal estriol and estetrol are produced almost solely by fetal steroid precursors. Thus, levels of these steroids were used in the past as an indicator of fetal well-being. However, low sensitivity and specificity of such tests have caused them to be discarded.

Enzymatic Considerations

There is very low expression of the microsomal enzyme 3α-hydroxysteroid dehydrogenase, Δ^{5-4}-isomerase (3βHSD) in adrenal fetal zone cells (Doody, 1990; Rainey, 2001). This limits the conversion of pregnenolone to progesterone and of 17α-hydroxypregnenolone to 17α-hydroxyprogesterone, an obligatory step in cortisol biosynthesis. There is, however, very active steroid sulfotransferase activity in the fetal adrenal glands. As a consequence, the principal secretory products of the fetal adrenal glands are pregnenolone sulfate and DHEA-S. Comparatively, cortisol, which likely arises primarily in the neocortex and transitional zone of the fetal adrenal glands and not in the fetal zone, is a minor secretory product until late in gestation.

Fetal Adrenal Steroid Precursor

The precursor for fetal adrenal steroidogenesis is cholesterol. The steroid biosynthesis rate in the fetal gland is so great that its steroidogenesis alone is equivalent to a fourth of the total daily LDL cholesterol turnover in adults. Fetal adrenal glands synthesize cholesterol from acetate. All enzymes involved in cholesterol biosynthesis are elevated compared with that of the adult adrenal gland (Rainey, 2001). Thus, the de novo cholesterol synthesis rate by fetal adrenal tissue is extremely high. Even so, it is insufficient to account for the steroids produced by these glands. Therefore, cholesterol must be assimilated from the fetal circulation. Plasma cholesterol and its esters are present in the form of very-low-density lipoprotein (VLDL), LDL, and HDL.

Simpson and colleagues (1979) found that fetal glands take up lipoproteins as a source of cholesterol for steroidogenesis. LDL was most effective, HDL was much less, and VLDL was devoid of stimulatory activity. They also evaluated relative contributions of cholesterol synthesized de novo and that of cholesterol derived from LDL uptake. These authors confirmed that fetal adrenal glands are highly dependent on circulating LDL as a source of cholesterol for

Most fetal plasma cholesterol arises by de novo synthesis in the fetal liver (Carr, 1984). The low LDL cholesterol level in fetal plasma is not the consequence of impaired fetal LDL synthesis but instead, results from the rapid use of LDL by the fetal adrenal glands for steroidogenesis (Parker, 1980, 1983). As expected, in the anencephalic newborn with atrophic adrenal glands, the LDL cholesterol levels in umbilical cord plasma are high.

Fetal Conditions That Affect Estrogen Production

Several fetal disorders alter the availability of substrate for placental steroid synthesis and thus highlight the interdependence of fetal development and placental function.

Fetal Demise

Fetal death is followed by a striking reduction in urinary estrogen levels. Similarly, after ligation of the umbilical cord with the fetus and placenta left in situ, placental estrogens production decline markedly (Cassmer, 1959). However, placental progesterone production was maintained. It was concluded that an important source of precursors of placental estrogen—but not progesterone—biosynthesis was eliminated upon fetal death.

Fetal Anencephaly

With absence of the adrenal cortex fetal zone, as seen with anencephaly, the placental estrogen formation rate—especially estriol—is severely limited because of diminished availability of C_{19}-steroid precursors. Therefore, almost all estrogens produced in women pregnant with an anencephalic fetus arise from placental use of maternal plasma DHEA-S. Furthermore, in such pregnancies, estrogen production can be increased by maternal administration of ACTH, which stimulates the DHEA-S secretion rate by the maternal adrenal gland. Because ACTH does not cross the placenta, there is no fetal adrenal stimulation. Finally, placental estrogen production is decreased in women pregnant with an anencephalic fetus when a potent glucocorticoid is given to the mother. This suppresses ACTH secretion and thus decreases the DHEA-S secretion rate from the maternal adrenal cortex (MacDonald, 1965a).

Fetal Adrenal Hypoplasia

Congenital adrenal cortical hypoplasia occurs in perhaps 1 in 12,500 births (McCabe, 2001). Estrogen production in these pregnancies is limited, which suggests the absence of C_{19}-precursors.

Fetal-Placental Sulfatase Deficiency

Placental estrogen formation is generally regulated by the availability of C_{19}-steroid prohormones in fetal and maternal plasma. Specifically, there is no rate-limiting enzymatic reaction in the placental pathway from C_{19}-steroids to estrogen biosynthesis. An exception to this generalization is placental sulfatase deficiency, which is associated with very low estrogen levels in otherwise normal pregnancies (France, 1969). Sulfatase deficiency precludes the hydrolysis of C_{19}-steroid sulfates, the first enzymatic step in the placental use of these circulating prehormones for estrogen biosynthesis. This deficiency is an X-linked disorder, and all affected fetuses are male. Its estimated frequency is 1 in 2000 to 5000 births and is associated with delayed onset of labor. It also is associated with the development of ichthyosis in affected males later in life (Bradshaw,
Fetal-Placental Aromatase Deficiency

There are a few well-documented examples of aromatase deficiency (Grumbach, 2011; Simpson, 2000). Fetal adrenal DHEA-S, which is produced in large quantities, is converted in the placenta to androstenedione, but in cases of placental aromatase deficiency, androstenedione cannot be converted to estradiol. Rather, androgen metabolites of DHEA produced in the placenta, including androstenedione and some testosterone, are secreted into the maternal or fetal circulation, or both, causing virilization of the mother and the female fetus (Belgorosky, 2009; Harada, 1992; Shozu, 1991).

Trisomy 21—Down Syndrome

Second-trimester maternal serum screening for abnormal levels of hCG, alpha-fetoprotein, and other analytes has become universal (Chap. 14, p. 290). As a result, it was discovered that serum unconjugated estriol levels were low in women with Down syndrome fetuses (Benn, 2002). The likely reason for this is inadequate formation of C₁₉-steroids in the adrenal glands of these trisomic fetuses.

Deficiency in Fetal LDL Cholesterol Biosynthesis

A successful pregnancy in a woman with β-lipoprotein deficiency has been described (Parker, 1986). The absence of LDL in the maternal serum restricted progesterone formation in both the corpus luteum and placenta. In addition, estriol levels were lower than normal. Presumably, the diminished estrogen production was the result of decreased fetal LDL formation, which limited fetal adrenal production of estrogen precursors.

Fetal Erythroblastosis

In some cases of severe fetal D-antigen alloimmunization, maternal plasma estrogen levels are elevated. A likely cause is increased placental mass from hypertrophy, which can be seen with such fetal hemolytic anemia (Chap. 15, p. 315).

Maternal Conditions That Affect Placental Estrogen Production

Glucocorticoid Treatment

The administration of glucocorticoids to pregnant women causes a striking reduction in placental estrogen formation. Glucocorticoids inhibit ACTH secretion from the maternal and fetal pituitary glands. This leads to decreased maternal and fetal adrenal secretion of the placental estrogen precursor DHEA-S.

Maternal Adrenal Dysfunction

In pregnant women with Addison disease, maternal urinary estrogen levels are decreased (Baulieu, 1956). The decrease principally affects estrone and estradiol. The fetal adrenal contribution to estriol synthesis, particularly in later pregnancy, is quantitatively much more important.

Maternal Ovarian Androgen-Producing Tumors
The extraordinary efficiency of the placenta in the aromatization of C_{19}-steroids may be exemplified by two considerations. First, Edman and associates (1981) found that virtually all androstenedione entering the intervillous space is taken up by syncytiotrophoblast and converted to estradiol. None of this C_{19}-steroid enters the fetus. Second, a female fetus is rarely virilized if there is a maternal androgen-secreting ovarian tumor. The placenta efficiently converts aromatizable C_{19}-steroids, including testosterone, to estrogens, thus precluding transplacental passage. Indeed, virilized female fetuses of women with an androgen-producing tumor may be cases in which a nonaromatizable C_{19}-steroid androgen is produced by the tumor—for example, 5α-dihydrotestosterone. Another explanation is that testosterone is produced very early in pregnancy in amounts that exceed the placental aromatase capacity at that time.

**Gestational Trophoblastic Disease**

With complete hydatidiform mole or choriocarcinoma, there is no fetal adrenal source of C_{19}-steroid precursor for trophoblast estrogen biosynthesis. Consequently, placental estrogen formation is limited to the use of C_{19}-steroids in the maternal plasma, and therefore the estrogen produced is principally estradiol (MacDonald, 1964, 1966). Great variation is observed in the rates of both estradiol and progesterone formation in molar pregnancies.

Obstetrical practice has always emphasized that gross examination of the placenta is integral following delivery. In some cases, findings prompt further action by the obstetrician or pediatrician. In addition, great strides have been made concerning the histopathological examination of placental tissue to provide clinically useful information. Pioneering efforts in this field include those of Benirschke, Driscoll, Fox, Naeye, Salafia, and Faye-Petersen.

HISTOPATHOLOGICAL EXAMINATION

We agree with most authorities that routine placental examination by a pathologist is not indicated, although there is still debate as to which placentas should be submitted. For example, the College of American Pathologists recommends routine examination for an extensive list of indications (Langston, 1997). However, data may be insufficient to support all of these. Certainly, the placenta and cord should be examined in the delivery room. As some correlation of specific placental findings with both short- and long-term neonatal outcomes is possible, the decision to request pathological examination should be based on clinical and placental findings (Redline, 2008; Roberts, 2008). Shown in Table 6-1 are indications used at Parkland Hospital to submit a placenta to the Pathology Department.

\(^{a}\)Indications are organized alphabetically.
Placental abnormalities are better understood with knowledge of placental implantation, development, and anatomy presented in Chapter 5 (p. 88). At term, the “typical” placenta weighs 470 g, is round to oval with a 22-cm diameter, and has a central thickness of 2.5 cm (Benirschke, 2012). It is composed of a placental disc, extraplacental membranes, and three-vessel umbilical cord. The maternal surface is the basal plate, which is divided by clefts into portions—termed cotyledons. These clefts mark the site of internal septa, which extend into the intervillous space. The fetal surface is the chorionic plate, into which the umbilical cord inserts, typically in the center. Large fetal vessels that originate from the cord vessels then spread and branch across the chorionic plate before entering stem villi of the placenta parenchyma. In tracing these, fetal arteries almost invariably cross over veins. The chorionic plate and its vessels are covered by thin amnion, which can be easily peeled away from a postdelivery specimen.

Sonographically, the normal placenta is homogenous and 2 to 4 cm thick, lies against the myometrium, and indents into the amnionic sac. The retroplacental space is a hypoechoic area that separates the myometrium from the placenta’s basal plate and measures less than 1 to 2 cm. During prenatal sonographic examinations, placental location and relationship to the internal cervical os are recorded. The umbilical cord is also imaged, its fetal and placental insertion sites examined, and its vessels counted.

Many placental lesions can be identified grossly or sonographically, but many abnormalities require histopathological examination for clarification. A detailed description of these is beyond the scope of this chapter, and interested readers are referred to textbooks by Benirschke (2012), Fox (2007), Faye-Petersen (2006), and their colleagues.

ABNORMALITIES OF THE PLACENTA

Shape and Size

In contrast to the normal architecture described earlier, placentas may infrequently form as separate, nearly equally sized discs. This is a bilobate placenta, but is also known as bipartite placenta or placenta duplex. In these, the cord inserts between the two placental lobes—either into a connecting chorionic bridge or into intervening membranes.

A placenta containing three or more equally sized lobes is rare and termed multilobate. However, more frequently, one or more small accessory lobes—succenturiate lobes—may develop in the membranes at a distance from the main placenta (Fig. 6-1). These lobes have vessels that course through the membranes. If these vessels overlie the cervix to create a vasa previa, they can cause dangerous fetal hemorrhage if torn (p. 123). An accessory lobe may also be retained in the uterus after delivery and cause postpartum uterine atony and hemorrhage.
FIGURE 6-1 Succenturiate lobe. A. Vessels extend from the main placental disk to supply the small round succenturiate lobe located beneath it. (Photograph contributed by Dr. Jaya George.) B. Sonographic imaging with color Doppler shows the main placental disk implanted posteriorly (asterisk). The succenturiate lobe is located on the anterior uterine wall across the amnionic cavity. Vessels are identified as the long red and blue crossing tubular structures that travel within the membranes to connect these two portions of placenta.
Rarely, the portion of fetal membranes covered by functioning villi varies from the norm. With placenta membranacea, all or nearly all of the membranes are covered with villi. This placentation may occasionally give rise to serious hemorrhage because of associated placenta previa or accreta (Greenberg, 1991). A ring-shaped placenta may be a variant of placenta membranacea. The placenta is annular, and a partial or complete ring of placental tissue is present. These abnormalities appear to be associated with a greater likelihood of antepartum and postpartum bleeding and fetal-growth restriction (Faye-Petersen, 2006). With placenta fenestrata, the central portion of a placental disc is missing. In some instances there is an actual hole in the placenta, but more often, the defect involves only villous tissue, and the chorionic plate remains intact. Clinically, it may erroneously prompt a search for a retained placental cotyledon.

During pregnancy, the normal placenta increases its thickness at a rate of approximately 1 mm per week. Although not measured as a component of routine sonographic evaluation, this thickness typically does not exceed 40 mm (Hoddick, 1985). Placentomegaly defines those thicker than 40 mm and commonly results from striking villous enlargement. This may be secondary to maternal diabetes or severe maternal anemia, or to fetal hydrops or infection caused by syphilis, toxoplasmosis, or cytomegalovirus. Less commonly, villi are enlarged and edematous and fetal parts are present, such as in cases of partial mole or a complete mole that coexists with a normal twin (Chap. 20, p. 398). Cystic vesicles are also seen with placental mesenchymal dysplasia. Vesicles in this rare condition correspond to enlarged stem villi, but unlike molar pregnancy, there is not excessive trophoblast proliferation (Woo, 2011). And in some cases, rather than villous enlargement, placentomegaly may result from collections of blood or fibrin. Examples of this that are subsequently discussed on page 119 include massive perivillous fibrin deposition, intervillous or subchorionic thromboses, and large retroplacental hematomas.

**Extrachorial Placentation**

The chorionic plate normally extends to the periphery of the placenta and has a diameter similar to that of the basal plate. With extrachorial placentation, however, the chorionic plate fails to extend to this periphery and leads to a chorionic plate that is smaller than the basal plate (Fig. 6-2). In a circummarginate placenta, fibrin and old hemorrhage lie between the placenta and the overlying amniochorion. In contrast, with a circumvallate placenta the peripheral chorion is a thickened, opaque, gray-white circular ridge composed of a double fold of chorion and amnion. Sonographically, the double fold can be seen as a thick, linear band of echoes extending from one placental edge to the other. On cross section, it appears as a “shelf.” This is important clinically because its location may help to differentiate this shelf from amnionic bands and amnionic sheets, which are described subsequently.
In this illustration, circummarginate (left) and circumvallate (right) varieties of extrachorial placentation are shown. A circummarginate placenta is covered by a single layer of amniochorion. B. This transabdominal gray-scale sonographic image shows a circumvallate placenta. The double fold of amnion and chorion creates a broad, opaque white ring and ridge on the fetal surface.

Clinically, most pregnancies with an extrachorial placenta have normal outcomes. In observational studies in which the diagnosis was made by placental examination, circumvallate placenta was associated with increased risk for antepartum bleeding and preterm birth (Lademacher, 1981; Suzuki, 2008a). In a prospective sonographic investigation, however, Sher and colleagues (2007a) found a circumvallate placenta—described as a placental “shelf”—in more than 10 percent of early second-trimester pregnancies. Importantly, they reported that these were transient and benign.

### Placenta Accreta, Increta, and Percreta

These clinically important placental abnormalities develop when trophoblast invades the myometrium to varying depths to cause abnormal adherence. They are much more likely when there is placenta previa or when the placenta implants over a prior uterine incision or perforation. As discussed further in Chapter 41 (p. 804), torrential hemorrhage is a frequent complication.

### Circulatory Disturbances

These are clinically important syndromes, and in most cases, the placenta is a target organ of maternal disease. Functionally, placental perfusion disorders can be grouped into: (1) those in which there is disrupted maternal blood flow to or within the intervillous space and (2) those with disturbed fetal blood flow through the villi. These lesions are frequently identified in the normal, mature placenta. Although they can limit maximal placental blood flow, placental functional reserve prevents harm in most cases. Indeed, some estimate that up to 30 percent of placental villi
can be lost without untoward fetal effects (Fox, 2007). If extensive, however, these lesions can profoundly limit fetal growth.

Placental lesions that cause abnormal perfusion are frequently seen grossly or sonographically, whereas smaller lesions are seen only by microscopic examination. Sonographically, many of these lesions, such as subchorionic fibrin deposition, per villous fibrin deposition, and intervillous thrombosis, may appear as focal sonolucencies within the placenta. Importantly, in the absence of maternal or fetal complications, isolated placental sonolucencies are considered incidental findings.

**Maternal Blood Flow Disruption**

**Subchorionic Fibrin Deposition.** These are caused by slowing of maternal blood flow within the intervillous space with subsequent fibrin deposition. Blood stasis specifically occurs in the subchorionic area, and lesions that develop are commonly seen as white or yellow firm plaques on the fetal surface.

**Per villous Fibrin Deposition.** Maternal blood flow stasis around an individual villus results in fibrin deposition and can lead to diminished villous oxygenation and syncytiotrophoblastic necrosis (Fig. 6-3). Within limits, these grossly visible small yellow-white placental nodules are considered to be normal placental aging.
FIGURE 6-3 Potential sites of maternal- and fetal-related placental circulatory disturbances. (Adapted from Faye-Petersen, 2006.)

**Maternal Floor Infarction.** This extreme variant of perivillous fibrinoid deposition is a dense fibrinoid layer within the placental basal plate and is erroneously termed an infarction. The lesion has a thick, white, firm, corrugated surface that impedes normal maternal blood flow into the intervillus space. These lesions are associated with miscarriage, fetal-growth restriction, preterm delivery, and stillbirths (Andres, 1990; Mandsager, 1994). These adverse outcomes occasionally recur in subsequent pregnancies. Their etiopathogenesis is not well defined, but some cases are associated with lupus anticoagulant (Sebire, 2002, 2003). Although unsettled, other cases may be associated with maternal thrombophilias (Gogia, 2008; Katz, 2002). These lesions are not reliably imaged with prenatal sonography, but they may create a thicker basal plate.

**Intervillous Thrombus.** This is a collection of coagulated maternal blood normally found in the intervillous space mixed with fetal blood from a break in a villus. Grossly, these round or oval collections vary in size up to several centimeters. They appear red if recent or white-yellow if older, and they develop at any placental depth. Intervillous thrombi are common and typically not associated with adverse fetal sequelae. Because there is potential for a communication between maternal and fetal circulations, they can cause elevated maternal serum alpha-fetoprotein levels (Salafia, 1988).

**Infarction.** Chorionic villi themselves receive oxygen solely from maternal circulation supplied to the intervillous space. Any uteroplacental disease that diminishes or obstructs this supply can result in infarction of individual villus. These are common lesions in mature placentas and are benign in limited numbers. If they are numerous, however, placental insufficiency can develop. When they are thick, centrally located, and randomly distributed, they may be associated with preeclampsia or lupus anticoagulant.

**Hematoma.** The maternal-placental-fetal unit can develop a number of hematoma types as depicted in Figure 6-3. These include: (1) retroplacental hematoma—between the placenta and its adjacent decidua; (2) marginal hematoma—between the chorion and decidua at the placental periphery—known clinically as subchorionic hemorrhage; (3) subchorial thrombosis—also known as Breus mole—along the roof of the intervillous space and beneath the chorionic plate; and (4) subamnionic hematoma—these are of fetal vessel origin and found beneath the amnion but above the chorionic plate.

Sonographically, these hematomas may resemble a crescent-shaped fluid collection that is hyperechoic to isoechoic in the first week after hemorrhage, hypoechoic at 1 to 2 weeks, and finally, anechoic after 2 weeks. Most subchorionic hematomas visible sonographically are fairly small and of no clinical consequence. Extensive retroplacental, marginal, and subchorial collections have been associated with higher rates of miscarriage, placental abruption, fetal-growth restriction, preterm delivery, and adherent placenta (Ball, 1996; Madu, 2006; Nagy, 2003). In essence, placental abruption is a large clinically significant retroplacental hematoma (Chap. 41, p. 793)

**Fetal Blood Flow Disruption**

Placental lesions that arise from fetal circulatory disturbances are also depicted in Figure 6-3.

**Fetal Thrombotic Vasculopathy.** Deoxygenated fetal blood flows from the two umbilical arteries
into arteries within the chorionic plate that divide and send branches out across the placental surface. These eventually supply individual stem villi, and their thrombosis will obstruct fetal blood flow. Distal to the obstruction, affected portions of the villus become infarcted and nonfunctional. Thrombi in limited numbers are normally found in mature placentas, but these may be clinically significant if many villi become infarcted.

**Subamnionic Hematoma.** As indicated earlier, these hematomas lie between the placenta and amnion. They most often are acute events during third-stage labor when cord traction ruptures a vessel near the cord insertion. Chronic lesions may cause fetomaternal hemorrhage or fetal-growth restriction (Deans, 1998). They also may be confused with other placental masses such as chorioangioma, which is discussed subsequently (Sepulveda, 2000; Van Den Bosch, 2000; Volpe, 2008). In most cases, Doppler interrogation will show absence of internal blood flow that permits differentiation of hematomas from other placental masses.

**Placental Calcification**
Calcium salts may be deposited throughout the placenta, but are most common on the basal plate. Calcification accrues with advancing gestation and is associated with nulliparity, smoking, higher socioeconomic status, and increasing maternal serum calcium levels (Fox, 2007). Calcifications can easily be seen sonographically, and Grammmum and coworkers (1979) created a grading scale from 0 to 3 that reflected increasing calcification with increasing numerical grade. However, such grading criteria have not been found useful to predict neonatal outcome (Hill, 1983; McKenna, 2005; Montan, 1986; Sau, 2004).

**Placental Tumors**

**Gestational Trophoblastic Disease**
These pregnancy-related trophoblastic proliferative abnormalities are discussed in Chapter 20 (p. 396).

**Chorioangioma**
These benign tumors have components similar to blood vessels and stroma of the chorionic villus. Also called chorangioma, these placental tumors have an incidence of approximately 1 percent (Guschmann, 2003). In some cases, maternal serum alpha-fetoprotein (MSAFP) levels may be elevated with these tumors, an important diagnostic finding as discussed in Chapter 14 (p. 285). Their characteristic sonographic appearance has a well-circumscribed, rounded, predominantly hypoechoic lesion near the chorionic surface and protruding into the amniotic cavity. As shown in Figure 6-4, documenting increased blood flow by color Doppler helps to distinguish these lesions from other placental masses such as hematoma, partial hydatidiform mole, teratoma, metastases, and leiomyoma (Prapas, 2000).
Small chorioangiomas are usually asymptomatic. Large tumors, typically those measuring > 5 cm, may be associated with significant arteriovenous shunting within the placenta that can cause fetal anemia and hydrops. Hemorrhage, preterm delivery, amniotic fluid abnormalities, and fetal-growth restriction may also complicate large tumors (Sepulveda, 2003a; Zalel, 2002). Because of this, some have treated large tumors by interdicting excessive blood flow using vessel occlusion or ablation (Lau, 2003; Nicolini, 1999; Quintero, 1996; Sepulveda, 2009).

Tumors Metastatic to the Placenta
Malignant tumors rarely metastasize to the placenta. Of those that do, melanomas, leukemias and lymphomas, and breast cancer are the most common (Al-Adnani, 2007a). Tumor cells usually are confined within the intervillous space. As a result, metastasis to the fetus is uncommon but is most often seen with melanoma (Alexander, 2003; Altman, 2003). These are discussed further in Chapter 63 (p. 1233).

ABNORMALITIES OF THE MEMBRANES

There are a few abnormalities of the fetal membranes that may be associated with adverse outcomes.

Meconium Staining
Fetal passage of meconium before or during labor is common with cited incidences that range from 12 to 20 percent (Ghidini, 2001; Oyelese, 2006; Tran, 2004). Importantly, staining of the amnion can be obvious within 1 to 3 hours, but its passage cannot be timed or dated accurately (Benirschke, 2012). This subject and its clinical implications are discussed in detail in Chapter 33 (p. 637).

Chorioamnionitis
Normal genital-tract flora can colonize and infect the membranes, umbilical cord, and eventually the fetus. Bacteria most commonly ascend after prolonged membrane rupture and during labor to cause infection. Organisms initially infect the chorion and adjacent decidua in the area overlying the internal os. Subsequently, progression leads to full-thickness involvement of the membranes—chorioamnionitis. Organisms may then spread along the chorioamnionic surface to colonize and replicate in amniotic fluid. Subsequently, inflammation of the chorionic plate and of the umbilical cord—funisitis—may follow (Al-Adnani, 2007b; Goldenberg, 2000; Redline, 2006).

Fetal infection may result from hematogenous spread if the mother has bacteremia, but more likely is from aspiration, swallowing, or other direct contact with infected amniotic fluid. Most commonly, there is microscopic or occult chorioamnionitis, which is caused by a wide variety of microorganisms. This is frequently cited as a possible explanation for many otherwise unexplained cases of ruptured membranes, preterm labor, or both as discussed in Chapter 42 (p. 838). In some
cases, gross infection is characterized by membrane clouding and is sometimes accompanied by a foul odor that depends on bacterial species.

**Other Membrane Abnormalities**

The condition of amnion nodosum is characterized by numerous small, light-tan nodules on the amnion overlying the chorionic plate. These may be scraped off the fetal surface and contain deposits of fetal squames and fibrin that reflect prolonged and severe oligohydramnios (Adeniran, 2007).

There are at least two band-like structures that can be formed by the fetal membranes. Amnionic band sequence is an anatomic fetal disruption sequence caused by bands of amnion that entrap fetal structures and impair their growth and development. The most widely held theory concerning their etiology is that early rupture of the amnion results in adherence of part of the fetus to the underlying “sticky” chorion (Torpin, 1965). Amnionic bands commonly involve the extremities to cause limb-reduction defects and more subtle deformations. They may also affect other fetal structures such as the cranium, causing encephaloclele.

In contrast, an amnionic sheet is formed by normal amniochorion draped over a preexisting uterine synechia. Generally these sheets pose little fetal risk, although slightly higher rates of preterm membrane rupture and placental abruption were recently described (Tuuli, 2012).

**ABNORMALITIES OF THE UMBILICAL CORD**

**Length**

Most umbilical cords are 40 to 70 cm long, and very few measure < 32 cm or > 100 cm. Cord length is influenced positively by both amnionic fluid volume and fetal mobility. Short cords may be associated with fetal-growth restriction, congenital malformations, intrapartum distress, and a twofold risk of death (Berg, 1995; Krakowiak, 2004). Excessively long cords are more likely to be linked with cord entanglement or prolapse and with fetal anomalies, acidemia, and demise.

Because antenatal determination of cord length is technically limited, cord diameter has been used as a predictive marker for fetal outcomes. Some have linked lean cords with poor fetal growth and large-diameter cords with macrosomia. However, the clinical utility of this parameter is still unclear (Barbieri, 2008; Cromi, 2007; Raio 1999, 2003).

**Coiling**

Although cord coiling characteristics have been reported, these are not currently part of standard sonography (Predanic, 2005a). Usually the umbilical vessels spiral through the cord in a sinistral, that is, left-twisting direction (Lacro, 1987). The number of complete coils per centimeter of cord length has been termed the umbilical coiling index (Strong, 1994). A normal antepartum index derived sonographically is 0.4, and this contrasts with a normal value of 0.2 derived postpartum by actual measurement (Sebire, 2007). Clinically, hypocoiling has been linked with fetal demise, whereas hypercoiling has been associated with fetal-growth restriction and intrapartum fetal acidosis. Both have been reported in the setting of trisomic fetuses and with single umbilical artery (de Laat, 2006, 2007; Predanic, 2005b).
Occasionally, the usual arrangement of two thick-walled arteries and one thin, larger umbilical vein is altered. The most common aberration is that of a single umbilical artery, with a cited incidence of 0.63 percent in liveborn neonates, 1.92 percent with perinatal deaths, and 3 percent in twins (Heifetz, 1984).

The cord vessel number is a component of the standard prenatal ultrasound examination (Fig. 6-5). Identification of a single umbilical artery frequently prompts consideration for targeted sonography and possibly fetal echocardiography. As an isolated finding in an otherwise low-risk pregnancy with no apparent fetal anomalies, it does not significantly increase the fetal aneuploidy risk. But fetuses with major malformations frequently have a single umbilical artery. And when seen in an anomalous fetus, the aneuploidy risk is greatly increased, and amniocentesis is recommended (Dagklis, 2010; Lubusky, 2007). The most frequent anomalies described are cardiovascular and genitourinary. A single artery has also been associated with fetal-growth restriction in some but not all studies (Chetty-John, 2010; Hua, 2010; Murphy-Kaulbeck, 2010; Predanic, 2005c).

**FIGURE 6-5** Two umbilical arteries are typically documented sonographically in the second trimester. They encircle the fetal bladder (*asterisk*) as extensions of the superior vesical arteries. In this color Doppler sonographic image, a single umbilical artery, shown in red, runs along the bladder wall before joining the umbilical vein (*blue*) in the cord. Below this, the two vessels of the cord, seen as a larger red and smaller blue circle, are also seen floating in a cross section of a cord segment.

A rare anomaly is that of a fused umbilical artery with a shared lumen. It arises from failure of the two arteries to split during embryological development. The common lumen may extend through the entire cord, but if partial, is typically found near the placental insertion site (Yamada,
In one report, these were associated with a higher incidence of marginal or velamentous cord insertion, but not congenital fetal anomalies (Fujikura, 2003).

Remnants and Cysts
A number of structures are housed in the umbilical cord during fetal development, and their remnants may be seen when the mature cord is viewed transversely. Recall that embryos in early development initially have two umbilical veins, and thus an umbilical vein remnant may be seen on careful inspection. Indeed, Jauniaux and colleagues (1989) sectioned 1000 cords, and in one fourth of the specimens, they found remnants of vitelline duct, allantoic duct, and embryonic vessels. These were not associated with congenital malformations or perinatal complications.

Cysts occasionally are found along the course of the cord. They are designated according to their origin. True cysts are epithelium-lined remnants of the allantoic or vitelline ducts and tend to be located closer to the fetal insertion site. In contrast, the more common pseudocysts form from local degeneration of Wharton jelly and occur anywhere along the cord. Both have a similar sonographic appearance. Single umbilical cord cysts identified in the first trimester tend to resolve completely, however, multiple cysts may portend miscarriage or aneuploidy (Ghezzi, 2003; Gilboa, 2011). Cysts persisting beyond this time are associated with a risk for structural defects and chromosomal anomalies (Bonilla, 2010; Zangen, 2010).

Insertion
The cord normally inserts centrally into the placental disc, but eccentric, marginal, or velamentous insertions are variants. The latter two are clinically important in that the cord or its vessels may be torn during labor and delivery. Of these, marginal insertion is a common variant—sometimes referred to as a battledore placenta—in which the cord anchors at the placental margin. These are more frequent with multifetal pregnancy, especially those conceived using assisted reproductive technology, and they may be associated with weight discordance (Delbaere, 2007; Kent, 2011). This common insertion variant rarely causes problems, but it occasionally results in the cord being pulled off during delivery of the placenta (Liu, 2002).

A velamentous insertion is a variant of considerable clinical importance. The umbilical vessels characteristically spread within the membranes at a distance from the placental margin, which they reach surrounded only by a fold of amnion (Fig. 6-6) As a result, vessels are vulnerable to compression, which may lead to fetal hypoperfusion and acidemia. The incidence of velamentous insertion is approximately 1 percent, but it is more commonly seen with placenta previa and multifetal gestations (Feldman, 2002; Fox, 2007; Papinnemi, 2007). When seen during prenatal sonography, cord vessels with velamentous insertion are seen traveling along the uterine wall before entering the placental disc.
FIGURE 6-6 Velamentous cord insertion. A. The umbilical cord inserts into the membranes. From here, the cord vessels branch and are supported only by membrane until they reach the placental disk. B. When viewed sonographically and using color Doppler, the cord vessels appear to lie against the myometrium as they travel to insert marginally into the placental disk, which lies at the top of this image.

Last, with the very uncommon furcate insertion, the topographic site of cord connection onto the placental disc is central, but umbilical vessels lose their protective Wharton jelly shortly before they insert. As a result, they are covered only by an amnion sheath and prone to compression, twisting, and thrombosis.

Vasa Previa
This is a particularly dangerous variation of velamentous insertion in which the vessels within the membranes overlie the cervical os. The vessels can be interposed between the cervix and the presenting fetal part. Hence, they are vulnerable to compression and also to laceration or avulsion with rapid fetal exsanguination. Vasa previa is uncommon, and Lee and coworkers (2000) identified it in 1 in 5200 pregnancies. Risk factors include bilobate or succenturiate placentas and second-trimester placenta previa, with or without later migration (Baulies, 2007; Suzuki, 2008b). It is also increased in pregnancies conceived by in vitro fertilization (Schachter, 2003).

Because antepartum diagnosis has improved perinatal survival compared with intrapartum diagnosis, vasa previa would ideally be identified early (Oyelese, 2004). Unfortunately, this is not always possible. Clinically, an examiner is occasionally able to palpate or directly see a tubular fetal vessel in the membranes overlying the presenting part. With transvaginal sonography, cord vessels may be seen inserting into the membranes—rather than directly into the placenta—with vessels running above the cervical internal os (Fig. 6-7). Routine color Doppler interrogation of the placental cord insertion site, particularly in cases of placenta previa or low-lying placenta,
Once vasa previa is identified, early scheduled cesarean delivery is planned. Bed rest apparently has no added advantage. Robinson and Grobman (2011) performed a decision analysis and recommend elective cesarean delivery at 34 to 35 weeks to balance the risks of perinatal exsanguination versus preterm birth morbidity. At delivery, the infant is expeditiously delivered after the hysterotomy incision in case a vessel is lacerated during uterine entry.

Whenever there is otherwise unexplained hemorrhage either antepartum or intrapartum, vasa previa with a lacerated fetal vessel should be considered. In many cases, bleeding is rapidly fatal, and infant salvage is not possible. With less hemorrhage, however, it may be possible to distinguish fetal versus maternal bleeding. Various tests may be used, and each relies on the characteristically increased resistance of fetal hemoglobin to denaturation by alkaline or acid reagents (Lindqvist, 2007; Oyelese, 1999).

Knots, Strictures, and Loops

Various mechanical and vascular abnormalities can impede cord vessel blood flow either toward or away from the fetus, and these sometimes cause fetal harm. True knots are caused by fetal movement and are seen in approximately 1 percent of births. They are especially common and dangerous in monoamnionic twins as described in Chapter 45 (p. 901). When true knots are associated with singleton fetuses, the stillbirth risk is increased four- to tenfold (Airas, 2002; SØrnes, 2000). Abnormal fetal heart rate tracings are more often encountered during labor. However, cesarean delivery rates are not increased, and cord blood acid-base values are usually...
normal (Airas, 2002; Maher, 1996). False knots are of no clinical significance and appear as knobs protruding from the cord surface. These are focal redundancies of a vessel or Wharton jelly.

A cord stricture is a focal narrowing of its diameter that usually develops near the fetal cord insertion (Peng, 2006). Characteristic pathological features of strictures are absence of Wharton jelly and stenosis or obliteration of cord vessels at the narrow segment (Sun, 1995). In most instances, the fetus is stillborn (French, 2005). Even less common is a cord stricture caused by an amnionic band.

Cord loops are frequently encountered and are caused by coiling around various fetal parts during movement. As expected, they are more common with longer cords. A cord around the neck—a nuchal cord—is extremely common. One loop is reported in 20 to 34 percent of deliveries; two loops in 2.5 to 5 percent; and three loops in 0.2 to 0.5 percent (Kan, 1957; SØrnes, 1995; Spellacy, 1966). During labor these loops can result in fetal heart rate decelerations that persist during a contraction. Up to 20 percent of fetuses with a nuchal cord have moderate to severe variable heart rate decelerations, and these are associated with a lower umbilical artery pH (Hankins, 1987). Despite their frequency, nuchal cords are relatively uncommon causes of adverse perinatal outcome (Mastrobattista, 2005; Sheiner, 2006).

A funic presentation describes when the umbilical cord is the presenting part in labor. These are uncommon and most often are associated with fetal malpresentation. A funic presentation in some cases is identified with placental sonography and color flow Doppler (Ezra, 2003). Fetal heart rate abnormalities and overt or occult cord prolapse may complicate labor and lead to cesarean delivery.

**Vascular**

Cord hematomas are uncommon and have been associated with abnormal cord length, umbilical vessel aneurysm, trauma, entanglement, umbilical vessel venipuncture, and funisitis (Gualandri, 2008). They can follow varix rupture, which is usually of the umbilical vein. They are recognized sonographically as hypoechoic masses that lack blood flow.

Umbilical cord vessel thromboses are in utero events. Approximately 70 percent are venous, 20 percent are venous and arterial, and 10 percent are arterial thromboses (Heifetz, 1988). Compared with venous thromboses, those in the artery have higher perinatal morbidity and mortality rates and are associated with fetal-growth restriction, fetal acidosis, and stillbirths (Sato, 2006).

Another rare anomaly is an umbilical vein varix, which is a marked focal dilatation that can be within either the intraamnionic or fetal intraabdominal portion of the umbilical vein. The latter anomalies are associated with increased rates of fetal structural anomalies and aneuploidy (Byers, 2009; Mankuta, 2011). Complications may include rupture or thrombosis, compression of the umbilical artery, and fetal cardiac failure due to increased preload (Mulch, 2006). They may be visualized during sonography as a cystic dilatation of the umbilical vein. Continuity of the varix with a normal-caliber portion of the umbilical vein is confirmed using color-flow Doppler.

The rare umbilical artery aneurysm is caused by congenital thinning of the vessel wall with diminished support from Wharton jelly. Indeed, most form at or near the cord’s placental insertion, where support is absent. These are associated with single umbilical artery, trisomy 18, amniotic fluid volume abnormalities, fetal-growth restriction, and stillbirth (Hill, 2010; Weber, 2007). At least theoretically, these aneurysms could cause fetal compromise and death by compression of the umbilical vein. These aneurysms may appear sonographically as a cyst with a hyperechoic rim. Within the aneurysm, color flow and spectral Doppler interrogation demonstrate either low-velocity or turbulent nonpulsatile flow (Olog, 2011; Sepulveda, 2003b; Shen, 2007b).

Contemporary obstetrics includes physiology and pathophysiology of the fetus, its development, and its environment. An important result is that fetal status has been elevated to that of a patient who, in large measure, can be given the same meticulous care that obstetricians provide for pregnant women. Normal fetal development is considered in this chapter. Anomalies, injuries, and diseases that affect the fetus and newborn are addressed in Chapter 33 and others.

GESTATIONAL AGE VARIOUSLY DEFINED

Several terms are used to define pregnancy duration, and thus fetal age (Fig. 7-1). Gestational age or menstrual age is the time elapsed since the first day of the last menstrual period, a time that actually precedes conception. This starting time, which is usually about 2 weeks before ovulation and fertilization and nearly 3 weeks before blastocyst implantation, has traditionally been used because most women know their last period. Embryologists describe embryo-fetal development in ovulation age, or the time in days or weeks from ovulation. Another term is postconceptional age, nearly identical to ovulation age.
Clinicians customarily calculate gestational age as menstrual age. Approximately 280 days, or 40 weeks, elapse on average between the first day of the last menstrual period and the birth. This corresponds to 9 and 1/3 calendar months. A quick estimate of a pregnancy due date based on menstrual data can be made as follows: add 7 days to the first day of the last period and subtract 3 months. For example, if the first day of the last menses was July 5, the due date is 07–05 minus 3 (months) plus 7 (days) = 04–12, or April 12 of the following year. This calculation has been termed Naegele rule. Many women undergo first- or early second-trimester sonographic examination to confirm gestational age. In these cases, the sonographic estimate is usually a few days later than that determined by the last period. To rectify this inconsistency—and to reduce the number of pregnancies diagnosed as postterm—some have suggested assuming that the average pregnancy is actually 283 days long and that 10 days be added to the last menses instead of 7 (Olsen, 1998). The period of gestation can also be divided into three units, each 13 to 14 weeks long. These three trimesters are important obstetrical milestones.

**EMBRYO-FETAL GROWTH AND DEVELOPMENT**

The complexity of embryo-fetal development is almost beyond comprehension. Shown in Figure 7-2 is a schematic sequence of various organ systems as they develop. New information regarding organ development continues to accrue using modern technologies. For example, imaging techniques help evaluate the role of gene regulation and tissue interaction on eventual 3-dimensional organ morphology (Mohun, 2011). And, Williams and colleagues (2009) described the sequence of gene activation that underlies cardiac development.
Zygote and Blastocyst Development

During the first 2 weeks after ovulation and then fertilization, the zygote develops to the blastocyst stage, which undergoes implantation 6 or 7 days following fertilization. The 58-cell blastocyst differentiates into five embryo-producing cells—*the inner cell mass*—and the remaining 53 cells form the placental trophoblast. Details of implantation and early development of the blastocyst and placenta are described in Chapter 5 (p. 88).
Embryonic Period

The conceptus is termed an embryo at the beginning of the third week after ovulation and fertilization. Primitive chorionic villi form, and this coincides with the expected day of menses. The embryonic period lasts 8 weeks, during which organogenesis takes place. The embryonic disc is well defined, and most pregnancy tests that measure human chorionic gonadotropin (hCG) become positive by this time. As shown in Figures 7-3 and 7-4, the body stalk is now differentiated, and the chorionic sac is approximately 1 cm in diameter. There are villous cores in which angioblastic chorionic mesoderm can be distinguished and a true intervillous space that contains maternal blood. During the third week, fetal blood vessels in the chorionic villi appear. In the fourth week, a cardiovascular system has formed, and thereby, a true circulation is established both within the embryo and between the embryo and the chorionic villi. By the end of the fourth week, the chorionic sac is 2 to 3 cm in diameter, and the embryo is 4 to 5 mm in length (Figs. 7-5 and 7-6). Partitioning of the primitive heart begins in the middle of the fourth week. Arm and leg buds are present, and the amnion is beginning to unsheathe the body stalk, which thereafter becomes the umbilical cord.

Lateral view of embryo-fetus at 56 days, which marks the end of the embryonic period and the beginning of the fetal period. The liver is within the fine, white circle. (From Werth, 2002, with permission.)

At the end of the sixth week, the embryo is 22 to 24 mm long, and the head is large compared with the trunk. The earliest synapses in the spinal cord develop at 6 to 7 weeks (Kadic, 2012). The heart is completely formed. Fingers and toes are present, and the arms bend at the elbows. The upper lip is complete, and the external ears form definitive elevations on either side of the head. Three-dimensional images and videos of human embryos from the MultiDimensional Human Embryo project are found at: http://embryo.soad.umich.edu/.

Fetal Period

Transition from the embryonic period to the fetal period is arbitrarily designated by most embryologists to begin 8 weeks after fertilization—or 10 weeks after onset of last menses. At this time, the embryo-fetus is nearly 4 cm long (see Fig. 7-6C).

Development during the fetal period consists of growth and maturation of structures that were formed during the embryonic period. Crown-to-rump measurements, which correspond to the sitting height, are most accurate for dating (Table 7-1).

*These measurements are average and so may not apply to specific cases; dimensional variations increase with age. These weights refer to fetuses that have been fixed for approximately 2 weeks in 10-percent formalin. Fresh specimens usually weigh approximately 5 percent less.*

Modified from Moore, 2013.

### 12 Gestational Weeks

The uterus usually is just palpable above the symphysis pubis, and the fetal crown-rump length is 6 to 7 cm. Centers of ossification have appeared in most fetal bones, and the fingers and toes have become differentiated. Skin and nails have developed, and scattered rudiments of hair appear. The external genitalia are beginning to show definitive signs of male or female gender. The fetus begins to make spontaneous movements.

### 16 Gestational Weeks

The fetal crown-rump length is 12 cm, and the weight is 110 g. By 14 weeks, gender can be determined by experienced observers by inspection of the external genitalia. Eye movements begin at 16 to 18 weeks, coinciding with midbrain maturation.

### 20 Gestational Weeks
This is the midpoint of pregnancy as estimated from the beginning of the last menses. The fetus now weighs somewhat more than 300 g, and weight increases in a linear manner. From this point onward, the fetus moves about every minute and is active 10 to 30 percent of the time (DiPietro, 2005). The fetal skin has become less transparent, a downy lanugo covers its entire body, and some scalp hair has developed. Cochlear function develops between 22 and 25 weeks, and its maturation continues for six months after delivery.

24 Gestational Weeks
The fetus now weighs approximately 630 g. The skin is characteristically wrinkled, and fat deposition begins. The head is still comparatively large, and eyebrows and eyelashes are usually recognizable. The canalicular period of lung development, during which the bronchi and bronchioles enlarge and alveolar ducts develop, is nearly completed. A fetus born at this time will attempt to breathe, but many will die because the terminal sacs, required for gas exchange, have not yet formed. By 26 weeks, nociceptors are present over all the body, and the neural pain system is developed (Kadic, 2012).

28 Gestational Weeks
The crown-rump length is approximately 25 cm, and the fetus weighs about 1100 g. The thin skin is red and covered with vernix caseosa. The pupillary membrane has just disappeared from the eyes. Isolated eye blinking peaks at 28 weeks. The otherwise normal neonate born at this age has a 90-percent chance of survival without physical or neurological impairment.

32 and 36 Gestational Weeks
At 32 weeks, the fetus has attained a crown-rump length of about 28 cm and a weight of approximately 1800 g. The skin surface is still red and wrinkled. In contrast, by 36 weeks, the fetal crown-rump length averages about 32 cm, and the weight is approximately 2500 g. Because of subcutaneous fat deposition, the body has become more rotund, and the previous wrinkled facial appearance has been lost.

40 Gestational Weeks
This is considered term from the onset of the last menstrual period. The fetus is now fully developed. The average crown-rump length is about 36 cm, and the weight is approximately 3400 g.

PLACENTAL PHYSIOLOGY AND FETAL GROWTH

The placenta is the organ of transfer between mother and fetus. At this maternal-fetal interface, there is transfer of oxygen and nutrients from the mother to the fetus and carbon dioxide and metabolic wastes from fetus to mother. There are no direct communications between fetal blood, which is contained in the fetal capillaries of the chorionic villi, and maternal blood, which remains in the intervillous space. Instead, bidirectional transfer depends on the processes that permit or aid the transport through the syncytiotrophoblast that line chorionic villi.

That said, there are occasional breaks in the chorionic villi, which permit escape of fetal cells into the maternal circulation. This leakage is the mechanism by which some D-negative women become sensitized by the erythrocytes of their D-positive fetus (Chap. 15, p. 306). It can also lead
to chimerism from entrance of allogeneic fetal cells, including trophoblast, into maternal blood (Sunami, 2010). These are estimated to range from 1 to 6 cells/mL around midpregnancy, and some are “immortal” (Lissauer, 2007). A clinical corollary is that some maternal autoimmune diseases may be provoked by such chimerism (Bloch, 2011; Boyon, 2011). This is also discussed in Chapter 59 (p. 1168).

The Intervillous Space

Maternal blood within the intervillous space is the primary unit of maternal–fetal transfer. Blood from the maternal spiral arteries directly bathes the trophoblasts. Substances transferred from mother to fetus first enter the intervillous space and are then transported to the syncytiotrophoblast. Thus, the chorionic villi and intervillous space function together as the fetal lung, gastrointestinal tract, and kidney.

Circulation within the intervillous space is described in Chapter 5 (p. 95). Intervillous and uteroplacental blood flow increases throughout the first trimester of normal pregnancies (Mercé, 2009). At term, the residual volume of the intervillous space measures about 140 mL. Before delivery, however, the volume of this space may be twice this value (Aherne, 1966). Uteroplacental blood flow near term has been estimated to be 700 to 900 mL/min, with most of the blood apparently going to the intervillous space.

Active labor contractions reduce blood flow into the intervillous space. The degree of reduction depends on the contraction intensity. Blood pressure within the intervillous space is significantly less than uterine arterial pressure, but somewhat greater than venous pressure. The latter, in turn, varies depending on several factors, including maternal position. When supine, for example, pressure in the lower part of the inferior vena cava is elevated, and consequently, pressure in the uterine and ovarian veins, and in turn in the intervillous space, is increased.

Placental Transfer

Substances that pass from maternal to fetal blood must first traverse the syncytiotrophoblast, then villous stroma, and finally, the fetal capillary wall. Although this histological barrier separates maternal and fetal circulations, it is not a simple physical barrier. First, throughout pregnancy, syncytiotrophoblast actively or passively permits, facilitates, and adjusts the amount and rate of substance transfer to the fetus. The maternal-facing syncytiotrophoblast surface is characterized by a complex microvillus structure. The fetal-facing basal cell membrane is the site of transfer to the intravillous space. Finally, the villous capillaries are an additional site for transport from the intravillous space into fetal blood, or vice versa. In determining the effectiveness of the human placenta as an organ of transfer, at least 10 variables are important, as shown in Table 7-2 and described next.

Mechanisms of Transfer

Most substances with a molecular mass less than 500 Da pass readily through placental tissue by simple diffusion. These include oxygen, carbon dioxide, water, most electrolytes, and anesthetic gases (Carter, 2009). Some low-molecular-weight compounds undergo transfer facilitated by syncytiotrophoblast. These are usually those that have low concentrations in maternal plasma but are essential for normal fetal development.

Insulin, steroid hormones, and thyroid hormones cross the placenta, but very slowly. The hormones synthesized in situ in the trophoblasts enter both the maternal and fetal circulations, but not equally (Chap. 5, p. 101). Examples are concentrations of chorionic gonadotropin and placental lactogen, which are much lower in fetal plasma than in maternal plasma. Substances of high molecular weight usually do not traverse the placenta, but there are important exceptions. One is immunoglobulin G—molecular weight 160,000 Da—which is transferred by way of a specific trophoblast receptor-mediated mechanism.

Transfer of Oxygen and Carbon Dioxide

Placental oxygen transfer is blood-flow limited. Using estimated uteroplacental blood flow, Longo (1991) calculated oxygen delivery to be approximately 8 mL O₂/min/kg of fetal weight. Normal values for oxygen, carbon dioxide, and pH in fetal blood are presented in Figure 7-7. Because of the continuous passage of oxygen from maternal blood in the intervillous space to the fetus, its oxygen saturation resembles that in maternal capillaries. The average oxygen saturation of intervillous blood is estimated to be 65 to 75 percent, with a partial pressure (Po₂) of 30 to 35 mm Hg. The oxygen saturation of umbilical vein blood is similar, but with a somewhat lower oxygen partial pressure.
FIGURE 7-7 Umbilical venous oxygen pressure ($P_{O_2}$) (A); carbon dioxide pressure ($P_{CO_2}$) (B);
The placenta is highly permeable to carbon dioxide, which traverses the chorionic villus by diffusion more rapidly than oxygen. Near term, the partial pressure of carbon dioxide ($P_{CO_2}$) in the umbilical arteries averages about 50 mm Hg, or approximately 5 mm Hg more than in the maternal intervillous blood. Fetal blood has less affinity for carbon dioxide than does maternal blood, thereby favoring carbon dioxide transfer from fetus to mother. Also, mild maternal hyperventilation results in a fall in $P_{CO_2}$ levels, favoring a transfer of carbon dioxide from the fetal compartment to maternal blood (Chap. 4, p. 63).

Selective Transfer and Facilitated Diffusion

Although simple diffusion is an important method of placental transfer, the trophoblast and chorionic villus unit demonstrate enormous selectivity in transfer. This results in different metabolite concentrations on the two sides of the villus. Importantly, the levels of many substances that are not synthesized by the fetus are several times higher in fetal than in maternal blood. Ascorbic acid is one example. This relatively low-molecular-weight substance might be expected to traverse the placenta by simple diffusion. The concentration of ascorbic acid, however, is two to four times higher in fetal plasma than in maternal plasma (Morriss, 1994). Another example is the unidirectional transfer of iron. Typically, the mother’s plasma iron concentration is much lower than that of her fetus. Even with severe maternal iron deficiency anemia, the fetal hemoglobin mass is normal.

FETAL NUTRITION

Because of the small amount of yolk in the human ovum, growth of the embryo-fetus is dependent on maternal nutrients during the first 2 months. During the first few days after implantation, blastocyst nutrition comes from the interstitial fluid of the endometrium and the surrounding maternal tissue.

Maternal adaptations to store and transfer nutrients to the fetus are discussed in Chapter 4 and summarized here. Three major maternal storage depots—the liver, muscle, and adipose tissue—and the storage-hormone insulin are intimately involved in the metabolism of the nutrients absorbed from the maternal gut.

Insulin secretion is sustained by increased serum levels of glucose and amino acids. The net effect is storage of glucose as glycogen primarily in liver and muscle, retention of some amino acids as protein, and storage of the excess as fat. Storage of maternal fat peaks in the second trimester and then declines as fetal energy demands increase in the third trimester (Pipe, 1979). Interestingly, the placenta appears to act as a nutrient sensor, altering transport based on the maternal supply and environmental stimuli (Fowden, 2006; Jansson, 2006b).

During times of fasting, glucose is released from glycogen, but maternal glycogen stores cannot provide an adequate amount of glucose to meet requirements for maternal energy and fetal growth. Augmentation is provided by cleavage of triacylglycerols, stored in adipose tissue, which result in free fatty acids and activation of lipolysis.
Glucose and Fetal Growth

Although dependent on the mother for nutrition, the fetus also actively participates in providing for its own nutrition. At midpregnancy, fetal glucose concentration is independent of and may exceed maternal levels (Bozzetti, 1988). Glucose is the major nutrient for fetal growth and energy. Logically, mechanisms exist during pregnancy to minimize maternal glucose use so that the limited maternal supply is available to the fetus. Human placental lactogen (hPL), a hormone normally abundant in the mother but not the fetus, is believed to block peripheral uptake and use of glucose, while promoting mobilization and use of free fatty acids by maternal tissues (Chap. 5, p. 104).

Glucose Transport

The transfer of d-glucose across cell membranes is accomplished by a carrier-mediated, stereospecific, nonconcentrating process of facilitated diffusion. There are 14 glucose transport proteins (GLUTs) encoded by the SLC2A gene family and characterized by tissue-specific distribution (Leonce, 2006). GLUT-1 and GLUT-3 primarily facilitate glucose uptake by the placenta and are located in the plasma membrane of the syncytiotrophoblast microvilli (Korgun, 2005). DNA methylation regulates expression of placental GLUT genes, with epigenetic modification across gestation (Novakovic, 2013). GLUT-1 expression is essential for decidualization. It increases as pregnancy advances and is induced by almost all growth factors (Frolova, 2011; Sakata, 1995).

Lactate is a product of glucose metabolism and is also transported across the placenta by facilitated diffusion. By way of cotransport with hydrogen ions, lactate is probably transported as lactic acid.

Glucose and Insulin Role in Fetal Macrosomia

The precise biomolecular events in the pathophysiology of fetal macrosomia are not defined. Nonetheless, it seems clear that fetal hyperinsulinemia is one driving force (Schwartz, 1994). As discussed in Chapter 44 (p. 872), insulin-like growth factor and fibroblast growth factor are important regulators of placental development and function (Forbes, 2010; Giudice, 1995). In addition, recent work has shown that placental corticotropin-releasing hormone (CRH) stimulates trophoblastic production of GLUT-1 and inhibits expression of GLUT-3 through interaction on the CRH-R1 receptor. This suggests a role for CRH in the nutritional regulation of fetal growth and development (Gao, 2012).

Leptin

This polypeptide hormone was originally identified as a product of adipocytes and a regulator of energy homeostasis. It also contributes to angiogenesis, hemopoiesis, osteogenesis, pulmonary maturation, and neuroendocrine, immune, and reproductive functions (Henson, 2006; Maymó, 2009). Leptin is produced by the mother, fetus, and placenta. It is expressed in syncytiotrophoblast and fetal vascular endothelial cells. Of placental production, 5 percent enters fetal circulation, whereas 95 percent is transferred to the mother (Hauguel-de Mouzon, 2006). As a result, the placenta greatly contributes to maternal leptin levels.

Fetal leptin levels begin rising at approximately 34 weeks and are correlated with fetal weight. Abnormal levels have been associated with growth disorders and preeclampsia. Postpartum, leptin levels decline in both the newborn and mother (Grisaru-Granovsky, 2008). Perinatal leptin is associated with the development of metabolic syndromes later in life (Granado, 2012).
Free Fatty Acids and Triglycerides

The newborn has a large proportion of fat, which averages 15 percent of body weight (Kimura, 1991). Thus, late in pregnancy, a substantial part of the substrate transferred to the human fetus is stored as fat. Although maternal obesity affects placental fatty acid uptake, it appears to have no effect on fetal growth (Dube, 2012). Neutral fat in the form of triacylglycerols does not cross the placenta, but glycerol does. There is preferential placental-fetal transfer of long-chain polyunsaturated fatty acids (Gil-Sanchez, 2012). Lipoprotein lipase is present on the maternal but not on the fetal side of the placenta. This arrangement favors hydrolysis of triacylglycerols in the maternal intervillous space while preserving these neutral lipids in fetal blood. Fatty acids transferred to the fetus can be converted to triacylglycerols in the fetal liver.

The placental uptake and use of low-density lipoprotein (LDL) is an alternative mechanism for fetal assimilation of essential fatty acids and amino acids (Chap. 5, p. 109). The LDL binds to specific receptors in the coated-pit regions of the syncytiotrophoblast microvilli. The large—about 250,000 Da—LDL particle is taken up by a process of receptor-mediated endocytosis. The apoprotein and cholesterol esters of LDL are hydrolyzed by lysosomal enzymes in the syncytiotrophoblast to give: (1) cholesterol for progesterone synthesis; (2) free amino acids, including essential amino acids; and (3) essential fatty acids, primarily linoleic acid. Indeed, the concentration of arachidonic acid, which is synthesized from linoleic acid in fetal plasma, is greater than that in maternal plasma. Linoleic acid or arachidonic acid or both must be assimilated from maternal dietary intake.

Amino Acids

The placenta concentrates many amino acids in the syncytiotrophoblast, which are then transferred to the fetal side by diffusion (Lemons, 1979). Based on data from cordocentesis blood samples, the amino acid concentration in umbilical cord plasma is greater than in maternal venous or arterial plasma (Morriss, 1994). Transport system activity is influenced by gestational age and environmental factors. These include heat stress, hypoxia, and under- and overnutrition, as well as hormones such as glucocorticoids, growth hormone, and leptin (Fowden, 2006). Trophoblastic mammalian target of rapamycin complex 1 (mTORC1) regulates placental amino acid transporters and modulates transfer across the placenta (Jansson, 2012). In vivo studies suggest an upregulation of transport for certain amino acids and an increased fetal delivery in women with gestational diabetes associated with fetal overgrowth (Jansson, 2006a).

Proteins

Placental transfer of larger proteins is limited, but there are exceptions. Immunoglobulin G (IgG) crosses the placenta in large amounts via endocytosis and trophoblast Fc receptors. IgG transfer depends on maternal levels of total IgG, gestational age, placental integrity, IgG subclass, and antigen nature (Palmeira, 2012). IgA and IgM of maternal origin are effectively excluded from the fetus (Gitlin, 1972).

Ions and Trace Metals

Iodide transport is clearly attributable to a carrier-mediated, energy-requiring active process. And indeed, the placenta concentrates iodide. The concentrations of zinc in the fetal plasma also are
greater than those in maternal plasma. Conversely, copper levels in fetal plasma are less than those in maternal plasma. This fact is of particular interest because important copper-requiring enzymes are necessary for fetal development.

Placental Sequestration of Heavy Metals
The heavy-metal–binding protein metallothionein-1 is expressed in human syncytiotrophoblast. This protein binds and sequesters a host of heavy metals, including zinc, copper, lead, and cadmium. Lead enters the fetal environment at a level 90 percent of maternal concentrations, but placental transfer of cadmium is limited (Kopp, 2012). The most common source of environmental cadmium is cigarette smoke. Cadmium levels in maternal blood and placenta are increased with maternal smoking, but there is no increase in cadmium transfer into the fetus. In the rat, data suggest that cadmium reduces the number of trophoblasts, leading to poor placental growth (Lee, 2009).

Metallothionein also binds and sequesters copper (Cu\(^{2+}\)) in placental tissue. This accounts for the low levels of Cu\(^{2+}\) in cord blood (Iyengar, 2001). Several enzymes require Cu\(^{2+}\), and its deficiency results in inadequate collagen cross-linking and, in turn, diminished tensile strength of tissues. This may be important because the concentration of cadmium in amnionic fluid is similar to that in maternal blood. The incidence of preterm membrane rupture is increased in women who smoke. It is possible that cadmium provokes metallothionein synthesis in the amnion. This may cause sequestration of Cu\(^{2+}\), a pseudocopper deficiency, and in turn, a weakened amnion.

Calcium and Phosphorus
These minerals also are actively transported from mother to fetus. Calcium is transferred for fetal skeletal mineralization (Olausson, 2012). A calcium-binding protein is produced in placenta. Parathyroid hormone-related protein (PTH-rP), as the name implies, acts as a surrogate PTH in many systems (Chap. 5, p. 105). PTH is not demonstrable in fetal plasma. However, PTH-rP is present, suggesting that PTH-rP is the fetal parathormone. The expression of PTH-rP in cytotrophoblasts is modulated by the extracellular concentration of Ca\(^{2+}\) (Hellman, 1992). It seems possible, therefore, that PTH-rP synthesized in decidua, placenta, and other fetal tissues is important in fetal Ca\(^{2+}\) transfer and homeostasis.

Vitamins
The concentration of vitamin A (retinol) is greater in fetal than in maternal plasma and is bound to retinol-binding protein and to prealbumin. Retinol-binding protein is transferred from the maternal compartment across the syncytiotrophoblast. The transport of vitamin C—ascorbic acid—from mother to fetus is accomplished by an energy-dependent, carrier-mediated process. The levels of the principal vitamin D—cholecalciferol—metabolites, including 1,25-dihydroxycholecalciferol, are greater in maternal plasma than are those in fetal plasma. The 1\(\beta\)-hydroxylation of 25-hydroxyvitamin D\(_3\) is known to take place in placenta and in decidua.
In early pregnancy, amnionic fluid is an ultrafiltrate of maternal plasma. By the second trimester, it consists largely of extracellular fluid that diffuses through the fetal skin and thus reflects the composition of fetal plasma (Gilbert, 1993). After 20 weeks, the cornification of fetal skin prevents this diffusion, and amnionic fluid is composed largely of fetal urine. Fetal kidneys start producing urine at 12 weeks, and by 18 weeks, they are producing 7 to 14 mL per day. Fetal urine contains more urea, creatinine, and uric acid than fetal plasma. Amnionic fluid also contains desquamated fetal cells, vernix, lanugo, and various secretions. Because these are hypotonic, the net effect is that amnionic fluid osmolality decreases with advancing gestation. Pulmonary fluid contributes a small proportion of the amnionic volume, and fluid filtering through the placenta accounts for the rest. Aquaporins 8 and 9 play a role in water flow via intramembranous absorption and placental water transfer (Jiang, 2012).

The volume of amnionic fluid at each week is variable (Chap. 11, p. 231). In general, the volume increases by 10 mL per week at 8 weeks and increases to 60 mL per week at 21 weeks, then peaks at 34 weeks (Brace, 1989).

Amnionic fluid serves to cushion the fetus, allowing musculoskeletal development and protecting it from trauma. It also maintains temperature and has a minimal nutritive function. Epidermal growth factor (EGF) and EGF-like growth factors, such as transforming growth factor-\( \beta \), are present in amnionic fluid. Ingestion of fluid into the gastrointestinal tract and inhalation into the lung may promote growth and differentiation of these tissues. Animal studies have shown that pulmonary hypoplasia can be produced by draining amnionic fluid, by chronically draining pulmonary fluid through the trachea, or by physically preventing the prenatal chest excursions that mimic breathing (Adzick, 1984; Alcorn, 1977). Thus, intrapulmonary fluid formation and, at least as important, the alternating egress and retention of fluid in the lungs by breathing movements are essential to normal pulmonary development.

### Cardiovascular System

The fetal circulation is substantially different from that of the adult and functions until birth, when it is required to change dramatically. For example, because fetal blood does not need to enter the pulmonary vasculature to be oxygenated, most of the right ventricular output bypasses the lungs. In addition, the fetal heart chambers work in parallel, not in series, which effectively supplies the brain and heart with more highly oxygenated blood than the rest of the body.

Oxygen and nutrient materials required for fetal growth and maturation are delivered from the placenta by the single umbilical vein (Fig. 7-8). The vein then divides into the ductus venosus and the portal sinus. The ductus venosus is the major branch of the umbilical vein and traverses the liver to enter the inferior vena cava directly. Because it does not supply oxygen to the intervening tissues, it carries well-oxygenated blood directly to the heart. In contrast, the portal sinus carries blood to the hepatic veins primarily on the left side of the liver, and oxygen is extracted. The relatively deoxygenated blood from the liver then flows back into the inferior vena cava, which also receives less oxygenated blood returning from the lower body. Blood flowing to the fetal heart from the inferior vena cava, therefore, consists of an admixture of arterial-like blood that passes directly through the ductus venosus and less well-oxygenated blood that returns from most of the veins below the level of the diaphragm. The oxygen content of blood delivered to the heart from the inferior vena cava is thus lower than that leaving the placenta.
The intricate nature of the fetal circulation is evident. The degree of blood oxygenation in various vessels differs appreciably from that in the postnatal state. aa = arteries; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle; v = vein.

In contrast to postnatal life, the ventricles of the fetal heart work in parallel, not in series. Well-oxygenated blood enters the left ventricle, which supplies the heart and brain, and less oxygenated blood enters the right ventricle, which supplies the rest of the body. These two separate circulations are maintained by the right atrium structure, which effectively directs entering blood to either the left atrium or the right ventricle, depending on its oxygen content. This separation of blood according to its oxygen content is aided by the pattern of blood flow in the inferior vena cava. The well-oxygenated blood tends to course along the medial aspect of the inferior vena cava and the less oxygenated blood flows along the lateral vessel wall. This aids their shunting into opposite sides of the heart. Once this blood enters the right atrium, the configuration of the upper interatrial septum—the crista dividens—preferentially shunts the well-oxygenated blood from the medial side of the inferior vena cava through the foramen ovale into the left heart and then to the heart and brain (Dawes, 1962). After these tissues have extracted needed oxygen, the resulting less oxygenated blood returns to the right atrium through the superior vena cava.

The less oxygenated blood coursing along the lateral wall of the inferior vena cava enters the right atrium and is deflected through the tricuspid valve to the right ventricle. The superior vena cava courses inferiorly and anteriorly as it enters the right atrium, ensuring that less well-oxygenated blood returning from the brain and upper body also will be shunted directly to the right ventricle. Similarly, the ostium of the coronary sinus lies just superior to the tricuspid valve so that less oxygenated blood from the heart also returns to the right ventricle. As a result of this blood flow pattern, blood in the right ventricle is 15 to 20 percent less saturated than blood in the left ventricle.

Almost 90 percent of blood exiting the right ventricle is shunted through the ductus arteriosus to the descending aorta. High pulmonary vascular resistance and comparatively lower resistance in the ductus arteriosus and the umbilical-placental vasculature ensure that only about 15 percent of right ventricular output—8 percent of the combined ventricular output—goes to the lungs (Teitel, 1992). Thus, one third of the blood passing through the ductus arteriosus is delivered to the body. The remaining right ventricular output returns to the placenta through the two hypogastric arteries, which distally become the umbilical arteries. In the placenta, this blood picks up oxygen and other nutrients and is recirculated through the umbilical vein.

Circulatory Changes at Birth

After birth, the umbilical vessels, ductus arteriosus, foramen ovale, and ductus venosus normally constrict or collapse. With the functional closure of the ductus arteriosus and the expansion of the lungs, blood leaving the right ventricle preferentially enters the pulmonary vasculature to become oxygenated before it returns to the left heart. Virtually instantaneously, the ventricles, which had worked in parallel in fetal life, now effectively work in series. The more distal portions of the hypogastric arteries, which course from the level of the bladder along the abdominal wall to the umbilical ring and into the cord as the umbilical arteries, undergo atrophy and obliteration within 3 to 4 days after birth. These become the umbilical ligaments, whereas the intraabdominal remnants of the umbilical vein form the ligamentum teres. The ductus venosus constricts by 10 to 96 hours after birth and is anatomically closed by 2 to 3 weeks, resulting in formation of the ligamentum venosum (Clymann, 1981).
Hematological Development

Hemopoiesis

In the early embryo, hemopoiesis is demonstrable first in the yolk sac, followed by the liver and finally bone marrow. The first erythrocytes released into the fetal circulation are nucleated and macrocytic. Mean cell volumes are expressed in femtoliters (fL), and one femtoliter equals one cubic micrometer. The mean cell volume is at least 180 fL in the embryo and decreases to 105 to 115 fL at term. The erythrocytes of aneuploid fetuses generally do not undergo this maturation and maintain high mean cell volumes—130 fL on average (Sipes, 1991). As fetal development progresses, more and more of the circulating erythrocytes are smaller and nonnucleated. With fetal growth, both the blood volume in the common fetoplacental circulation and hemoglobin concentration increase. Hemoglobin content of fetal blood rises to approximately 12 g/dL at midpregnancy and to 18 g/dL at term (Walker, 1953). Because of their large size, fetal erythrocytes have a short life span, which progressively lengthens to approximately 90 days at term (Pearson, 1966). As a consequence, red blood cell production is increased. Reticulocytes are initially present at high levels, but decrease to 4 to 5 percent of the total at term. Fetal erythrocytes differ structurally and metabolically from those of the adult. They are more deformable, which serves to offset their higher viscosity. They also contain several enzymes with appreciably different activities (Smith, 1981).

Erythropoiesis is controlled primarily by fetal erythropoietin because maternal erythropoietin does not cross the placenta. Fetal hormone production is influenced by testosterone, estrogen, prostaglandins, thyroid hormone, and lipoproteins (Stockman, 1992). Serum erythropoietin levels increase with fetal maturity. Although the exact production site is disputed, the fetal liver appears to be an important source until renal production begins. There is a close correlation between the erythropoietin concentration in amnionic fluid and that in umbilical venous blood obtained by cordocentesis. After birth, erythropoietin normally may not be detectable for up to 3 months.

In contrast, platelet production reaches stable levels by mid-pregnancy, although there is some variation across gestation (Fig. 7-9). The fetal and neonatal platelet count is subject to various agents as discussed in Chapter 15 (p. 313).
Platelet counts by gestational age obtained the first day of life. Mean values and 5th and 95th percentiles are shown. (Data from Christensen, 2012.)

Fetoplacental Blood Volume
Although precise measurements of human fetoplacental blood volume are lacking, Usher and associates (1963) reported values in term normal newborns to average 78 mL/kg when immediate cord clamping was conducted. Gruenwald (1967) found the fetal blood volume contained in the placenta after prompt cord clamping to average 45 mL/kg of fetal weight. Thus, fetoplacental blood volume at term is approximately 125 mL/kg of fetal weight.

Fetal Hemoglobin
This tetrameric protein is composed of two copies of two different peptide chains, which determine the type of hemoglobin produced. Normal adult hemoglobin A is made of α and β chains. During embryonic and fetal life, various α and β chain precursors are produced. This results in the serial production of several different embryonic hemoglobins. Genes for β-type chains are on chromosome 11 and for α-type chains on chromosome 16. This sequence is shown in Figure 7-10. Each of these genes is turned on and then off during fetal life, until the α and β genes, which direct the production of hemoglobin A, are permanently activated.
The timing of the production of each of these early hemoglobins corresponds to the site of hemoglobin production. Fetal blood is first produced in the yolk sac, where hemoglobins Gower 1, Gower 2, and Portland are made. Erythropoiesis then moves to the liver, where fetal hemoglobin F is produced. When hemopoiesis finally moves to the bone marrow, adult-type hemoglobin A appears in fetal red blood cells and is present in progressively greater amounts as the fetus matures (Pataryas, 1972).

The final adult version of the α chain is produced exclusively by 6 weeks. After this, there are no functional alternative versions. If an α-gene mutation or deletion occurs, there is no alternate α-type chain that could substitute to form functional hemoglobin. In contrast, at least two versions of the β chain—δ and γ—remain in production throughout fetal life and beyond. In the case of a β-gene mutation or deletion, these two other versions of the β chain often continue to be produced, resulting in hemoglobin A₂ or hemoglobin F, which substitute for the abnormal or missing hemoglobin.

Genes are turned off by methylation of their control region, which is discussed in Chapter 13 (p. 272). In some situations, methylation does not occur. For example, in newborns of diabetic women, hemoglobin F may persist due to hypomethylation of the γ gene (Perrine, 1988). With sickle-cell anemia, the γ gene remains unmethylated, and large quantities of fetal hemoglobin continue to be produced (Chap. 56, p. 1108). Increased hemoglobin F levels are associated with fewer sickle-cell disease symptoms, and pharmacological modification of these levels by hemoglobin F-inducing drugs is one approach to disease treatment (Trompeter, 2009).

There is a functional difference between hemoglobins A and F. At any given oxygen tension and at identical pH, fetal erythrocytes that contain mostly hemoglobin F bind more oxygen than do those that contain nearly all hemoglobin A (Fig. 47-2, p. 945). This is because hemoglobin A binds 2,3-diphosphoglycerate (2,3-DPG) more avidly than does hemoglobin F, thus lowering the affinity of hemoglobin A for oxygen (De Verdier, 1969). During pregnancy, maternal 2,3-DPG levels are
increased, and because fetal erythrocytes have lower concentrations of 2,3-DPG, the latter has increased oxygen affinity.

The amount of hemoglobin F in fetal erythrocytes begins to decrease in the last weeks of pregnancy. At term, approximately three fourths of total hemoglobin is hemoglobin F. During the first 6 to 12 months of life, the hemoglobin F proportion continues to decrease and eventually reaches the low levels found in adult erythrocytes. Glucocorticosteroids mediate the switch from fetal to adult hemoglobin, and the effect is irreversible (Zitnik, 1995).

Coagulation Factors

There are no embryonic forms of the various hemostatic proteins. With the exception of fibrinogen, the fetus starts producing normal, adult-type procoagulant, fibrinolytic, and anticoagulant proteins by 12 weeks. Because they do not cross the placenta, their concentrations at birth are markedly below the levels that develop within a few weeks of life (Corrigan, 1992). In normal neonates, the levels of factors II, VII, IX, X, and XI, as well as those of prekallikrein, protein S, protein C antithrombin, and plasminogen, are all approximately 50 percent of adult levels. In contrast, levels of factors V, VIII, XIII, and fibrinogen are closer to adult values (Saracco, 2009). Without prophylactic treatment, the vitamin K-dependent coagulation factors usually decrease even further during the first few days after birth. This decline is amplified in breast-fed infants and may lead to newborn hemorrhage (Chap. 33, p. 644).

Fetal fibrinogen, which appears as early as 5 weeks, has the same amino acid composition as adult fibrinogen but has different properties (Klagsbrun, 1988). It forms a less compressible clot, and the fibrin monomer has a lower degree of aggregation (Heimark, 1988). Plasma fibrinogen levels at birth are less than those in nonpregnant adults, however, the protein is functionally more active than adult fibrinogen (Ignjatovic, 2011).

Levels of functional fetal factor XIII—fibrin-stabilizing factor—are significantly reduced compared with those in adults (Henriksson, 1974). Nielsen (1969) described low levels of plasminogen and increased fibrinolytic activity in cord plasma compared with that of maternal plasma. Platelet counts in cord blood are in the normal range for nonpregnant adults (see Fig. 7-9).

Despite this relative reduction in procoagulants, the fetus appears to be protected from hemorrhage because fetal bleeding is rare. Excessive bleeding does not usually occur even after invasive fetal procedures such as cordocentesis. Ney and coworkers (1989) have shown that amnionic fluid thromboplastins and a factor(s) in Wharton jelly combine to aid coagulation at the umbilical cord puncture site.

Various thrombophilias may cause thromboses and pregnancy complications in adults (Chap. 52, p. 1029). If the fetus inherits one of these mutations, thrombosis and infarction can develop in the placenta or in fetal organs. This is usually seen with homozygous inheritance.

Plasma Proteins

Liver enzymes and other plasma proteins are produced by the fetus, and these levels do not correlate with maternal levels (Weiner, 1992). Concentrations of plasma proteins, albumin, lactic dehydrogenase, aspartate aminotransferase, γ-glutamyl transpeptidase, and alanine transferase all increase, whereas prealbumin levels decrease with gestational age (Fryer, 1993). At birth, mean total plasma protein and albumin concentrations in fetal blood are similar to maternal levels (Foley, 1978).
Infections in utero have provided an opportunity to examine mechanisms of the fetal immune response. Evidence of immunological competence has been reported as early as 13 weeks (Kohler, 1973; Stabile, 1988). In cord blood at or near term, the average level for most components is approximately half that of the adult values (Adinolfi, 1977).

In the absence of a direct antigenic stimulus such as infection, fetal plasma immunoglobulins consist almost totally of transferred maternal immunoglobulin G (IgG). Thus, antibodies in the newborn are most often reflective of maternal immunological experiences.

**Immunoglobulin G**

Maternal IgG transport to the fetus begins at approximately 16 weeks and increases thereafter. The bulk of IgG is acquired during the last 4 weeks of pregnancy (Gitlin, 1971). Accordingly, preterm neonates are endowed relatively poorly with protective maternal antibodies. Newborns begin to slowly produce IgG, and adult values are not attained until 3 years of age. In certain situations, the transfer of IgG antibodies from mother to fetus can be harmful rather than protective to the fetus. The classic example is hemolytic disease of the fetus and newborn resulting from D-antigen alloimmunization (Chap. 15, p. 306).

**Immunoglobulin M and A**

In the adult, production of immunoglobulin M (IgM) in response to an antigenic stimulus is superseded in a week or so predominantly by IgG production. In contrast, very little IgM is produced by normal fetuses, and that produced may include antibody to maternal T lymphocytes (Hayward, 1983). With infection, the IgM response is dominant in the fetus and remains so for weeks to months in the newborn. And because IgM is not transported from the mother, any IgM in the fetus or newborn is that which it produced. Increased levels of IgM are found in newborns with congenital infection such as rubella, cytomegalovirus infection, or toxoplasmosis. Serum IgM levels in umbilical cord blood and identification of specific antibodies may be useful in intrauterine infection diagnosis. In infants, adult levels of IgM are normally attained by age 9 months.

Immunoglobulin A (IgA) ingested in colostrum provides mucosal protection against enteric infections. This role as an immune barrier against infection may explain the small amount of fetal secretory IgA found in amnionic fluid (Quan, 1999).

**Lymphocytes and Monocytes**

The immune system develops early. B lymphocytes appear in fetal liver by 9 weeks and in blood and spleen by 12 weeks. T lymphocytes begin to leave the thymus at approximately 14 weeks. Despite this, the newborn responds poorly to immunization, and especially poorly to bacterial capsular polysaccharides. This immature response may be due to either deficient response of newborn B cells to polyclonal activators, or lack of T cells that proliferate in response to specific stimuli (Hayward, 1983). In the newborn, monocytes are able to process and present antigen when tested with maternal antigen-specific T cells. DNA methylation patterns are developmentally regulated during monocyte-macrophage differentiation and contribute to the antiinflammatory phenotype in macrophages (Kim, 2012).

**Skull**

Fetal head size is important because an essential feature of labor is the adaptation between the
head and the maternal bony pelvis. The firm skull is composed of two frontal, two parietal, and two temporal bones, along with the upper portion of the occipital bone and the wings of the sphenoid. These bones are separated by membranous spaces termed sutures (Fig. 7-11).

**FIGURE 7-11** Fetal head at term showing fontanels and sutures.

The most important sutures are the frontal, between the two frontal bones; the sagittal, between the two parietal bones; the two coronal, between the frontal and parietal bones; and the two lambdoid, between the posterior margins of the parietal bones and upper margin of the occipital bone. The term fontanel describes the irregular space enclosed by a membrane at the junction of several sutures (see Fig. 7-11). The greater, or anterior, fontanel is a lozenge-shaped space situated at the junction of the sagittal and the coronal sutures. The lesser, or posterior, fontanel is a small triangular area at the intersection of the sagittal and lambdoid sutures. The localization of these fontanels gives important information concerning the presentation and position of the fetus during labor.

It is customary to measure certain critical diameters and circumferences of the newborn head (Fig. 7-12). These include:
1. The occipitofrontal (11.5 cm), which follows a line extending from a point just above the root of the nose to the most prominent portion of the occipital bone.

2. The biparietal (9.5 cm), the greatest transverse diameter of the head, which extends from one parietal boss to the other.

3. The bitemporal (8.0 cm), which is the greatest distance between the two temporal sutures.

4. The occipitomental (12.5 cm), which extends from the chin to the most prominent portion of the occiput.

5. The suboccipitobregmatic (9.5 cm), which follows a line drawn from the middle of the large fontanel to the undersurface of the occipital bone where it joins the neck.

The greatest circumference of the head, which corresponds to the plane of the occipitofrontal diameter, averages 34.5 cm, a size too large to fit through the pelvis. The smallest circumference, corresponding to the plane of the suboccipitobregmatic diameter, is 32 cm. The cranial bones are normally connected only by a thin fibrous tissue layer. This allows considerable shifting or sliding of each bone to accommodate the size and shape of the maternal pelvis. This process is termed molding. The head position and degree of skull ossification result in a spectrum of cranial plasticity. In some cases, this contributes to fetopelvic disproportion, a leading indication for cesarean delivery (Chap. 23, p. 463).

Central Nervous System and Spinal Cord

Brain Development

There is a steady gestational-age-related change in the fetal brain appearance so that it is possible to identify fetal age from its external appearance (Dolman, 1977). Neuronal proliferation and
migration proceed along with gyral growth and maturation (Fig. 7-13). Sequential maturation studies have characterized the developing fetal brain imaged using magnetic resonance (MR) imaging (Fig. 10-41, p. 224). (Manganaro, 2007). Recent studies also using MR imaging have quantified development of subcortical brain structures from 12 to 22 weeks (Meng, 2012). Myelination of the ventral roots of the cerebrospinal nerves and brainstem begins at approximately 6 months, but most myelination occurs after birth. This lack of myelin and incomplete skull ossification permit fetal brain structure to be seen with sonography throughout gestation.

**FIGURE 7-13** Neuronal proliferation and migration are complete at 20 to 24 weeks. During the second half of gestation, organizational events proceed with gyral formation and proliferation, differentiation, and migration of cellular elements. Approximate gestational ages are listed. **A.** 20 weeks. **B.** 35 weeks. **C.** 40 weeks.

**Spinal Cord and Sensory Organs**
The spinal cord extends along the entire length of the vertebral column in the embryo, but after that it grows more slowly. By 24 weeks, the spinal cord extends to S1, at birth to L3, and in the adult to L1. Spinal cord myelination begins at midgestation and continues through the first year of life. Synaptic function is sufficiently developed by the eighth week to demonstrate flexion of the neck and trunk (Temiras, 1968). During the third trimester, integration of nervous and muscular function proceeds rapidly.

The internal, middle, and external components of the ear are well developed by midpregnancy (see Fig. 7-2).

**Gastrointestinal System**
Swallowing begins at 10 to 12 weeks, coincident with the ability of the small intestine to undergo peristalsis and transport glucose actively (Koldovsky, 1965; Miller, 1982). Much of the water in swallowed fluid is absorbed, and unabsorbed matter is propelled to the lower colon (Fig. 7-14). It is not clear what stimulates swallowing, but the fetal neural analogue of thirst, gastric emptying, and change in the amnionic fluid composition are potential factors (Boyle, 1992). The fetal taste buds may play a role because saccharin injected into amnionic fluid increases swallowing, whereas injection of a noxious chemical inhibits it (Liley, 1972).

Figure 7-14 Radiograph of a 115-g fetus at about 16 weeks’ gestational age showing radiopaque dye in the lungs, esophagus, stomach, and entire intestinal tract after injection into the amnionic cavity 26 hours before delivery. These reflect inhalation as well as active swallowing of amnionic fluid. (From Davis, 1946, with permission.)

Fetal swallowing appears to have little effect on amnionic fluid volume early in pregnancy because the volume swallowed is small compared with the total. Late in pregnancy, however, amnionic fluid regulation is substantially affected by fetal swallowing. For example, if swallowing is inhibited, hydramnios is common (Chap. 11, p. 233). Term fetuses swallow between 200 and 760 mL per day—an amount comparable to that of the neonate (Pritchard, 1966).

Hydrochloric acid and some digestive enzymes are present in the stomach and small intestine in
very small amounts in the early fetus. Intrinsic factor is detectable by 11 weeks, and pepsinogen by 16 weeks. The preterm neonate, depending on the gestational age when born, may have transient deficiencies of these enzymes (Lebenthal, 1983).

Stomach emptying appears to be stimulated primarily by volume. Movement of amniotic fluid through the gastrointestinal system may enhance growth and development of the alimentary canal. That said, other regulatory factors likely are involved because anencephalic fetuses, in whom swallowing is limited, often have normal amniotic fluid volumes and normal-appearing gastrointestinal tracts. Gitlin (1974) demonstrated that late in pregnancy, approximately 800 mg of soluble protein is ingested daily by the fetus.

Several anomalies can affect normal fetal gastrointestinal function. Hirschsprung disease—known also as congenital aganglionic megacolon, prevents the bowel from undergoing parasympathetic-mediated relaxation and thus from emptying normally (Watkins, 1992). It may be recognized prenatally by grossly enlarged bowel during sonography. Obstructions such as duodenal atresia, megacystis-microcolon syndrome, or imperforate anus can also prevent normal bowel emptying. Meconium ileus, commonly found with fetal cystic fibrosis, is bowel obstruction caused by thick, viscid meconium that blocks the distal ileum.

### Meconium

Fetal bowel contents consist of various products of secretion, such as glycerophospholipids from the lung, desquamated fetal cells, lanugo, scalp hair, and vernix. It also contains undigested debris from swallowed amniotic fluid. The dark greenish-black is caused by pigments, especially biliverdin. Meconium can pass from normal bowel peristalsis in the mature fetus or from vagal stimulation. It can also pass when hypoxia stimulates arginine vasopressin (AVP) release from the fetal pituitary gland. AVP stimulates colonic smooth muscle to contract, resulting in intraamnionic defecation (DeVane, 1982; Rosenfeld, 1985).

### Liver

Serum liver enzyme levels increase with gestational age. However, the fetal liver has a gestational-age-related diminished capacity for converting free unconjugated bilirubin to conjugated bilirubin (Chap. 33, p. 644). Because the life span of normal fetal macrocytic erythrocytes is shorter than that of adult erythrocytes, relatively more unconjugated bilirubin is produced. As noted, the fetal liver conjugates only a small fraction, and this is excreted into the intestine and ultimately oxidized to biliverdin. Most of the unconjugated bilirubin is excreted into the amniotic fluid after 12 weeks and transferred across the placenta (Bashore, 1969).

Importantly, placental transfer is bidirectional. Thus, a pregnant woman with severe hemolysis from any cause has excess unconjugated bilirubin that readily passes to the fetus and then into the amniotic fluid. Conversely, conjugated bilirubin is not exchanged to any significant degree between mother and fetus.

Most fetal cholesterol is from hepatic synthesis, which satisfies the large demand for LDL cholesterol by the fetal adrenal glands. Hepatic glycogen is present in low concentration during the second trimester, but near term there is a rapid and marked increase to levels two to three times those in the adult liver. After birth, glycogen content falls precipitously.

### Pancreas

Insulin-containing granules can be identified by 9 to 10 weeks, and insulin is detectable in fetal plasma at 12 weeks (Adam, 1969). The pancreas responds to hyperglycemia by secreting insulin.
Glucagon has been identified in the fetal pancreas at 8 weeks. In the adult rhesus monkey, hypoglycemia and infused alanine cause an increase in maternal glucagon levels. Although, similar stimuli do not evoke a fetal response in the human, by 12 hours after birth, the newborn is capable of responding (Chez, 1975). At the same time, however, fetal pancreatic α cells do respond to L-dopa infusions (Epstein, 1977). Therefore, nonresponsiveness to hypoglycemia is likely the consequence of failure of glucagon release rather than inadequate production. This is consistent with developmental expression of pancreatic genes in the fetus (Mally, 1994).

Most pancreatic enzymes are present by 16 weeks. Trypsin, chymotrypsin, phospholipase A, and lipase are found in the 14-week fetus, and their concentrations increase with gestation (Werlin, 1992). Amylase has been identified in amnionic fluid at 14 weeks (Davis, 1986). The exocrine function of the fetal pancreas is limited. Physiologically important secretion occurs only after stimulation by a secretagogue such as acetylcholine, which is released locally after vagal stimulation (Werlin, 1992). Cholecystokinin normally is released only after protein ingestion and thus ordinarily would not be found in the fetus.

**Urinary System**

Two primitive urinary systems—the pronephros and the mesonephros—precede the development of the metanephros, which forms the final kidney (Chap. 3, p. 36). The pronephros has involuted by 2 weeks, and the mesonephros is producing urine at 5 weeks and degenerates by 11 to 12 weeks. Failure of these two structures either to form or to regress may result in anomalous urinary system development. Between 9 and 12 weeks, the ureteric bud and the nephrogenic blastema interact to produce the metanephros. The kidney and ureter develop from intermediate mesoderm. The bladder and urethra develop from the urogenital sinus. The bladder also develops in part from the allantois.

By week 14, the loop of Henle is functional and reabsorption occurs (Smith, 1992). New nephrons continue to be formed until 36 weeks. In preterm neonates, their formation continues after birth. Although the fetal kidneys produce urine, their ability to concentrate and modify the pH is limited even in the mature fetus. Fetal urine is hypotonic with respect to fetal plasma and has low electrolyte concentrations.

Renal vascular resistance is high, and the filtration fraction is low compared with values in later life (Smith, 1992). Fetal renal blood flow and thus urine production are controlled or influenced by the renin-angiotensin system, the sympathetic nervous system, prostaglandins, kallikrein, and atrial natriuretic peptide. The glomerular filtration rate increases with gestational age from less than 0.1 mL/min at 12 weeks to 0.3 mL/min at 20 weeks. In later gestation, the rate remains constant when corrected for fetal weight (Smith, 1992). Hemorrhage or hypoxia generally results in a decrease in renal blood flow, glomerular filtration rate, and urine output.

Urine usually is found in the bladder even in small fetuses. The fetal kidneys start producing urine at 12 weeks. By 18 weeks, they are producing 7 to 14 mL/day, and at term, this increases to 27 mL/hr or 650 mL/day (Wladimiroff, 1974). Maternally administered furosemide increases fetal urine formation, whereas uteroplacental insufficiency, fetal-growth restriction, and other types of fetal disorders decrease it. Obstruction of the urethra, bladder, ureters, or renal pelves can damage renal parenchyma and distort fetal anatomy. With urethral obstruction, the bladder may become sufficiently distended that it ruptures or dystocia results. Kidneys are not essential for survival in utero, but are important in the control of amnionic fluid composition and volume. Thus, abnormalities that cause chronic anuria are usually accompanied by oligohydramnios and
pulmonary hypoplasia. Pathological correlates and prenatal therapy of urinary tract obstruction are discussed in Chapter 16 (p. 330).

**Lung Development**

Lung maturation and the biochemical indices of functional fetal lung maturity are of considerable interest to the obstetrician. Morphological or functional immaturity at birth leads to the development of the respiratory distress syndrome (Chap. 34, p. 653). A sufficient amount of surface-active materials—collectively referred to as surfactant—in the amniotic fluid is evidence of fetal lung maturity. As Liggins (1994) emphasized, however, the structural and morphological maturation of fetal lung also is extraordinarily important to proper lung function.

**Anatomical Maturation**

Like the branching of a tree, lung development proceeds along an established timetable that apparently cannot be hastened by antenatal or neonatal therapy. The limits of viability appear to be determined by the usual process of pulmonary growth. There are four essential lung development stages as described by Moore (2013). First, the pseudoglandular stage entails growth of the intrasegmental bronchial tree between 6 and 16 weeks. During this period, the lung looks microscopically like a gland. Second, during the canalicular stage, from 16 to 26 weeks, the bronchial cartilage plates extend peripherally. Each terminal bronchiole gives rise to several respiratory bronchioles, and each of these in turn divides into multiple saccular ducts. Next, the terminal sac stage begins at 26 weeks. During this stage, respiratory bronchioles give rise to primitive pulmonary alveoli—the terminal sacs. Last, the alveolar stage begins at 32 weeks, although the exact transition from the terminal sac stage is unclear. During the alveolar stage, the alveolar epithelial lining thins to improve gas exchange. Simultaneously, an extracellular matrix develops from proximal to distal lung segments until term. An extensive capillary network is built, the lymph system forms, and type II pneumocytes begin to produce surfactant. At birth, only approximately 15 percent of the adult number of alveoli is present. Thus, the lung continues to grow, adding more alveoli for up to 8 years.

Various insults can upset this process, and their timing determines the sequelae. With fetal renal agenesis, for example, there is no amniotic fluid at the beginning of lung growth, and major defects occur in all three stages. A fetus with membrane rupture before 20 weeks and subsequent oligohydramnios usually exhibits nearly normal bronchial branching and cartilage development but has immature alveoli. Membrane rupture after 24 weeks may have little long-term effect on pulmonary structure.

**Pulmonary Surfactant**

After the first breath, the terminal sacs must remain expanded despite the pressure imparted by the tissue-to-air interface, and surfactant keeps them from collapsing. Surfactant is formed in type II pneumocytes that line the alveoli. These cells are characterized by multivesicular bodies that produce the lamellar bodies in which surfactant is assembled. During late fetal life, at a time when the alveolus is characterized by a water-to-tissue interface, the intact lamellar bodies are secreted from the lung and swept into the amniotic fluid during respiration-like movements that are termed fetal breathing. At birth, with the first breath, an air-to-tissue interface is produced in the lung alveolus. Surfactant uncoils from the lamellar bodies, and it then spreads to line the alveolus to prevent alveolar collapse during expiration. Thus, it is the capacity for fetal lungs to produce surfactant, and not the actual laying down of this material in the lungs in utero, that establishes lung
**Surfactant Composition.** Gluck and associates (1967, 1970, 1972) and Hallman and coworkers (1976) found that approximately 90 percent of surfactant dry weight is lipid. Proteins account for the other 10 percent. Approximately 80 percent of the glycerophospholipids are phosphatidylcholines (lecithins). The principal active component of surfactant is a specific lecithin—dipalmitoylphosphatidylcholine (DPPC or PC)—which accounts for nearly 50 percent. Phosphatidylglycerol (PG) accounts for another 8 to 15 percent. Its precise role is unclear because newborns without phosphatidylglycerol usually do well. The other major constituent is phosphatidylinositol (PI). The relative contributions of each component are shown in Figure 7-15.

![Figure 7-15](image_url) Relation between the levels of lecithin, or dipalmitoylphosphatidylcholine (PC), phosphatidylinositol (PI), and phosphatidylglycerol (PG) in amniotic fluid as a function of gestational age.

**Surfactant Synthesis.** Biosynthesis takes place in the type II pneumocytes. The apoproteins are produced in the endoplasmic reticulum, and the glycerophospholipids are synthesized by cooperative interactions of several cellular organelles. Phospholipid is the primary surface tension-lowering component of surfactant, whereas the apoproteins aid the forming and reforming of a surface film. The surface properties of the surfactant phospholipids are determined principally by the composition and degree of saturation of their long-chain fatty acids.

The major apoprotein is surfactant A (SP-A), which is a glycoprotein with a molecular weight of 28,000 to 35,000 Da (Whitsett, 1992). It is synthesized in the type II cells, and its content in amniotic fluid increases with gestational age and fetal lung maturity. SP-A may also play a role in the onset of parturition (Mendelson, 2005). Synthesis of SP-A is increased by treatment of fetal lung tissue with cyclic adenosine monophosphate (AMP) analogues, epidermal growth factors, and triiodothyronine. Increased apoprotein synthesis precedes surfactant glycerophospholipid synthesis.

SP-A gene expression is demonstrable by 29 weeks (Snyder, 1988). There are two separate
genes on chromosome 10. These are \( SP-A1 \) and \( SP-A2 \), and their regulation is distinctive and different (McCormick, 1994). Specifically, cyclic AMP is more important in \( SP-A2 \) expression, whereas dexamethasone decreases \( SP-A2 \) expression.

Several smaller apoproteins such as \( SP-B \) and \( SP-C \) are likely important in optimizing the action of surfactant. For example, deletions in \( SP-B \) gene are incompatible with survival despite production of large amounts of surfactant.

**Corticosteroids and Fetal Lung Maturation.** Since Liggins (1969) first observed lung maturation in lamb fetuses given glucocorticosteroids before preterm delivery, many suggested that fetal cortisol stimulates lung maturation and surfactant synthesis. It is unlikely that corticosteroids are the only stimulus for augmented surfactant formation. There is evidence, however, that glucocorticosteroids administered at certain critical times during gestation improve fetal lung maturation. The use of betamethasone and dexamethasone to accelerate fetal lung maturity, as well as neonatal replacement surfactant therapy, is discussed in Chapter 34 (p. 653).

**Breathing**

Within a few minutes after birth, the respiratory system must provide oxygen as well as eliminate carbon dioxide. Respiratory muscles develop early, and fetal chest wall movements are detected by sonography as early as 11 weeks (Boddy, 1975). From the beginning of the fourth month, the fetus is capable of respiratory movement sufficiently intense to move amniotic fluid in and out of the respiratory tract.

---

**Endocrine Gland Development**

**Pituitary Gland**

The fetal endocrine system is functional for some time before the central nervous system reaches maturity (Mulchahey, 1987). The anterior pituitary gland develops from oral ectoderm—Rathke pouch, whereas the posterior pituitary gland derives from neuroectoderm.

**Anterior and Intermediate Lobes.** The adenohypophysis, or anterior pituitary, differentiates into five cell types that secrete six protein hormones: (1) lactotropes produce prolactin—PRL; (2) somatotropes produce growth hormone—GH; (3) corticotropes produce corticotropin—ACTH; (4) thyrotropes produce thyrotropin or thyroid-stimulating hormone—TSH; and (5) gonadotropes produce luteinizing hormone—LH and follicle-stimulating hormone—FSH.

ACTH is first detected in the fetal pituitary gland at 7 weeks, and GH and LH have been identified by 13 weeks. By the end of the 17th week, the fetal pituitary gland synthesizes and stores all pituitary hormones. Moreover, the fetal pituitary is responsive to hormones and is capable of secreting these early in gestation (Grumbach, 1974). The fetal pituitary secretes \( \beta \)-endorphin, and cord blood levels of \( \beta \)-endorphin and \( \beta \)-lipotropin increase with fetal \( P_{CO_2} \) (Browning, 1983).

There is a well-developed intermediate lobe in the fetal pituitary gland. The cells of this structure begin to disappear before term and are absent from the adult pituitary. The principal secretory products of the intermediate lobe cells are \( \alpha \)-melanocyte—stimulating hormone (\( \alpha \)-MSH) and \( \beta \)-endorphin.

**Neurohypophysis.** The posterior pituitary gland or neurohypophysis is well developed by 10 to 12 weeks, and oxytocin and arginine vasopressin (AVP) are demonstrable. Both hormones probably
function in the fetus to conserve water by actions largely at the lung and placenta rather than kidney. AVP levels in umbilical cord plasma are strikingly higher than maternal levels (Chard, 1971; Polin, 1977). Elevated fetal blood AVP appears to be associated with fetal stress (DeVane, 1982).

**Thyroid Gland**

The pituitary–thyroid system is functional by the end of the first trimester. The thyroid gland is able to synthesize hormones by 10 to 12 weeks, and thyrotropin, thyroxine, and thyroxine-binding globulin (TBG) have been detected in fetal serum as early as 11 weeks (Ballabio, 1989). The placenta actively concentrates iodide on the fetal side, and by 12 weeks and throughout pregnancy, the fetal thyroid concentrates iodide more avidly than does the maternal thyroid. Thus, maternal administration of either radioiodide or appreciable amounts of ordinary iodide is hazardous after this time. Normal fetal levels of free thyroxine (T₄), free triiodothyronine (T₃), and thyroxine-binding globulin increase steadily throughout gestation (Ballabio, 1989). Compared with adult levels, by 36 weeks, fetal serum concentrations of TSH are higher, total and free T₃ concentrations are lower, and T₄ is similar. This suggests that the fetal pituitary may not become sensitive to feedback until late in pregnancy (Thorpe-Beeston, 1991; Wenstrom, 1990).

Fetal thyroid hormone plays a role in the normal development of virtually all fetal tissues, especially the brain. Its influence is illustrated by congenital hyperthyroidism, which occurs when maternal thyroid-stimulating antibody crosses the placenta to stimulate the fetal thyroid. These fetuses develop tachycardia, hepatosplenomegaly, hematological abnormalities, craniosynostosis, and growth restriction. As children, they have perceptual motor difficulties, hyperactivity, and reduced growth (Wenstrom, 1990). Neonatal effects of fetal thyroid deficiency are discussed in Chapter 58 (p. 1147).

The placenta prevents substantial passage of maternal thyroid hormones to the fetus by rapidly deiodinating maternal T₄ and T₃ to form reverse T₃, a relatively inactive thyroid hormone (Vulsma, 1989). Several antithyroid antibodies cross the placenta when present in high concentrations. Those include the long-acting thyroid stimulators (LATS), LATS-protector (LATS-P), and thyroid-stimulating immunoglobulin (TSI). It was previously believed that normal fetal growth and development, which occurred despite fetal hypothyroidism, provided evidence that T₄ was not essential for fetal growth. It is now known, however, that growth proceeds normally because small quantities of maternal T₄ prevent antenatal cretinism in fetuses with thyroid agenesis (Vulsma, 1989). The fetus with congenital hypothyroidism typically does not develop stigmata of cretinism until after birth. Because administration of thyroid hormone will prevent this, all newborns are tested for high serum levels of TSH (Chap. 32, p. 631).

Immediately after birth, there are major changes in thyroid function and metabolism. Cooling to room temperature evokes sudden and marked increase in TSH secretion. This in turn causes a progressive increase in serum T₄ levels that are maximal 24 to 36 hours after birth. There are nearly simultaneous elevations of serum T₃ levels.

**Adrenal Glands**

The fetal adrenal glands are much larger in relation to total body size than in adults. The bulk is made up of the inner or fetal zone of the adrenal cortex and involutes rapidly after birth. This zone is scant to absent in rare instances in which the fetal pituitary gland is congenitally absent. The function of the fetal adrenal glands is discussed in detail in Chapter 5 (p. 108).
Embryology of Uterus and Oviducts

The uterus and tubes arise from the müllerian ducts, which first appear near the upper pole of the urogenital ridge in the fifth week of embryonic development (Fig. 7-16). This ridge is composed of the mesonephros, gonad, and associated ducts. The first indication of müllerian duct development is a thickening of the coelomic epithelium at approximately the level of the fourth thoracic segment. This becomes the fimbriated extremity of the fallopian tube, which invaginates and grows caudally to form a slender tube at the lateral edge of the urogenital ridge. In the sixth week, the growing tips of the two müllerian ducts approach each other in the midline. One week later, they reach the urogenital sinus. At that time, the two müllerian ducts fuse to form a single canal at the level of the inguinal crest. This crest gives rise to the gubernaculum, which is the primordium of the round ligament.

Figure 7-16 A. Cross section of an embryo at 4 to 6 weeks. B. Large ameboid primordial germ.
cells migrate (arrows) from the yolk sac to the area of germinal epithelium, within the genital ridge. **C.** Migration of sympathetic cells from the spinal ganglia to a region above the developing kidney. (Redrawn from Moore, 1988.)

Thus, the upper ends of the müllerian ducts produce the fallopian tubes, and the fused parts give rise to the uterus. The vaginal canal is not patent throughout its entire length until the sixth month (Koff, 1933). Because of the clinical importance of anomalies that arise from abnormal fusion and dysgenesis of these structures, their embryogenesis is discussed in detail in Chapter 3 (p. 37).

---

**Embryology of the Ovaries**

At approximately 4 weeks, gonads form on the ventral surface of the embryonic kidney at a site between the eighth thoracic and fourth lumbar segments. The coelomic epithelium thickens, and clumps of cells bud off into the underlying mesenchyme. This circumscribed area is called the **germinal epithelium.** By the fourth to sixth week, however, there are many large ameboid cells in this region that have migrated into the embryo body from the yolk sac (see Fig. 7-16). These primordial germ cells are distinguishable by their large size and certain morphological and cytochemical features.

When the primordial germ cells reach the genital area, some enter the germinal epithelium and others mingle with groups of cells that proliferate from it or lie in the mesenchyme. By the end of the fifth week, rapid division of all these cell types results in development of a prominent genital ridge. The ridge projects into the body cavity medially to a fold in which there are the mesonephric (wolffian) and paramesonephric (müllerian) ducts (Fig. 7-17). By the seventh week, this ridge is separated from the mesonephros except at the narrow central zone, the future hilum, where blood vessels enter. At this time, the sexes can be distinguished, because the testes can be recognized by well-defined radiating strands of cells termed sex cords. These cords are separated from the germinal epithelium by mesenchyme that is to become the tunica albuginea. The sex cords, which consist of large germ cells and smaller epithelioid cells derived from the germinal epithelium, develop into the seminiferous tubules and tubuli rete. The latter establishes connection with the mesonephric tubules that develop into the epididymis. The mesonephric ducts become the vas deferens.
In the female embryo, the germinal epithelium proliferates for a longer time. The groups of cells thus formed lie at first in the region of the hilum. As connective tissue develops between them, these appear as sex cords. These cords give rise to the medulla cords and persist for variable times (Forbes, 1942). By the third month, medulla and cortex are defined (see Fig. 7-17). The bulk of the ovary is made up of cortex, a mass of crowded germ and epithelioid cells that show some signs of grouping, but there are no distinct cords as in the testis. Strands of cells extend from the germinal epithelium into the cortical mass, and mitoses are numerous. The rapid succession of mitoses soon reduces germ-cell size to the extent that these no longer are differentiated clearly.
from the neighboring cells. These germ cells are now called oogonia.

By the fourth month, some germ cells in the medullary region begin to enlarge. These are called primary oocytes at the beginning of the growth phase that continues until maturity. During this cell growth period, many oocytes undergo degeneration, both before and after birth. A single layer of flattened follicular cells that were derived originally from the germinal epithelium soon surrounds the primary oocytes. These structures are now called primordial follicles and are seen first in the medulla and later in the cortex. Some follicles begin to grow even before birth, and some are believed to persist in the cortex almost unchanged until menopause.

By 8 months, the ovary has become a long, narrow, lobulated structure that is attached to the body wall along the line of the hilum by the mesovarium. The germinal epithelium has been separated for the most part from the cortex by a band of connective tissue—tunica albuginea. This band is absent in many small areas where strands of cells, usually referred to as cords of Pflüger, are in contact with the germinal epithelium. Among these cords are cells believed by many to be oogonia that resemble the other epithelial cells as a result of repeated mitosis. In the underlying cortex, there are two distinct zones. Superficially, there are nests of germ cells in meiotic synapsis, interspersed with Pflüger cords and strands of connective tissue. In the deeper zone, there are many groups of germ cells in synapsis, as well as primary oocytes, prospective follicular cells, and a few primordial follicles.

---

### Fetal Gender

Theoretically, there should be a primary gender ratio of 1:1 at the time of fertilization because there are equal numbers of X- and Y-bearing spermatozoa. This is not the case, however, and many factors have been shown to contribute to gender ratios at conception. These include differential susceptibility to environmental exposures as well as medical disorders. Also, couples with a large age discrepancy are more likely to have a male offspring (Manning, 1997). Whatever the cause, it is impossible to determine the primary gender ratio because this would require gender assignment to zygotes that fail to cleave, blastocysts that fail to implant, and other early pregnancy losses.

The secondary gender ratio pertains to fetuses that reach viability and is usually held to be approximately 106 males to 100 females. The unbalanced secondary gender ratio is explicable by the loss of more female than male embryo-fetuses during early pregnancy. That said, Davis and colleagues (1998) report a significant decline in male births since 1950 in Denmark, Sweden, The Netherlands, the United States, Germany, Norway, and Finland. Similarly, Allan and associates (1997) reported that male births in Canada since 1970 dropped by 2.2 per 1000 live births.

---

### Gender Assignment at Birth

In the delivery room, parents first want to know the gender of their newborn. If the external genitalia of the newborn are ambiguous, the obstetrician faces a profound dilemma. In these cases, assignment requires knowledge of the karyotypic sex, gonadal sex, hormonal milieu to which the fetus was exposed, exact anatomy, and all possibilities for surgical correction. In the past, newborns with a small or likely insufficient phallus were often assigned to the female gender. Based on what is now known of the role of fetal exposure to hormones in establishing gender preference and behavior, it can be seen why such a policy may have caused gender identity disorder (Slijper, 1998). Thus, it seems best to inform the parents that although their newborn appears healthy, the gender will need to be determined by a series of tests. To develop a plan that can assist in determining the cause of ambiguous genitalia, the mechanisms of normal and abnormal
sexual differentiation must be considered.

Sexual Differentiation

Phenotypic gender differentiation is determined by the chromosomal complement acting in conjunction with gonadal development.

Chromosomal Gender

Genetic gender—XX or XY—is established at fertilization, but for the first 6 weeks, development of male and female embryos is morphologically indistinguishable. The differentiation of the primordial gonad into testis or ovary heralds the establishment of gonadal sex.

Gonadal Gender

As described earlier and shown in Figure 7-16, primordial germ cells that originate in the yolk sac endoderm migrate to the genital ridge to form the indifferent gonad. If a Y chromosome is present, at about 6 weeks after conception, the gonad begins developing into a testis (Simpson, 1997). Testis development is directed by a gene located on the short arm of Y—testis-determining factor (TDF), also called sex-determining region (SRY). This gene encodes a transcription factor that acts to modulate the transcription rate of a number of genes involved in gonadal differentiation. The SRY gene is specific to the Y chromosome and is expressed in the human single-cell zygote upon ovum fertilization. It is not expressed in spermatozoa (Fiddler, 1995; Gustafson, 1994). In addition, testis development requires a dose-dependent sex reversal (DDS) region on the X chromosome, as well as other autosomal genes (Brown, 2005).

The contribution of chromosomal gender to gonadal gender is illustrated by several paradoxical conditions. The incidence of 46,XX phenotypic human males is estimated to be approximately 1 in 20,000 male births (Page, 1985). These infants apparently result from translocation of the Y chromosome fragment containing TDF to the X chromosome during meiosis of male germ cells (George, 1988). Similarly, individuals with XY chromosomes can appear phenotypically female if they carry a mutation in the TDF/SRY gene. There is evidence that genes on the short arm of the X chromosome are capable of suppressing testicular development, despite the presence of the SRY gene. Indeed, this accounts for a form of X-linked recessive gonadal dysgenesis.

The existence of autosomal sex-determining genes is supported by several genetic syndromes in which disruption of an autosomal gene causes, among other things, gonadal dysgenesis. For example, camptomelic dysplasia, localized to chromosome 17, is associated with XY phenotypic sex reversal. Similarly, male pseudohermaphroditism has been associated with a mutation in the Wilms tumor suppressor gene on chromosome 11.

Phenotypic Gender

Urogenital tract development in both sexes is indistinguishable before 8 weeks. Thereafter, development and differentiation of the internal and external genitalia to the male phenotype is dependent on testicular function. In the absence of a testis, female differentiation ensues irrespective of genetic gender. The fundamental experiments to determine the testis role in male sexual differentiation were conducted by the French anatomist Alfred Jost. Ultimately, he established that the induced phenotype is male and that secretions from the gonads are not necessary for female differentiation. Specifically, the fetal ovary is not required for female sexual differentiation. Jost and associates (1973) found that if castration of rabbit fetuses was conducted
before differentiation of the genital anlagen, all newborns were phenotypic females with female external and internal genitalia. Thus, the müllerian ducts developed into uterus, fallopian tubes, and upper vagina.

If fetal castration was conducted before differentiation of the genital anlagen, and thereafter a testis was implanted on one side in place of the removed gonad, the phenotype of all fetuses was male. Thus, the external genitalia of such fetuses were masculinized. On the side of the testicular implant, the wolfian duct developed into the epididymis, vas deferens, and seminal vesicle. With castration, on the side without the implant, the müllerian duct developed but the wolfian duct did not.

Wilson and Gloyna (1970) and Wilson and Lasnitzki (1971) demonstrated that testosterone action was amplified by conversion to 5α-dihydrotestosterone (5α-DHT). In most androgen-responsive tissues, testosterone is converted by 5α-reductase to 5α-DHT. This hormone acts primarily and almost exclusively in the genital tubercle and labioscrotal folds.

**Mechanisms of Gender Differentiation**

Based on these observations, the physiological basis of gender differentiation can be summarized. Genetic gender is established at fertilization. Gonadal gender is determined primarily by factors encoded by genes on the Y chromosome, such as the SRY gene. In a manner not yet understood, differentiation of the primitive gonad into a testis is accomplished.

**Fetal Testicles and Male Sexual Differentiation**

The fetal testis secretes a proteinaceous substance called müllerian-inhibiting substance, a dimeric glycoprotein with a molecular weight of approximately 140,000 Da. It acts locally as a paracrine factor to cause müllerian duct regression. Thus, it prevents the development of uterus, fallopian tube, and upper vagina. Müllerian-inhibiting substance is produced by the Sertoli cells of the seminiferous tubules. Importantly, these tubules appear in fetal gonads before differentiation of Leydig cells, which are the cellular site of testosterone synthesis. Thus, müllerian-inhibiting substance is produced by Sertoli cells even before differentiation of the seminiferous tubules and is secreted as early as 7 weeks. Müllerian duct regression is completed by 9 to 10 weeks, which is before testosterone secretion has commenced. Because it acts locally near its site of formation, if a testis were absent on one side, the müllerian duct on that side would persist, and the uterus and fallopian tube would develop on that side. Female external genital differentiation is complete by 11 weeks, whereas male external genital differentiation is complete by 14 weeks (Sobel, 2004).

**Fetal Testosterone Secretion**

Apparently through stimulation initially by human chorionic gonadotropin (hCG), and later by fetal pituitary LH, the fetal testes secrete testosterone. This hormone acts directly on the wolfian duct to effect the development of the vas deferens, epididymis, and seminal vesicles. Testosterone also enters fetal blood and acts on the external genitalia anlagen. In these tissues, however, testosterone is converted to 5α-DHT to cause virilization of the external genitalia.

**Genital Ambiguity of the Newborn**

Ambiguity of the neonatal genitalia results from excessive androgen action in a fetus that was destined to be female or from inadequate androgen representation for one destined to be male.
Rarely, genital ambiguity indicates true hermaphroditism. Several transcription factors—SOX9, SF1, and WT1, and disruptions of signaling molecules—hedgehog, WNT, cyclin-dependent kinase, and Ras/MAP kinase—cause disorders of sexual development. Examples are congenital adrenal hyperplasia and androgen insensitivity syndrome (Larson, 2012). Abnormalities of gender differentiation causing genital ambiguity can be assigned to one of four clinically defined categories: (1) female pseudohermaphroditism; (2) male pseudohermaphroditism; (3) dysgenetic gonads, including true hermaphroditism; and rarely (4) true hermaphroditism (Low, 2003).

**Category 1: Female Pseudohermaphroditism**

In this condition, müllerian-inhibiting substance is not produced. Androgen exposure is excessive, but variable, for a fetus genetically predestined to be female. The karyotype is 46,XX and ovaries are present. Therefore, by genetic and gonadal gender, all are predestined to be female, and the basic abnormality is androgen excess. Because müllerian-inhibiting substance is not produced, the uterus, fallopian tubes, and upper vagina develop.

If affected fetuses were exposed to a small amount of excess androgen reasonably late in fetal development, the only genital abnormality will be slight to modest clitoral hypertrophy, with an otherwise normal female phenotype.

With somewhat greater androgen exposure, clitoral hypertrophy will be more pronounced, and the posterior labia will fuse. If androgen levels increase earlier in embryonic development, then more severe virilization can be seen. This includes labioscrotal fold formation; development of a urogenital sinus, in which the vagina empties into the posterior urethra; and development of a penile urethra with scrotal formation—the empty scrotum syndrome (Fig. 7-18A).

**FIGURE 7-18** Ambiguous genitalia. A. Female pseudohermaphroditism caused by congenital adrenal hyperplasia. Infant was 46,XX and has severe virilization with scrotal formation without a testis and has a penile urethra. B. Male pseudohermaphroditism caused by incomplete androgen insensitivity syndrome. Infant is 46,XY with external genitalia demonstrating clitoral hypertrophy. C. True hermaphroditism in an infant with 46,XX/46,XY. A hemiscrotum is seen and there are different skin tones on each side. (Photographs contributed by Dr. Lisa Halvorson.)

**Congenital Adrenal Hyperplasia.** This is the most common cause of androgenic excess in fetuses with female pseudohermaphroditism. The hyperplastic glands synthesize defective enzymes that
cause impaired cortisol synthesis. This leads to excessive pituitary ACTH stimulation of the fetal adrenal glands with secretion of large amounts of cortisol precursors, including androgenic prehormones. These prehormones, for example, androstenedione, are converted to testosterone in fetal extraadrenal tissues.

Mutations may involve any of several enzymes, but the most common are steroid 21-hydroxylase, 11β-hydroxylase, and 3β-hydroxysteroid dehydrogenase. Deficiency of the last prevents synthesis of virtually all steroid hormones. Deficiency of either 17β- or 11β-hydroxylase results in increased deoxycorticosterone production to cause hypertension and hypokalemic acidosis. These forms of congenital adrenal hyperplasia thus constitute medical emergencies in the newborn (Fritz, 2011). Currently, 21-hydroxylase deficiency can be diagnosed in utero through molecular fetal DNA analysis. Prenatal maternal dexamethasone administration has been used to reduce fetal genital virilization, however, this is controversial (Miller, 2013; New, 2012). This fetal therapy is discussed in Chapter 16 (p. 323).

**Excessive Androgen from Maternal Sources.** Transfer of androgen from the maternal compartment may arise from the ovaries with hyperreactio luteinalis or theca-lutein cysts or from Leydig cell and Sertoli-Leydig cell ovarian tumors (Chap. 63, p. 1228). In most of these conditions, the female fetus does not become virilized. This is because during most of pregnancy, the fetus is protected from excess maternal androgen by the extraordinary capacity of the syncytiotrophoblast to convert most C_{19}-steroids, including testosterone, to estradiol-17β. The only exception to this generalization is fetal aromatase deficiency, which produces both maternal and fetal virilization (Chap. 5, p. 110). Some drugs also can cause female fetal androgen excess. Most commonly, the drugs implicated are synthetic progestins or anabolic steroids (Chap. 12, p. 249). Importantly, except those with aromatase deficiency, all with female pseudohermaphroditism can be normal, fertile women if the proper diagnosis is made and appropriate and timely treatment initiated.

**Category 2: Male Pseudohermaphroditism**

This is characterized by incomplete and variable androgenic exposure of a fetus predestined to be male. The karyotype is 46,XY, and there are either testes or no gonads. In some cases, incomplete masculinization follows inadequate production of testosterone by the fetal testis. It also may arise from diminished responsiveness of the genital anlage to normal quantities of androgen—including failure of the in situ formation of 5α-DHT in androgen-responsive tissue. Because testes were present for at least some time in embryonic life, müllerian-inhibiting substance is produced. Thus, the uterus, fallopian tubes, and upper vagina do not develop.

Fetal testicular testosterone production may fail if there is an enzymatic defect of steroidogenesis that involves any one of four enzymes in the biosynthetic pathway for testosterone synthesis. Impaired fetal testicular steroidogenesis can also be caused by an abnormality in the LH-hCG receptor and by Leydig cell hypoplasia.

With embryonic testicular regression, the testes regress during embryonic or fetal life, and there is no testosterone production thereafter (Edman, 1977). This results in a phenotypic spectrum that varies from a normal female with absent uterus, fallopian tubes, and upper vagina, to a normal male phenotype with anorchia.

Androgen resistance or deficiencies in androgen responsiveness are caused by an abnormal or absent androgen receptor protein or by enzymatic failure of conversion of testosterone to 5α-DHT in appropriate tissues (Wilson, 1978).
Androgen Insensitivity Syndrome. Formerly called testicular feminization, this is the most extreme form of the androgen resistance syndrome, and there is no tissue responsiveness to androgen. More than 800 mutations that cause this syndrome have been reported in the androgen receptor, which is an eight-exon gene on the long arm of the X chromosome (Hughes, 2012; The Lady Davis Institute for Medical Research, 2013).

These result in a female phenotype with a short, blind-ending vagina, no uterus or fallopian tubes, and no wolffian duct structures. At the expected time of puberty, testosterone levels in affected individuals increase to values for normal men. Nonetheless, virilization does not occur, and even pubic and axillary hair does not develop because of end-organ resistance. Presumably, because of androgen resistance at the level of the brain and pituitary, LH levels also are elevated. In response to high concentrations of LH, there is increased testicular secretion of estradiol-17β compared with that in normal men (MacDonald, 1979). Increased estrogen secretion and absence of androgen responsiveness act in concert to cause feminization in the form of breast development.

Individuals with incomplete androgen insensitivity are slightly responsive to androgen. They usually have modest clitoral hypertrophy at birth (see Fig. 7-18B). And at the expected time of puberty, pubic and axillary hair develops but virilization does not occur. These patients also develop feminine breasts, presumably through the same endocrine mechanisms as in those with the complete form of the disorder (Madden, 1975). Insensitivity may also be due to germline missense mutations in the X-linked androgen-receptor gene in the highly structured DNA and ligand binding domains (Lagarde, 2012).

Another group has been referred to as familial male pseudohermaphroditism, type I (Walsh, 1974). Also commonly referred to as Reifenstein syndrome, it constitutes a spectrum of incomplete genital virilization. Phenotypes can vary from a phenotype similar to that of individuals with incomplete androgen insensitivity to that of a male phenotype with only a bifid scrotum, infertility, and gynecomastia.

The gene encoding the androgen-receptor protein is located on the X chromosome. More than 100 different mutations have been demonstrated. This accounts for the wide variability in androgen responsiveness among persons in whom the androgen-receptor protein is absent or abnormal and for the many different mutations associated with one disorder (McPhaul, 1991; Patterson, 1994).

An alternate form of androgen resistance is caused by 5α-reductase deficiency in androgen-responsive tissues. Because androgen action in the external genitalia anlagen is mediated by 5α-DHT, persons with this enzyme deficiency have external genitalia that are female but with modest clitoral hypertrophy. But because androgen action in the wolffian duct is mediated directly by testosterone, there are well-developed epididymides, seminal vesicles, and vas deferens, and the male ejaculatory ducts empty into the vagina (Walsh, 1974).

Category 3: Dysgenetic Gonads

In affected individuals, karyotype varies and is commonly abnormal. As the name describes, most have abnormally developed gonads, and streak gonads are typically found. As a result, müllerian-inhibiting substance is not produced and fetal androgen exposure is variable. The uterus, fallopian tubes, and upper vagina are present.

The most common form of gonadal dysgenesis is Turner syndrome (46,X). The phenotype is female, but secondary gender characteristics do not develop at the time of expected puberty, and genital infantilism persists. In some persons with dysgenetic gonads, the genitalia are ambiguous, a finding indicating that an abnormal gonad produced androgen, albeit in small amounts, during embryonic and fetal life. Generally, there is mixed gonadal dysgenesis—one example is a
dysgenetic gonad on one side and an abnormal testis or dysontogenetic tumor on the other. Recombinant human growth hormone (hGH) is approved by the Food and Drug Administration for treatment of short stature in Turner syndrome (Chacko, 2012).

**Category 4: True Hermaphroditism**

In most cases, the guidelines for category 3 are met. External genitalia of such a case are shown in Figure 7-18C. In addition, true hermaphrodites have both ovarian and testicular tissues with germ cells for both ova and sperm in the abnormal gonads.

**Preliminary Diagnosis of the Cause of Genital Ambiguity**

A preliminary diagnosis of genital ambiguity can be made at the birth of an affected child. By history, during physical and sonographic examination of the newborn, an experienced examiner can ascertain a number of important findings. These include gonad location, phallus length and diameter, urethral meatus position, degree of labioscrotal fold fusion, and identification of a vagina, vaginal pouch, or urogenital sinus (Fritz, 2011). If the uterus is present, the diagnosis must be female pseudohermaphroditism, testicular or gonadal dysgenesis, or true hermaphroditism. A family history of congenital adrenal hyperplasia is helpful. If the uterus is not present, the diagnosis is male pseudohermaphroditism. Androgen resistance and enzymatic defects in testicular testosterone biosynthesis are often familial.

SCREENING TESTS

The Centers for Disease Control and Prevention defines preconceptional care as “a set of interventions that aim to identify and modify biomedical, behavioral, and social risks to a woman’s health or pregnancy outcome through prevention and management” (Johnson, 2006). The following goals were established for advancing preconceptional care:

1. Improve knowledge, attitudes, and behaviors of men and women related to preconceptional health.
2. Assure that all women of childbearing age receive preconceptional care services—including evidence-based risk screening, health promotion, and interventions—that will enable them to enter pregnancy in optimal health.
3. Reduce risks indicated by a previous adverse pregnancy outcome through interconceptional interventions to prevent or minimize recurrent adverse outcomes.
4. Reduce the disparities in adverse pregnancy outcomes.

The American College of Obstetricians and Gynecologists (2012c) also has reaffirmed the importance of preconceptional and interpregnancy care.

To illustrate potentially modifiable conditions, data that describe the health status of women who gave birth to liveborn infants in the United States in 2004 are reviewed. Table 8-1 demonstrates the high prevalence of many conditions that may be amenable to intervention during the preconceptional and interpregnancy periods (D’Angelo, 2007). To be successful, however, preventative strategies that mitigate these potential pregnancy risks must be provided before conception. By the time most women realize they are pregnant—usually 1 to 2 weeks after the first
missed period—the embryo has already begun to form. Thus, many prevention strategies—for example, folic acid to prevent neural-tube defects—will be ineffective if initiated at this time. Importantly, up to half of all pregnancies are unplanned, and often these are at greatest risk (Cheng, 2009).

<sup>a</sup>Among women who were not trying to become pregnant.

Data from D’Angelo, 2007.

Few randomized trials evaluate preconceptional counseling efficacy, in part because withholding such counseling would be unethical. Also, because pregnancy outcomes are dependent on the interaction of various maternal, fetal, and environmental factors, it is often difficult to ascribe salutary outcomes to a specific intervention (Moos, 2004). There are, however, prospective observational and case-control studies that demonstrate the successes of preconceptional counseling. Moos and coworkers (1996) assessed the effectiveness of a preconceptional counseling program administered during routine health care provision to reduce unintended pregnancies. The 456 counseled women had a 50-percent greater likelihood of subsequent pregnancies that they considered “intended” compared with 309 uncounseled women. Moreover, the counseled group had a 65-percent higher rate of intended pregnancy compared with women who had no health care before pregnancy. There are interesting ethical aspects of paternal
COUNSELING SESSION

Gynecologists, internists, family practitioners, and pediatricians have the best opportunity to provide preventive counseling during periodic health maintenance examinations. The occasion of a negative pregnancy test is also an excellent time for education. Jack and colleagues (1995) administered a comprehensive preconceptional risk survey to 136 such women, and almost 95 percent reported at least one problem that could affect a future pregnancy. These included medical or reproductive problems—52 percent, family history of genetic disease—50 percent, increased risk of human immunodeficiency virus infection—30 percent, increased risk of hepatitis B and illegal substance abuse—25 percent, alcohol use—17 percent, and nutritional risks—54 percent. Counselors should be knowledgeable regarding relevant medical diseases, prior surgery, reproductive disorders, or genetic conditions and must be able to interpret data and recommendations provided by other specialists. If the practitioner is uncomfortable providing guidance, the woman or couple should be referred to an appropriate counselor.

Women presenting specifically for preconceptional evaluation should be advised that information collection may be time consuming depending on the number and complexity of factors that require assessment. The intake evaluation includes a thorough review of the medical, obstetrical, social, and family histories. Useful information is more likely to be obtained by asking specific questions regarding each history and each family member than by asking general, open-ended questions. Some important information can be obtained by questionnaires that address these topics. Answers are reviewed with the couple to ensure appropriate follow-up, including obtaining relevant medical records.

MEDICAL HISTORY

With specific medical conditions, general points include how pregnancy will affect maternal health and how a high-risk condition might affect the fetus. Afterward, advice for improving outcome is provided. Detailed preconceptional information regarding a few conditions is found in the next sections as well as in the other topic-specific chapters of this text.

Diabetes Mellitus

Because maternal and fetal pathology associated with hyperglycemia is well known, diabetes is the prototype of a condition for which preconceptional counseling is beneficial. Diabetes-associated risks to both mother and fetus are discussed in detail in Chapter 57 (p. 1125). Many of these complications can be avoided if glucose control is optimized before conception. The American College of Obstetricians and Gynecologists (2012b) has concluded that preconceptional counseling for women with pregestational diabetes is both beneficial and cost-effective and should be encouraged. The American Diabetes Association has promulgated consensus recommendations for preconceptional care for diabetic women (Kitzmiller, 2008). These guidelines advise that a thorough inventory of disease duration and related complications be obtained and clinical and laboratory examination for end-organ damage be completed. Perhaps most importantly, they
encourage a preconceptional goal of the lowest hemoglobin A\textsubscript{1c} level possible without undue hypoglycemic risk to the mother. In addition to assessing diabetic control during the preceding 6 weeks, hemoglobin A\textsubscript{1c} measurement can also be used to compute risks for major anomalies (Fig. 8-1). Although these data are from women with severe overt diabetes, the incidence of fetal anomalies in women who have gestational diabetes with fasting hyperglycemia is increased fourfold compared with that in normal women (Sheffield, 2002).

![Figure 8-1](image)

**FIGURE 8-1** Relationship between first-trimester glycosylated hemoglobin values and risk for major congenital malformations in 320 women with insulin-dependent diabetes. (Data from Kitzmiller, 1991.)

Such counseling has been shown to be effective. In one review, Leguizamón and associates (2007) identified 12 studies that included more than 3200 pregnancies in women with insulin-dependent diabetes. Of the 1618 women without preconceptional counseling, 8.3 percent had a fetus with a major congenital anomaly, and this compared with a rate of 2.7 percent in the 1599 women who did have counseling. Tripathi and coworkers (2010) compared outcomes in 588 women with pregestational diabetes in whom about half had preconceptional counseling. Those women who received counseling had improved glycemic control before pregnancy and in the first trimester, had higher folate intake rates preconceptionally, and experienced lower rates of adverse outcomes—defined as a perinatal death or major congenital anomaly. These cited benefits are accompanied by reduced health-care costs in diabetic women. From their review, Reece and Homko (2007) found that each $1 expended for a preconceptional care program saved between $1.86 and $5.19 in averted medical costs. Despite such benefits, the proportion of diabetic women receiving preconceptional care is suboptimal. In their study of approximately 300 diabetic women in a managed-care plan, Kim and colleagues (2005) found that only about half had preconceptional counseling. Counseling rates are undoubtedly much lower among uninsured and indigent women.

**Epilepsy**

Women who have epilepsy have an undisputed two- to threefold risk of having infants with structural anomalies compared with unaffected women (Wide, 2004). Some early reports indicated that epilepsy conferred an increased a priori risk for congenital malformations that was
independent of any effects of anticonvulsant treatment. Although more recent publications have largely failed to confirm this increased risk in untreated women, it is difficult to refute entirely because women who are controlled without medication generally have less severe disease (Cassina, 2013). Fried and associates (2004) conducted a metaanalysis of studies comparing epileptic women, both treated and untreated, with controls. In this study, increased malformation rates could only be demonstrated in the offspring of women who had been exposed to anticonvulsant therapy. Veiby and coworkers (2009) used the Medical Birth Registry of Norway to compare pregnancy outcomes in 2861 deliveries by epileptic women with 369,267 control deliveries. They identified an increased malformation risk only in women who were exposed to valproic acid (5.6 percent) and polytherapy (6.1 percent). Untreated women had anomaly rates that were similar to those of nonepileptic controls.

Ideally, seizure control is optimized preconceptionally. Vajda and colleagues (2008) reported data from the Australian Register of Antiepileptic Drugs in Pregnancy. The risk of seizures during pregnancy was decreased by 50 to 70 percent if there were no seizures in the year preceding pregnancy. There were no further advantages that accrued if the seizure-free period exceeded a year.

Efforts should attempt to achieve seizure control with monotherapy and with medications considered less teratogenic (Aguglia, 2009; Tomson, 2009). As discussed in detail in Chapter 60 (p. 1190) and shown in Table 8-2, some one-drug regimens are more teratogenic than others. Valproic acid, in particular, should be avoided if possible, as this medication has consistently been associated with a greater risk for major congenital malformations than other antiepileptic drugs (Jentink, 2010). According to Jeha and Morris (2005), the American Academy of Neurology recommends consideration of antiseizure medication discontinuation before pregnancy in suitable candidates. These are women who satisfy the following criteria: have been seizure-free for 2 to 5 years, display a single seizure type, have a normal neurological examination and normal intelligence, and show electroencephalogram results that have normalized with treatment.

Epileptic women should be advised to take supplemental folic acid. However, it is not entirely clear that folate supplementation reduces the fetal malformation risk in pregnant women taking anticonvulsant therapy. In one case-control study, Kjær and associates (2008) reported that the congenital abnormality risk was reduced by maternal folate supplementation in fetuses exposed to carbamazepine, phenobarbital, phenytoin, and primidone. Conversely, from the United Kingdom Epilepsy and Pregnancy Register, Morrow and coworkers (2009) compared fetal outcomes of women who received preconceptional folic acid with those who did not receive it until later in pregnancy or not at all. In this study, a paradoxical increase in the number of major congenital malformations was observed in the group who received preconceptional folate. These investigators concluded that folate metabolism may be only a part of the mechanism by which malformations are induced in women taking these medications.

### Immunizations

Preconceptional counseling includes assessment of immunity against common pathogens. Also, depending on health status, travel plans, and time of year, other immunizations may be indicated as discussed in Chapter 9 (Table 9-9, p. 186). Vaccines that contain toxoids—for example, tetanus, or that consist of killed bacteria or viruses—such as influenza, pneumococcus, hepatitis B,
meningococcus, and rabies—have not been associated with adverse fetal outcomes and are not contraindicated preconceptionally or during pregnancy. Conversely, live-virus vaccines—including varicella-zoster, measles, mumps, rubella, polio, chickenpox, and yellow fever—are not recommended during pregnancy. Moreover, 1 month or longer should ideally pass between vaccination and conception attempts. That said, inadvertent administration of measles, mumps, rubella (MMR) or varicella vaccines during pregnancy should not generally be considered indications for pregnancy termination. Most reports indicate that the fetal risk is only theoretical. Immunization to smallpox, anthrax, and other bioterrorist diseases should be discussed if clinically appropriate (Chap. 64, p. 1258). Based on their study of approximately 300 women who received smallpox vaccination near the time of conception, Ryan and colleagues (2008) found that rates of pregnancy loss, preterm birth, and birth defects were not higher than expected.

**GENETIC DISEASES**

The Centers for Disease Control and Prevention (2013) estimate that 3 percent of neonates born each year in the United States will have at least one birth defect. Importantly, such defects are the leading cause of infant mortality and account for 20 percent of deaths. The benefits of preconceptional counseling usually are measured by comparing the incidence of new cases before and after initiation of a counseling program. Congenital conditions that clearly benefit from patient education include neural-tube defects, phenylketonuria, thalassemias, and other genetic diseases more common in individuals of Eastern European Jewish descent.

**Family History**

Pedigree construction using the symbols shown in Figure 8-2 is the most thorough method for obtaining a family history as a part of genetic screening. The health and reproductive status of each “blood relative” should be individually reviewed for medical illnesses, mental retardation, birth defects, infertility, and pregnancy loss. Certain racial, ethnic, or religious backgrounds may indicate increased risk for specific recessive disorders.
Although most women can provide some information regarding their history, their understanding may be limited. For example, several studies have shown that pregnant women often fail to report a birth defect in the family or they report it incorrectly. Thus, any disclosed defect or genetic disease should be confirmed by reviewing pertinent medical records or by contacting affected relatives for additional information.

**Neural-Tube Defects**

The incidence of neural-tube defects (NTDs) is 0.9 per 1000 live births, and they are second only to cardiac anomalies as the most frequent structural fetal malformation (Chap. 14, p. 283). Some NTDs, as well as congenital heart defects, are associated with specific mutations. One example is the 677C → T substitution in the gene that encodes methylene tetrahydrofolate reductase. For this and similar gene defects, the trial conducted by the Medical Research Council Vitamin Study Research Group (1991) showed that preconceptional folic acid therapy significantly reduced the risk for a recurrent NTD by 72 percent. More importantly, because more than 90 percent of infants with NTDs are born to women at low risk, Czeizel and Dudas (1992) showed that supplementation reduced the a priori risk of a first NTD occurrence. It is currently recommended, therefore, that all women who may become pregnant take 400 to 800 μg of folic acid orally daily before conception and through the first trimester (U.S Preventive Services Task Force, 2009). Folate fortification of cereal grains has been mandatory in the United States since 1998, and this practice has also resulted in decreased neural-tube defect rates (Mills, 2004). Despite the demonstrated benefits of folate supplementation, only half of women have taken folic acid supplementation periconceptionally (de Jong-van den Berg, 2005; Goldberg, 2006). The strongest predictor of use appears to be consultation with a health-care provider before conception.

**Phenylketonuria**

This inherited phenylalanine metabolism defect exemplifies diseases in which the fetus may not be at risk to inherit the disorder but may be damaged by maternal disease. Specifically, mothers with phenylketonuria (PKU) who eat an unrestricted diet have abnormally high blood phenylalanine levels. This amino acid readily crosses the placenta and can damage developing fetal organs, especially neural and cardiac tissues (Table 8-3). With appropriate preconceptional counseling and adherence to a phenylalanine-restricted diet before pregnancy, the incidence of fetal malformations is dramatically reduced (Guttler, 1990; Hoeks, 2009; Koch, 1990). It is recommended, therefore, that the phenylalanine concentration be normalized 3 months before conception and that these levels be maintained throughout pregnancy (American College of Obstetricians and Gynecologists, 2009b).

### Thalassemias

These disorders of globin-chain synthesis are the most common single-gene disorders worldwide. As many as 200 million people carry a gene for one of these hemoglobinopathies, and hundreds of mutations are known to cause thalassemia syndromes (Chap. 56, p. 1112). In endemic areas such as Mediterranean and Southeast Asian countries, counseling and other prevention strategies have reduced the incidence of new cases by up to 80 percent (Angastiniotis, 1998). For example, more than 25,000 students of Mediterranean origin were counseled and tested for β-thalassemia during a 20-year period (Mitchell, 1996). Within a few years of program initiation, all high-risk couples who requested prenatal diagnosis had completed the program, and remarkably, there were no affected children born during this period.

The American College of Obstetricians and Gynecologists (2013b) recommends that individuals of high-risk ancestry be offered carrier screening to allow them informed decision making regarding reproduction and prenatal diagnosis. One method—preimplantation genetic diagnosis, which is discussed in Chapter 14 (p. 301)—is available for patients at risk for certain thalassemia syndromes (Chen, 2008; Kuliev, 2011).

### Individuals of Eastern European Jewish Descent

Most individuals of Jewish ancestry in North America are descended from Ashkenazi Jewish communities and are at increased risk for having offspring with one of several autosomal recessive disorders. These include Tay-Sachs disease, Gaucher disease, cystic fibrosis, Canavan disease, familial dysautonomia, mucolipidosis IV, Niemann-Pick disease type A, Fanconi anemia group C, and Bloom syndrome. The American College of Obstetricians and Gynecologists (2009c) recommends preconceptional counseling and screening for these in this population. Carrier frequency and features of these conditions are discussed in Chapter 14 (Table 14-11, p. 298).

### REPRODUCTIVE HISTORY

During preconceptional screening, information should be sought regarding infertility; abnormal pregnancy outcomes that may include miscarriage, ectopic pregnancy, and recurrent pregnancy

loss; and obstetrical complications such as preeclampsia, placental abruption, and preterm delivery (Stubblefield, 2008). As discussed in Chapter 35 (p. 664), details involving a prior stillbirth are especially important. For example, Korteweg and associates (2008) identified chromosomal abnormalities in 13 percent of stillborns who underwent karyotyping. More recently, Reddy and colleagues (2012) confirmed that chromosomal microarray analysis yielded better detection of genetic abnormalities than did standard karyotyping, primarily because nonviable tissue can be used for the analysis. Identification of a genetic abnormality in stillborns can help determine the recurrence risk and aid in the preconceptional or prenatal management in subsequent pregnancies.

PARENTAL AGE

Maternal Age

Women at both ends of the reproductive-age spectrum have unique outcomes to be considered. First, according to the Centers for Disease Control and Prevention, in 2010, 3.4 percent of births in the United States were in women between the ages of 15 and 19 years (Martin, 2012). This rate represents a historical low in the United States for teenage births with a 45-percent decline since 1991. That said, adolescents are at increased risk for anemia, preterm delivery, and preeclampsia compared with women aged 20 to 35 years (Usta, 2008). The incidence of sexually transmitted diseases—common in adolescents—is even higher during pregnancy (Niccolai, 2003). Unfortunately, because most of their pregnancies are unplanned, adolescents rarely seek preconceptional counseling.

In contrast, conceptions after age 35 currently comprise approximately 15 percent of pregnancies in the United States (Martin, 2012). The older woman is more likely to request preconceptional counseling, either because she has postponed pregnancy and now wishes to optimize her outcome, or because she plans to undergo infertility treatment. Some studies—including data from Parkland Hospital presented in Figure 8-3—indicate that after age 35, there is an increased risk for obstetrical complications as well as perinatal morbidity and mortality (Cunningham, 1995; Huang, 2008). The older woman who has a chronic illness or who is in poor physical condition usually has readily apparent risks. For the physically fit woman without medical problems, however, the risks are much lower than previously reported.
Overall, the maternal mortality rate is higher in women aged 35 and older (Chap. 1, p. 5). Compared with women in their 20s, women aged 35 to 39 are 2.5 times more likely and women aged 40 or older are 5.3 times more likely to suffer pregnancy-related mortality (Geller, 2006). According to Buehler and coworkers (1986), improved medical care may ameliorate these risks. They reviewed maternal deaths in the United States from 1974 through 1982. Through 1978, older women had a fivefold increased relative risk of maternal death compared with that of younger women. By 1982, however, the mortality rates for older women had decreased by 50 percent.

For the fetus, maternal age-related risks primarily stem from: (1) indicated preterm delivery for maternal complications such as hypertension and diabetes, (2) spontaneous preterm birth, (3) fetal-growth disorders related to chronic maternal disease or multifetal gestation, (4) fetal aneuploidy, and (5) pregnancies resulting from assisted reproductive technology.

**Assisted Reproductive Technologies**

Recall that older women have subfertility problems. And although the incidence of dizygotic twinning increases with maternal age, the more important cause of multifetal gestation in older women follows the use of *assisted reproductive technology (ART)* and *ovulation induction*. Indeed, according to the Centers for Disease Control and Prevention, 40 percent of all multifetal gestations in the United States in 2005 were conceived with the use of ART (Martin, 2010). Multifetal pregnancies account for much of the morbidity and mortality from preterm delivery. Other obstetrical morbidities, such as placenta previa and abruption, are also risks associated with ART (Fong, 2014).

During the past decade, experience has accrued that links ART to increased major congenital
malformation rates. Davies and colleagues (2012) reported that of 308,974 births in South Australia, 8.3 percent of infants conceived by ART had major birth defects. In this analysis, after adjustment for maternal age and other risk factors, intracytoplasmic injection continued to be associated with a significantly increased risk for malformations, but in vitro fertilization did not.

**Paternal Age**

Although there is an increased incidence of genetic diseases in offspring caused by new autosomal-dominant mutations in older men, the incidence is still low (Chap. 13, p. 270). Accordingly, targeted sonographic examination performed solely for advanced maternal or paternal age is controversial.

### SOCIAL HISTORY

#### Recreational Drugs and Smoking

Fetal risks associated with alcohol, marijuana, cocaine, amphetamines, and heroin are discussed in Chapter 12 (p. 253). The first step in preventing drug-related fetal risk is for the woman to honestly assess her use. Questioning should be nonjudgmental. Screening for at-risk drinking can be accomplished using a number of validated tools, like the well-studied TACE questions (American College of Obstetricians and Gynecologists, 2013a). This is a series of four questions concerning tolerance to alcohol, being annoyed by comments about their drinking, attempts to cut down, and a history of drinking early in the morning—the *eye opener*.

In a Canadian study of more than 1000 postpartum patients, Tough and coworkers (2006) found that a high percentage of women reported alcohol use concurrent with conceptional attempts. Specifically, nearly half of those planning for pregnancy reported a mean of 2.2 drinks daily during early gestation before they recognized their pregnancy. Of note, Bailey and associates (2008) found that rates of binge drinking and marijuana use by men were unaffected by their partner’s pregnancy. The frequency and pattern of such behaviors clearly underscore the opportunity for preconceptional counseling.

In 2005, approximately 14 percent of women giving birth in the United States smoked cigarettes (Tong, 2009). This practice has been consistently associated with numerous adverse perinatal outcomes. These risks are largely mitigated by cessation before pregnancy, highlighting the importance of screening for tobacco use in the preconceptional period and during prenatal care as outlined in Chapter 9 (p. 172).

#### Environmental Exposures

Contact with environmental substances is inescapable. Thus, it is fortunate that only a few agents have been shown to cause adverse pregnancy outcomes (Windham, 2008). Exposures to infectious diseases have myriad deleterious effects, and these are detailed in Chapters 64 and 65 (p. 1239). Likewise, contact with some chemicals may impart significant maternal and fetal risks. As discussed in Chapters 8 and 12 (pp. 183 and 250), excess exposure to methyl mercury or lead is associated with neurodevelopmental disorders.

In the past, some concerns were raised over common everyday exposure to *electromagnetic*
fields such as emanated by high-voltage power lines, electric blankets, microwave ovens, and cellular phones. Fortunately, there is no human or animal evidence that any of these cause adverse fetal effects (O’Connor, 1999; Robert, 1999). The effects of electrical shock are discussed in Chapter 47 (p. 956).

Diet

Pica is the craving for and consuming of ice, laundry starch, clay, dirt, or other nonfood items. It should be discouraged due to its inherent replacement of healthful food with nutritionally empty products (Chap. 9, p. 188). In some cases, it may represent an unusual physiological response to iron deficiency (Federman, 1997). Many vegetarian diets are protein deficient but can be corrected by increasing egg and cheese consumption. Anorexia and bulimia increase maternal risks of nutritional deficiencies, electrolyte disturbances, cardiac arrhythmias, and gastrointestinal pathology (Becker, 1999). With these, pregnancy-related complications include greater risks of low birthweight, smaller head circumference, microcephaly, and small for gestational age (Kouba, 2005).

In contrast, obesity is linked with several maternal complications. As discussed in Chapter 48 (p. 965), these include hypertension, preeclampsia, gestational diabetes, labor abnormalities, cesarean delivery, and operative complications (American College of Obstetricians and Gynecologists, 2013c). Obesity also appears to be associated with a range of structural fetal anomalies (Stothard, 2009). By comparing changes in prepregnancy body mass index (BMI) Villamor and Cnattingius (2006) found that modest increases in BMI before pregnancy could result in perinatal complications, even if a woman does not become overweight.

Exercise

Conditioned pregnant women usually can continue to exercise throughout gestation (American College of Obstetricians and Gynecologists, 2009a). As discussed in Chapter 9 (p. 182), there are no data to suggest that exercise is harmful during pregnancy. One caveat is that as pregnancy progresses, balance problems and joint relaxation may predispose to orthopedic injury. A woman should be advised not to exercise to exhaustion, and she should augment heat dissipation and fluid replacement. Further avoidances include supine positions, activities requiring good balance, and extreme weather conditions.

Intimate Partner Violence

Pregnancy can exacerbate interpersonal problems and is a time of increased risk from an abusive partner. According to the American College of Obstetricians and Gynecologists (2012a), approximately 324,000 pregnant women are abused each year. As discussed in Chapter 47 (p. 951), intimate partner violence has been associated with an increased risk for several pregnancy-related complications, including hypertension, vaginal bleeding, hyperemesis, preterm delivery, and low-birthweight infants (Silverman, 2006). Because domestic violence can escalate during pregnancy, even to the point of homicide, the preconceptional period provides an ideal time for screening, and if indicated, intervention (Cheng, 2010). As outlined in Chapter 9 (p. 174), the American College of Obstetricians and Gynecologists (2012a) has provided recommendations and resources for screening both pregnant and nonpregnant women for domestic violence.
SCREENING TESTS

Certain laboratory tests may be helpful in assessing the risk for and preventing some complications during pregnancy. These include basic tests that are usually performed during prenatal care and are discussed in Chapter 9. More specific tests may assist evaluation of women with certain chronic medical diseases. Examples of some, but certainly not all, chronic diseases that ideally would be assessed before conception are highlighted in Table 8-4. With several of these, optimizing maternal condition before conception will improve pregnancy outcomes. Cox and coworkers (1992) reviewed pregnancy outcomes in 1075 high-risk women who received such evaluation. They reported that the 240 women with hypertension, asthma, or renal, thyroid, or cardiac disease had better outcomes compared with the outcomes from their previous pregnancies.

| Environmental exposure    | Chap. 9, p. 183   | **Methyl mercury**: Avoid shark, swordfish, king mackerel, and tile fish. Ingest no more than 12 ounces or 2 servings of canned tuna and no more than 6 ounces of albacore per week.  
**Lead**: Blood lead testing if a risk factor is identified from Table 9-9; treat if indicated according to recommendations.  
Calculate BMI yearly from Figure 48-1, p. 962  
*BMI* ≥ 25 kg/m²: Counsel on diet. Test for diabetes and metabolic syndrome if indicated. Consider weight loss prior to conception.  
*BMI* ≤ 18.5 kg/m²: Assess for eating disorder. |
| Abnormal weight           | Chap. 48, p. 961  | **Cardiovascular disease**: Chap. 49, p. 973  
Counsel on cardiac risks during pregnancy; discuss situations in which pregnancy is contraindicated. Optimize cardiac function. Discuss medication teratogenicity (warfarin, ACE inhibitor, ARB) and if possible, switch to less dangerous agent when conception planned. Offer genetic counseling to those with congenital cardiac anomalies (Table 49-4, p. 977).  
**Chronic hypertension**: Chap. 50, p. 1000  
Counsel on specific risks during pregnancy. Assess those with long-standing HTN for ventricular hypertrophy, retinopathy, and renal disease. Optimize blood pressure control. If medications indicated, select or switch to an agent appropriate for pregnancy.  
**Asthma**: Chap. 51, p. 1011  
Counsel on asthma risks during pregnancy. Optimize pulmonary function preconceptionally if possible. Treat women with pharmacological step therapy for chronic asthma based on ACOG·ACAAI (2000) recommendations.  
**Thrombophilia**: Chap. 52, p. 1028  
Question for personal or family history of thrombotic events or recurrent poor pregnancy outcomes. If a thrombophilia is found or known, counsel and offer least teratogenic appropriate anticoagulation regimen.  
**Renal disease**: Chap. 53, p. 1051  
Counsel on specific risks during pregnancy. Optimize blood pressure control before conception. Counsel women taking ACE inhibitors and ARBs on these drugs' teratogenicity and the need to switch agents before pregnancy if possible.  
**Gastrointestinal disease**: Chap. 54, p. 1076  
**Inflammatory bowel disease**: Counsel affected women on subfertility risks and risks of adverse pregnancy outcomes. Discuss teratogenicity of methotrexate and the other immunomodulators. Offer effective contraception during their use and switch agents, if possible, before conception.  
**Hepatobiliary disease**: Chap. 55, p. 1090  
**Hepatitis B**: Vaccinate all high-risk women before conception (Table 9-9, p. 185). Counsel chronic carriers on transmission prevention to partners and fetus.  
**Hepatitis C**: Screen high-risk women. Counsel affected women on risks of disease and transmission. If treatment indicated, discuss ramifications and appropriateness of pregnancy.  
**Hematological disease**: Chap. 56, p. 1101  
**Iron deficiency anemia**: Iron supplementation if identified.  
**Sickle-cell disease**: Screen all black women. Counsel those with trait or disease. Test partner if desired.  
**Thalassemias**: Screen women of Southeast Asian or Mediterranean ancestry.  
**Diabetes**: Chap. 57, p. 1125  
Optimize glycemic control to minimize teratogenicity of hyperglycemia. |

Infectious diseases

- Influenza: Vaccinate all women who will be pregnant during flu season.
- Malaria: Counsel to avoid travel to endemic areas during conception. If unable, offer effective contraception during travel or provide chemoprophylaxis for those planning pregnancy.
- Rubella: Screen for rubella immunity. If nonimmune, vaccinate and counsel on the need for effective contraception during the subsequent month.
- Tetanus: Update vaccination, as needed, in all reproductive-aged women.
- Varicella: Question regarding immunity. If nonimmune, vaccinate.

STDs

- Gonorrhea, syphilis, chlamydial infection: Screen high-risk women and treat as indicated.
- HIV: Screen at-risk women. Counsel affected women on risks during pregnancy and on perinatal transmission. Discuss initiation of treatment before pregnancy to decrease transmission risk. Offer effective contraception to those not desiring conception.
- HPV: Provide Pap smear screening per guidelines. Vaccinate candidate patients.
- HSV: Provide serological screening to asymptomatic women with affected partners. Counsel affected women on risks of perinatal transmission and of preventative measures during the third trimester and labor.

Prenatal Care

PRENATAL CARE IN THE UNITED STATES

DIAGNOSIS OF PREGNANCY

INITIAL PRENATAL EVALUATION

SUBSEQUENT PRENATAL VISITS

NUTRITIONAL COUNSELING

COMMON CONCERNS

As described by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012), “A comprehensive antepartum program involves a coordinated approach to medical care, continuous risk assessment, and psychological support that optimally begins before conception and extends throughout the postpartum period and interconceptional period.” Optimizing the health and well-being of women before pregnancy should logically be an integral prelude to prenatal care. Adequate and appropriate preconceptional care, as discussed in detail in Chapter 8, has the potential to assist women by reducing risks, promoting healthy lifestyles, and improving readiness for pregnancy.

PRENATAL CARE IN THE UNITED STATES

Almost a century after its introduction, prenatal care has become one of the most frequently used health services in the United States. In 2001, there were approximately 50 million prenatal visits. The median was 12.3 visits per pregnancy, and many women had 17 or more total visits. This information is gathered from birth certificates, and a revised form was introduced in 2003. It is now used by 27 states and Puerto Rico, whereas the remaining 23 states continue to use a 1989 form. Unfortunately, data regarding the timing of prenatal care from these two systems are not directly comparable (Osterman, 2011).

Since the early 1990s, the largest gains in timely prenatal care have been among minority groups. As shown in Figure 9-1, however, disparity continues. Of the 27 states using the revised birth certificate, the percentage of non-Hispanic white, Hispanic, and African-American women who received no prenatal care in 2008 was 1.1, 2.7, and 3.3, respectively (Osterman, 2011). Some of the obstetrical and medical risk factors or complications identifiable during prenatal care are
Importantly, many of these complications are treatable.

Data from Martin, 2002b.
Assessing Prenatal Care Adequacy

A commonly employed system for measuring prenatal care adequacy is the index of Kessner and colleagues (1973). This Kessner Index incorporates three items from the birth certificate: length of gestation, timing of the first prenatal visit, and number of visits. Although it does not measure the quality of care, the index remains a useful measure of prenatal care adequacy. Using this index, the National Center for Health Statistics concluded that 12 percent of American women who were delivered in 2000 received inadequate prenatal care (Martin, 2002a).

The Centers for Disease Control and Prevention (2000) analyzed birth certificate data for the years 1989 to 1997 and found that half of women with delayed or no prenatal care wanted to begin care earlier. Barriers to care varied by social and ethnic group, age, and payment method. The most common reason cited was late identification of pregnancy by the patient. The second most commonly cited barrier was lack of money or insurance. The third was inability to obtain an appointment.

Prenatal Care Effectiveness

Care designed during the early 1900s focused on lowering the extremely high maternal mortality rate. Such care undoubtedly contributed to the dramatic decline in this rate from 690 per 100,000 births in 1920 to 50 per 100,000 by 1955 (Loudon, 1992). As discussed in Chapter 1 (p. 5), the relatively low current maternal mortality rate of approximately 10 to 15 per 100,000 is likely associated with the high utilization of prenatal care (Xu, 2010). Indeed, in their analysis of data from 1998 to 2005 from the Pregnancy Mortality Surveillance System (PRAMS), Berg and associates (2010) identified a fivefold increased risk for maternal death in women who received no prenatal care.

There are other studies that attest to the efficacy of prenatal care. Herbst and colleagues (2003) found that lack of prenatal care was associated with more than a twofold increased risk of preterm birth. National Center for Health Statistics data showed that women with prenatal care had an overall stillbirth rate of 2.7 per 1000 compared with 14.1 per 1000 for women without prenatal care (Vintzileos, 2002a). These same investigators later reported that prenatal care was associated with lower rates of preterm birth as well as neonatal death associated with placenta previa, fetal-growth restriction, and postterm pregnancy (Vintzileos, 2002b, 2003). Evaluating the format of care, Ickovics and associates (2007) compared individual prenatal care and group prenatal care. The latter provided traditional pregnancy surveillance in a group setting with special focus on support, education, and active health-care participation. Women enrolled in group prenatal care had significantly reduced preterm birth rates compared with those receiving individual care.

DIAGNOSIS OF PREGNANCY

Pregnancy is usually identified when a woman presents with symptoms and possibly a positive home urine pregnancy test result. Typically, such women receive confirmatory testing of urine or blood for human chorionic gonadotropin (hCG). Further, there may be presumptive or diagnostic findings of pregnancy during examination. Sonography is often used, particularly if miscarriage or ectopic pregnancy is a concern.
Signs and Symptoms

Amenorrhea

The abrupt cessation of menstruation in a healthy reproductive-aged woman who previously has experienced spontaneous, cyclical, predictable menses is highly suggestive of pregnancy. As discussed in Chapter 5 (p. 80), menstrual cycles vary appreciably in length among women and even in the same woman. Thus, amenorrhea is not a reliable pregnancy indicator until 10 days or more after expected menses. Occasionally, uterine bleeding occurs after conception and can be somewhat suggestive of menstruation. During the first month of pregnancy, such episodes are likely the consequence of blastocyst implantation. Still, first-trimester bleeding should generally prompt evaluation for an abnormal pregnancy.

Lower-Reproductive-Tract Changes

During pregnancy, the vaginal mucosa usually appears dark-bluish red and congested—*Chadwick sign*, popularized by him in 1886. Although presumptive evidence of pregnancy, it is not conclusive. Also, there is increased cervical softening as pregnancy advances. Other conditions, however, such as estrogen–progestin contraceptives, may cause similar softening. As pregnancy progresses, the external cervical os and cervical canal may become sufficiently patulous to admit a fingertip, but the internal os should remain closed.

The substantial increase in progesterone secretion associated with pregnancy affects the consistency and microscopic appearance of cervical mucus. Specifically, microscopic observation of a fernlike pattern of mucus, which is typically seen in the midportion of the menstrual cycle, makes pregnancy unlikely (*Fig. 4-2*, p. 49).

Uterine Changes

During the first few weeks of pregnancy, uterine size grows principally in the anteroposterior diameter. During bimanual examination, it feels doughy or elastic. At 6 to 8 weeks’ menstrual age, the firm cervix contrasts with the now softer fundus and the compressible interposed softened isthmus—*Hegar sign*. Isthmic softening may be so marked that the cervix and uterine body seem to be separate organs. By 12 weeks’ gestation, the uterine body is almost globular, with an average diameter of 8 cm.

In later pregnancy, using a stethoscope for auscultation, one may hear the *uterine souffle*. This is a soft, blowing sound that is synchronous with the maternal pulse. It is produced by the passage of blood through the dilated uterine vessels and is heard most distinctly near the lower portion of the uterus. In contrast, the *funic souffle* is a sharp, whistling sound that is synchronous with the fetal pulse. It is caused by the rush of blood through the umbilical arteries and may not be heard consistently. Fetal heart tones can also be heard and are described on page 176.

Breast and Skin Changes

Anatomical changes in the breasts that accompany pregnancy are characteristic during a first pregnancy (*Chap. 4, p. 50*). These are less obvious in multiparas, whose breasts may contain a small amount of milky material or colostrum for months or even years after the birth of their last child, especially if the child was breast fed.

Increased pigmentation and visual changes in abdominal striae are common to, but not diagnostic of, pregnancy. They may be absent during pregnancy and may also be seen in women taking estrogen-containing contraceptives.
Fetal Movement

Maternal perception of fetal movement depends on factors such as parity and habitus. In general, after a first successful pregnancy, a woman may first perceive fetal movements between 16 and 18 weeks’ gestation. A primigravida may not appreciate fetal movements until approximately 2 weeks later. At about 20 weeks, depending on maternal habitus, an examiner can begin to detect fetal movements.

Pregnancy Tests

Detection of hCG in maternal blood and urine is the basis for endocrine assays of pregnancy. This hormone is a glycoprotein with high carbohydrate content. There are subtle hCG variants, and these differ by their carbohydrate moieties. The general structure of hCG is a heterodimer composed of two dissimilar subunits, designated \( \alpha \) and \( \beta \), which are noncovalently linked. As described in Chapter 5 (p. 101), the \( \alpha \)-subunit is identical to those of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). HCG prevents involution of the corpus luteum, which is the principal site of progesterone formation during the first 6 weeks of pregnancy.

Syncytiotrophoblast produce hCG in amounts that increase exponentially during the first trimester following implantation. With a sensitive test, the hormone can be detected in maternal serum or urine by 8 to 9 days after ovulation. The doubling time of serum hCG concentration is 1.4 to 2.0 days. As shown in Figure 9-2, serum hCG levels increase from the day of implantation and reach peak levels at 60 to 70 days. Thereafter, the concentration declines slowly until a plateau is reached at approximately 16 weeks.

**FIGURE 9-2** Mean concentration (95% CI) of human chorionic gonadotropin (hCG) in serum of women throughout normal pregnancy.

**Measurement of hCG**
As noted, hCG is composed of both an α- and a β-subunit, but the β-subunit is structurally distinct from that of LH, FSH, and TSH. With this recognition, antibodies were developed with high specificity for the hCG β-subunit. This specificity allows its detection, and numerous commercial immunoassays are available for measuring serum and urine hCG levels. Although each immunoassay detects a slightly different mixture of hCG variants, its free subunits, or its metabolites, all are appropriate for pregnancy testing (Cole, 1998).

One commonly employed technique is the \textit{sandwich-type immunoassay}. With this test, a monoclonal antibody against the β-subunit is bound to a solid-phase support. The attached antibody is then exposed to and binds hCG in the serum or urine specimen. A second antibody is then added, binds to another site on the hCG molecule, and “sandwiches” the bound hCG between the two antibodies. In some assays, the second antibody is linked to an enzyme, such as alkaline phosphatase. When substrate for the enzyme is added, a color develops. The color intensity is proportional to the amount of enzyme and thus to the amount of the second antibody bound. This, in turn, is a function of the hCG concentration in the test sample. The sensitivity for the laboratory detection of hCG in serum is as low as 1.0 mIU/mL using this technique. With extremely sensitive immunoradiometric assays, the detection limit is even lower (Wilcox, 2001).

False-positive hCG test results are rare (Braunstein, 2002). A few women have circulating serum factors that may bind erroneously with the test antibody directed to hCG in a given assay. The most common factors are heterophilic antibodies. These are produced by an individual and bind to the animal-derived test antibodies used in a given immunoassay. Thus, women who have worked closely with animals are more likely to develop such antibodies, and alternative laboratory techniques are available (American College of Obstetricians and Gynecologists, 2013a). Elevated hCG levels may also reflect molar pregnancy and its associated cancers (Chap. 20, p. 396). Other rare causes of positive assays without pregnancy are: (1) exogenous hCG injection used for weight loss, (2) renal failure with impaired hCG clearance, (3) physiological pituitary hCG, and (4) hCG-producing tumors that most commonly originate from gastrointestinal sites, ovary, bladder, or lung (Montagnana, 2011).

\textbf{Home Pregnancy Tests}

Millions of over-the-counter pregnancy test kits are sold annually in the United States. In one study, Cole and associates (2011) found that a detection limit of 12.5 mIU/mL would be required to diagnose 95 percent of pregnancies at the time of missed menses. They noted that only one brand had this degree of sensitivity. Two other brands gave false-positive or invalid results. In fact, with an hCG concentration of 100 mIU/mL, clearly positive results were displayed by only 44 percent of brands. As such, only about 15 percent of pregnancies could be diagnosed at the time of the missed menses. Some manufacturers of even newer home urine assays claim > 99-percent accuracy on the day of—and some up to 4 days before—the expected day of menses. But, careful analysis suggests that these assays are often not as sensitive as advertised (Cole, 2011).

\textbf{Sonographic Recognition of Pregnancy}

Transvaginal sonography has revolutionized early pregnancy imaging and is commonly used to accurately establish gestational age and confirm pregnancy location. A \textit{gestational sac}—a small anechoic fluid collection within the endometrial cavity—is the first sonographic evidence of pregnancy. It may be seen with transvaginal sonography by 4 to 5 weeks’ gestation. A fluid collection, however, can also be seen within the endometrial cavity with an ectopic pregnancy and is termed a \textit{pseudogestational sac} or \textit{pseudosac} (Fig. 19-5, p. 382). Thus, further evaluation may
be warranted if this is the only sonographic finding, particularly in a patient with pain or bleeding. A normal gestational sac implants eccentrically in the endometrium, whereas a pseudosac is seen in the midline of the endometrial cavity. Other potential indicators of early intrauterine pregnancy are an anechoic center surrounded by a single echogenic rim—the intradecidual sign—or two concentric echogenic rings surrounding the gestational sac—the double decidual sign (Fig. 9-3) (Chiang, 2004). If sonography yields equivocal findings—the so-called pregnancy of unknown location, then serial serum hCG levels can also help differentiate a normal intrauterine pregnancy from an extrauterine pregnancy or an early miscarriage (Chap. 19, p. 381).

Visualization of the yolk sac—a brightly echogenic ring with an anechoic center—confirms with certainty an intrauterine location for the pregnancy and can normally be seen by the middle of the fifth week. As shown in Figure 9-3, after 6 weeks, an embryo is seen as a linear structure immediately adjacent to the yolk sac, and cardiac motion is typically noted at this point. Up to 12 weeks’ gestation, the crown-rump length is predictive of gestational age within 4 days (Chap. 10, p. 195).

![FIGURE 9-3 Transvaginal sonogram of a first-trimester intrauterine pregnancy. The double decidual sign is noted surrounding the gestational sac and is defined by the decidua parietalis (white asterisk) and the decidua capsularis (yellow asterisk). The arrow notes the yolk sac, and the crown-rump length of the embryo is marked with measuring calipers. (Image contributed by Dr. Elysia Moschos.)](image)

**INITIAL PRENATAL EVALUATION**

Prenatal care should be initiated as soon as there is a reasonable likelihood of pregnancy. Major goals are to: (1) define the health status of the mother and fetus, (2) estimate the gestational age, and (3) initiate a plan for continuing obstetrical care. Typical components of the initial visit are
The initial plan for subsequent care may range from relatively infrequent routine visits to prompt hospitalization because of serious maternal or fetal disease.

</table>
Use of a standardized record within a perinatal health-care system greatly aids antepartum and intrapartum management. Standardizing documentation may allow communication and care continuity between providers and enable objective measures of care quality to be evaluated over time and across different clinical settings (Gregory, 2006). A prototype is provided by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) in their Guidelines for Perinatal Care, 7th edition.

Definitions

There are several definitions pertinent to establishment of an accurate prenatal record.

1. **Nulligravida**—a woman who currently is not pregnant nor has ever been pregnant.
2. **Gravida**—a woman who currently is pregnant or has been in the past, irrespective of the pregnancy outcome. With the establishment of the first pregnancy, she becomes a **primigravida**, and with successive pregnancies, a **multigravida**.
3. **Nullipara**—a woman who has never completed a pregnancy beyond 20 weeks’ gestation. She may not have been pregnant or may have had a spontaneous or elective abortion(s) or an ectopic pregnancy.
4. **Primipara**—a woman who has been delivered only once of a fetus or fetuses born alive or dead
with an estimated length of gestation of 20 or more weeks. In the past, a 500-g birthweight threshold was used to define parity. As discussed in Chapter 1 (p. 2), this threshold is now controversial because many states still use this weight to differentiate a stillborn fetus from an abortus. However, the survival of neonates with birthweights < 500 g is no longer uncommon.

5. **Multipara**—a woman who has completed two or more pregnancies to 20 weeks’ gestation or more. Parity is determined by the number of pregnancies reaching 20 weeks. It is not increased to a higher number if multiples are delivered in a given pregnancy. Moreover, stillbirth does not lower this number. In some locales, the obstetrical history is summarized by a series of digits connected by dashes. These refer to the number of term infants, preterm infants, abortuses younger than 20 weeks, and children currently alive. For example, a woman who is para 2–1–0–3 has had two term deliveries, one preterm delivery, no abortuses, and has three living children. Because these are nonconventional, it is helpful to specify the outcome of any pregnancy that did not end normally.

**Normal Pregnancy Duration**

The mean duration of pregnancy calculated from the first day of the last normal menstrual period is very close to 280 days or 40 weeks. In a study of 427,581 singleton pregnancies from the Swedish Birth Registry, Bergsjö and coworkers (1990) found that the mean pregnancy duration was 281 days with a standard deviation of 13 days.

It is customary to estimate the expected delivery date by adding 7 days to the date of the first day of the last normal menstrual period and counting back 3 months—*Naegele rule*. For example, if the last menstrual period began September 10, the expected date of delivery is June 17. However, a *gestational age* or *menstrual age* calculated in this way assumes pregnancy to have begun approximately 2 weeks before ovulation, which is not always the case.

Clinicians use this gestational age to mark temporal events during pregnancy. In contrast, embryologists and other reproductive biologists more often employ *ovulatory age* or *fertilization age*, both of which are typically 2 weeks earlier. Somewhat related, Bracken and Belanger (1989) tested the accuracy of various “pregnancy wheels” provided by three pharmaceutical companies and found that such devices predicted incorrect delivery dates in 40 to 60 percent of estimates, with a 5-day error being typical. As physicians and hospitals increasingly transition to electronic medical records, however, such errors should be largely obviated by more precise estimates of gestational age produced by calculator software applications.

**Trimesters**

It has become customary to divide pregnancy into three equal epochs of approximately 3 calendar months. Historically, the first trimester extends through completion of 14 weeks, the second through 28 weeks, and the third includes the 29th through 42nd weeks of pregnancy. Thus, there are three periods of 14 weeks each. Certain major obstetrical problems tend to cluster in each of these time periods. For example, most spontaneous abortions take place during the first trimester, whereas most women with hypertensive disorders due to pregnancy are diagnosed during the third trimester.

In modern obstetrics, the clinical use of trimesters to describe a specific pregnancy is imprecise. For example, it is inappropriate in cases of uterine hemorrhage to categorize the problem temporally as “third-trimester bleeding.” Appropriate management for the mother and her fetus will vary remarkably depending on whether bleeding begins early or late in the third trimester (Chap. 41, p. 782). Because precise knowledge of fetal age is imperative for ideal
obstetrical management, the clinically appropriate unit is \textit{weeks of gestation completed}. And more recently, clinicians designate gestational age using completed weeks and days, for example, 33\$^{4/7}\$ weeks or \(33 + 4\), for 33 completed weeks and 4 days.

**Previous and Current Health Status**

For the most part, the same essentials go into appropriate history taking from the pregnant woman as elsewhere in medicine. In addition to queries concerning medical or surgical disorders, detailed information regarding previous pregnancies is essential as many obstetrical complications tend to recur in subsequent pregnancies.

The \textit{menstrual history} is also important. The woman who spontaneously menstruates approximately every 28 days is most likely to ovulate at midcycle. Thus, gestational or menstrual age is the number of weeks since the onset of the last menstrual period. If her menstrual cycles were significantly longer than 28 to 30 days, ovulation more likely occurred well beyond 14 days. If the intervals were much longer and irregular, chronic anovulation is likely to have preceded some of the episodes identified as menses. Thus, without a history of regular, predictable, cyclic, spontaneous menses that suggest ovulatory cycles, accurate dating of pregnancy by history and physical examination is difficult.

It is also important to ascertain whether or not steroidal contraceptives were used before the pregnancy. Because ovulation may not have resumed 2 weeks after the onset of the last withdrawal bleeding and instead may have occurred at an appreciably later and highly variable date, using the time of ovulation for predicting the time of conception in this circumstance may be erroneous. Use of sonography in early pregnancy will clarify gestational age in these situations.

**Psychosocial Screening**

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) define psychosocial issues as nonbiomedical factors that affect mental and physical well-being. Women should be screened regardless of social status, education level, race, or ethnicity. Such screening should seek barriers to care, communication obstacles, nutritional status, unstable housing, desire for pregnancy, safety concerns that include intimate partner violence, depression, stress, and use of substances such as tobacco, alcohol, and illicit drugs. This screening should be performed on a regular basis, at least once per trimester, to identify important issues and reduce adverse pregnancy outcomes. Coker and colleagues (2012) compared pregnancy outcomes in women before and after implementation of a universal psychosocial screening program and found that screened women were less likely to have preterm or low-birthweight newborns. Although this study was observational, these investigators also reported decreased rates of gestational diabetes, premature rupture of membranes, and vaginal bleeding in women who underwent universal screening.

**Cigarette Smoking**

There are unequivocal adverse perinatal sequelae for smoking (United States Department of Health and Human Services, 2000). Such data have been included on the birth certificate since 1989. The number of pregnant women who smoke continues to decline. From 2000 to 2010, the prevalences were 12 to 13 percent (Tong, 2013). Based on the Pregnancy Risk Assessment Monitoring System (PRAMS), 13 percent of women admitted to smoking. These women were more likely younger, had less education, and were either Alaska Natives or American Indians
Numerous adverse outcomes have been linked to smoking during pregnancy. Potential teratogenic effects are reviewed in Chapter 12 (p. 255). There is a twofold risk of placenta previa, placental abruption, and premature membrane rupture compared with nonsmokers. Further, neonates born to women who smoke are more likely to be preterm, have lower birth-weights, and are more likely to die of sudden infant death syndrome (SIDS) than infants born to nonsmokers (Tong, 2009). In 2005, the incidence of low-birthweight infants born to American women who smoked during pregnancy was 11.9 percent compared with 7.5 percent born to nonsmokers (Martin, 2007). Risks for spontaneous abortion, fetal death, and fetal digital anomalies are also increased (Man, 2006). Finally, children who were exposed to smoking in utero are at increased risk for asthma, infantile colic, and childhood obesity (American College of Obstetricians and Gynecologists, 2013i).

Several pathophysiological mechanisms have been proposed to explain these adverse outcomes. They include fetal hypoxia from increased carboxyhemoglobin, reduced uteroplacental blood flow, and direct toxic effects of nicotine and other compounds in smoke (Jazayeri, 1998). Nicotine transfer is so efficient that fetal nicotine exposure is greater than that of the mother (Luck, 1985). Exposed fetuses have decreased heart rate variability due to impaired autonomic regulation (Zeskind, 2006).

**Smoking Cessation.** The United States Department of Health and Human Services recommends that clinicians offer counseling and effective intervention options to pregnant smokers at the first and subsequent prenatal visits. Although benefits are greatest if smoking ceases early in pregnancy or preferably preconceptionally, quitting at any stage of pregnancy can improve perinatal outcomes (England, 2001; Fiore, 2008).

Person-to-person psychosocial interventions are significantly more successful in achieving smoking abstinence in pregnancy than are simple advisements to quit (Fiore, 2008). One example is a brief counseling session covering the “5As” of smoking cessation (Table 9-3). This approach to counseling can be accomplished in 15 minutes or less and has been proven to be effective when initiated by health-care providers (American College of Obstetricians and Gynecologists, 2013i).

<table>
<thead>
<tr>
<th>TABLE 9-3. Five A’s of Smoking Cessation</th>
</tr>
</thead>
</table>

**ASK** about smoking at the first and subsequent prenatal visits. To improve assessment accuracy, a patient should choose the following statement that best describes her smoking status:

- I smoke regularly now; the same as before pregnancy.
- I smoke regularly now, but I’ve cut down with pregnancy. I smoke every once in a while.
- I have quit smoking since pregnancy.
- I wasn’t smoking before pregnancy, and I do not currently smoke.
- If smoking abstinence has already begun, then reinforce her decision to quit, congratulate her on success, and encourage her continued abstinence. For persistent smokers, proceed to the following steps:

**ADVISE** with clear, strong statements that explain the risks of continued smoking to the woman, fetus, and newborn.

**ASSESS** the patient’s willingness to attempt cessation.
ASSIST with pregnancy-specific, self-help smoking cessation materials. Offer a direct referral to the smoker’s quit line (1–800-QUIT NOW) to provide ongoing counseling and support. ARRANGE to track smoking abstinence progress at subsequent visits.

Adapted from Fiore, 2008.

Nicotine replacement products have not been sufficiently evaluated to determine their effectiveness and safety in pregnancy. Trials evaluating such therapy have yielded conflicting evidence. Wisborg and colleagues (2000) randomly assigned 250 women who smoked at least 10 cigarettes per day to receive a nicotine or placebo patch beginning after the first trimester. There were no significant differences in birthweights or in smoking cessation or preterm delivery rates between the two groups. Pollak and associates (2007) randomized 181 pregnant smokers to cognitive-behavioral therapy alone versus this therapy plus nicotine replacement. They identified significantly improved smoking cessation rates in the women with nicotine replacement at 7 weeks after randomization and at 38 weeks’ gestation. The trial was terminated early due to an increased rate of negative birth outcomes in the nicotine replacement arm. Some of these included neonatal intensive care unit admission, small-for-gestational age, and placental abruption. Because of limited available evidence to support pharmacotherapy for smoking cessation in pregnancy, the American College of Obstetricians and Gynecologists (2013i) has recommended that if nicotine replacement therapy is used, it should be done with close supervision and after careful consideration of the risks of smoking versus nicotine replacement.

Alcohol
Ethyl alcohol or ethanol is a potent teratogen that causes a fetal syndrome characterized by growth restriction, facial abnormalities, and central nervous system dysfunction (Chap. 12, p. 245). Women who are pregnant or considering pregnancy should abstain from using any alcoholic beverages. The Centers for Disease Control and Prevention (2012a) analyzed data from the Behavioral Risk Factor Surveillance System from 2006 to 2010 and estimated that 7.6 percent of pregnant women used alcohol and 1.4 percent reported binge drinking. By comparison, in 1999, rates of alcohol use and binge drinking were estimated to be 12.8 and 2.7 percent, respectively (Centers for Disease Control and Prevention, 2002). Among pregnant women, those most likely to use alcohol were aged 35 to 44 years, white, college graduates, or employed. The American College of Obstetricians and Gynecologists (2008), in their committee opinion on this topic, has reviewed methods for screening women during pregnancy for alcohol abuse and for illicit drug use.

Illicit Drugs
It is estimated that 10 percent of fetuses are exposed to one or more illicit drugs (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Agents may include heroin and other opiates, cocaine, amphetamines, barbiturates, and marijuana. Chronic use of large quantities is harmful to the fetus (Chap. 12, p. 253). Well-documented sequelae include fetal-growth restriction, low birthweight, and drug withdrawal soon after birth. Women who use such drugs frequently do not seek prenatal care, or if they do, they may not admit to substance abuse. El-Mohandes and associates (2003) reported that when women who use illicit drugs receive prenatal care, the risks for preterm birth and low birthweight are reduced. For women who abuse heroin, methadone maintenance can be initiated within a registered
methadone treatment program to reduce complications of illicit opioid use and narcotic withdrawal, to encourage prenatal care, and to avoid drug culture risks (American College of Obstetricians and Gynecologists, 2012c). Available programs can be found through the treatment locator of the Substance Abuse and Mental Health Services Administration at www.samhsa.gov. Methadone dosages usually are initiated at 10 to 30 mg daily and titrated as needed. Although less commonly used, buprenorphine alone or in combination with naloxone may also be offered and managed by physicians with specific credentialing.

**Intimate Partner Violence**

This term refers to a pattern of assaultive and coercive behaviors that may include physical injury, psychological abuse, sexual assault, progressive isolation, stalking, deprivation, intimidation, and reproductive coercion (American College of Obstetricians and Gynecologists, 2012a). Such violence has been recognized as a major public health problem. Unfortunately, most abused women continue to be victimized during pregnancy. With the possible exception of preeclampsia, domestic violence is more prevalent than any major medical condition detectable through routine prenatal screening (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). The prevalence during pregnancy is estimated to be between 4 and 8 percent. As discussed in Chapter 47 (p. 951), intimate partner violence is associated with an increased risk of several adverse perinatal outcomes including preterm delivery, fetal-growth restriction, and perinatal death.

The American College of Obstetricians and Gynecologists (2012a) has provided methods for domestic violence screening and recommends their use at the first prenatal visit, then again at least once per trimester, and again at the postpartum visit. Such screening should be done privately and away from family members and friends. Patient self-administered or computerized screenings appear to be as effective for disclosure as clinician-directed interviews (Ahmad, 2009; Chen, 2007). Physicians should be familiar with state laws that may require reporting of intimate partner violence. Coordination with social services can be invaluable in such cases. The National Domestic Violence Hotline (1–800–799-SAFE [7233]) is a nonprofit telephone referral service that provides individualized information regarding city-specific women's shelter locations, counseling resources, and legal advocacy.

**Clinical Evaluation**

A thorough, general physical examination should be completed at the initial prenatal encounter. Many of the expected changes that result from normal pregnancy are addressed throughout Chapter 4 (p. 46).

Pelvic examination is performed as part of the evaluation. The cervix is visualized employing a speculum lubricated with warm water or water-based lubricant gel. Bluish-red passive hyperemia of the cervix is characteristic, but not of itself diagnostic, of pregnancy. Dilated, occluded cervical glands bulging beneath the ectocervical mucosa—*nabothian cysts*—may be prominent. The cervix is not normally dilated except at the external os. To identify cytological abnormalities, a Pap smear is performed according to current guidelines noted in Chapter 63 (p. 1221). Specimens for identification of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are also obtained when indicated (p. 175).

Bimanual examination is completed by palpation, with special attention given to the consistency, length, and dilatation of the cervix; to uterine and adnexal size; to the bony pelvic architecture; and to any vaginal or perineal anomalies. Later in pregnancy, fetal presentation often
can also be determined. Lesions of the cervix, vagina, or vulva should be further evaluated as needed by colposcopy, biopsy, culture, or dark-field examination. The perianal region should be visualized, and digital rectal examination performed as required for complaints of rectal pain, bleeding, or mass.

**Gestational Age Assessment**

Precise knowledge of gestational age is one of the most important aspects of prenatal care because several pregnancy complications may develop for which optimal treatment will depend on fetal age. Gestational age can be estimated with considerable precision by appropriately timed and carefully performed clinical uterine size examination that is coupled with knowledge of the last menses. Uterine size similar to a small orange roughly correlates with a 6-week gestation; a large orange, with an 8-week pregnancy; and a grapefruit, with one at 12 weeks (Margulies, 2001). That said, a first-trimester crown-rump length is the most accurate tool for gestational age assignment and is performed as clinically indicated. As described in Chapter 10 (p. 198), later sonographic interrogation can also provide an estimated gestational age, but with declining accuracy.

**Laboratory Tests**

Recommended routine tests at the first prenatal encounter are listed in Table 9-2. Initial blood tests include a complete blood count, a determination of blood type with Rh status, and an antibody screen. The Institute of Medicine recommends universal human immunodeficiency virus (HIV) testing, with patient notification and right of refusal, as a routine part of prenatal care. The Centers for Disease Control and Prevention (2006) as well as the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) continue to support this practice. If a woman declines testing, this should be recorded in the prenatal record. All pregnant women should also be screened for hepatitis B virus, syphilis, and immunity to rubella at the initial visit. Based on their prospective investigation of 1000 women, Murray and coworkers (2002) concluded that in the absence of hypertension, routine urinalysis beyond the first prenatal visit was not necessary. A urine culture is performed because treating asymptomatic bacteruria significantly reduces the likelihood of developing symptomatic urinary tract infections in pregnancy (Chap. 53, p. 1053).

**Cervical Infections**

*Chlamydia trachomatis* is isolated from the cervix in 2 to 13 percent of pregnant women. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that all women be screened for chlamydia during the first prenatal visit, with additional third-trimester testing for those at increased risk. Risk factors include unmarried status, recent change in sexual partner or multiple concurrent partners, age younger than 25 years, inner-city residence, history or presence of other sexually transmitted diseases, and little or no prenatal care. Following treatment, a second testing—a so-called test of cure—is recommended in pregnancy 3 to 4 weeks after treatment completion (Chap. 65, p. 1270).

*Neisseria gonorrhoeae* is the gram-negative diplococcal bacteria responsible for causing gonorrhea. Risk factors for gonorrhea are similar for those for chlamydial infection. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that pregnant women with risk factors or those living in an area of high *N gonorrhoeae* prevalence be screened at the initial prenatal visit and again in the third trimester. Treatment is given for gonorrhea as well as possible coexisting chlamydial infection, as outlined in Chapter 65 (p. 1269). Test of cure is also recommended following treatment.
Pregnancy Risk Assessment

Many factors exist that can adversely affect maternal and/or fetal well-being. Some are evident at conception, but many become apparent during the course of pregnancy. The designation of “high-risk pregnancy” is overly vague for an individual patient and probably should be avoided if a more specific diagnosis has been assigned. Some common risk factors for which consultation is recommended by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) are shown in Table 9-4. Some conditions may require the involvement of a maternal-fetal medicine subspecialist, geneticist, pediatrician, anesthesiologist, or other medical specialist in the evaluation, counseling, and care of the woman and her fetus.

SUBSEQUENT PRENATAL VISITS

Subsequent prenatal visits have been traditionally scheduled at 4-week intervals until 28 weeks,
then every 2 weeks until 36 weeks, and weekly thereafter. Women with complicated pregnancies often require return visits at 1- to 2-week intervals. For example, in twin pregnancies, Luke and colleagues (2003) found that a specialized prenatal care program emphasizing nutrition and education and requiring return visits every 2 weeks resulted in improved outcomes.

In 1986, the Department of Health and Human Services convened an expert panel to review the content of prenatal care. This report was subsequently reevaluated and revised in 2005 (Gregory, 2006). The panel recommended, among other things, early and continuing risk assessment that is patient specific. It also endorsed flexibility in clinical visit spacing; health promotion and education, including preconceptional care; medical and psychosocial interventions; standardized documentation; and expanded prenatal care objectives—to include family health up to 1 year after birth.

The World Health Organization (WHO) conducted a multicenter randomized trial with almost 25,000 women comparing routine prenatal care with an experimental model designed to minimize visits (Villar, 2001). In the new model, women were seen once in the first trimester and screened for certain risks. Those without anticipated complications—80 percent of those screened—were seen again at 26, 32, and 38 weeks. Compared with routine prenatal care, which required a median of eight visits, the new model required a median of only five. No disadvantages were attributed to the regimen with fewer visits, and these findings were consistent with other randomized trials (Clement, 1999; McDuffie, 1996).

### Prenatal Surveillance

At each return visit, the well-being of mother and fetus are assessed (see Table 9-2). Fetal heart rate, growth, amniotic fluid volume, and activity are evaluated. Maternal blood pressure and weight and their extent of change are assessed. Symptoms such as headache, altered vision, abdominal pain, nausea and vomiting, bleeding, vaginal fluid leakage, and dysuria are sought. Uterine examination measures size from the symphysis to the fundus. In late pregnancy, vaginal examination often provides valuable information that includes confirmation of the presenting part and its station, clinical estimation of pelvic capacity and its general configuration, amniotic fluid volume adequacy, and cervical consistency, effacement, and dilatation (Chap. 22, p. 438).

### Fundal Height

Between 20 and 34 weeks, the height of the uterine fundus measured in centimeters correlates closely with gestational age in weeks (Calvert, 1982; Jimenez, 1983; Quaranta, 1981). This measurement is used to monitor fetal growth and amniotic fluid volume. It is measured as the distance along the abdominal wall from the top of the symphysis pubis to the top of the fundus. Importantly, the bladder must be emptied before fundal measurement. Worthen and Bustillo (1980) demonstrated that at 17 to 20 weeks, fundal height was 3 cm higher with a full bladder. Obesity or the presence of uterine masses such as leiomyomata may also limit fundal height accuracy. In such cases, sonography may be necessary for assessment. Moreover, using fundal height alone, fetal-growth restriction may be undiagnosed in up to a third of cases (American College of Obstetricians and Gynecologists, 2013b).

### Fetal Heart Sounds

Instruments incorporating Doppler ultrasound are often used to easily detect fetal heart action, and in the absence of maternal obesity, heart sounds are almost always detectable by 10 weeks with such instruments (Chap. 24, p. 474). The fetal heart rate ranges from 110 to 160 beats per minute.
and is typically heard as a double sound.

Using a standard nonamplified stethoscope, the fetal heart may be audible as early as 16 weeks in some women. Herbert and coworkers (1987) reported that the fetal heart was audible by 20 weeks in 80 percent of women, and by 22 weeks, heart sounds were heard in all. Because the fetus moves freely in amnionic fluid, the site on the maternal abdomen where fetal heart sounds can be heard best will vary.

**Sonography**

As described in detail in Chapter 10 (p. 199), sonography provides invaluable information regarding fetal anatomy, growth, and well-being, and most women in the United States have at least one prenatal sonographic examination during pregnancy (American College of Obstetricians and Gynecologists, 2011b). Recent trends suggest that the number of these examinations performed per pregnancy is increasing. Siddique and associates (2009) reported that the average number of sonographic evaluations per pregnancy increased from 1.5 in 1995 through 1997 to 2.7 almost 10 years later. This trend was noted in both high- and low-risk pregnancies. The actual clinical utility of increasing sonography use in pregnancy has not been demonstrated, and it is unclear that the cost-benefit ratio is justified (Washington State Health Care Authority, 2010). The American College of Obstetricians and Gynecologists (2011b) has concluded that sonography should be performed only when there is a valid medical indication under the lowest possible ultrasound exposure setting. The College further indicates that a physician is not obligated to perform sonography without a specific indication in a low-risk patient, but that if she requests sonographic screening, it is reasonable to honor her request.

**Subsequent Laboratory Tests**

If initial results were normal, most tests need not be repeated. Fetal aneuploidy screening may be performed at 11 to 14 weeks and/or at 15 to 20 weeks, depending on the protocol selected as described in Chapter 14. Serum screening for neural-tube defects is offered at 15 to 20 weeks (Chap. 14, p. 284). Hematocrit or hemoglobin determination, along with syphilis serology if it is prevalent in the population, should be repeated at 28 to 32 weeks (Hollier, 2003; Kiss, 2004). For women at increased risk for HIV acquisition during pregnancy, repeat testing is recommended in the third trimester, preferably before 36 weeks’ gestation (American College of Obstetricians and Gynecologists, 2011a). Similarly, women who engage in behaviors that place them at high risk for hepatitis B infection should be retested at the time of hospitalization for delivery (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Women who are D (Rh) negative and are unsensitized should have an antibody screening test repeated at 28 to 29 weeks, with administration of anti-D immune globulin if they remain unsensitized (Chap. 15, p. 311).

**Group B Streptococcal Infection**

The Centers for Disease Control and Prevention (2010b) recommend that vaginal and rectal group B streptococcal (GBS) cultures be obtained in all women between 35 and 37 weeks’ gestation, and the American College of Obstetricians and Gynecologists (2013g) has endorsed this recommendation. Intrapartum antimicrobial prophylaxis is given for those whose cultures are positive. Women with GBS bacteriuria or a previous infant with invasive disease are given empirical intrapartum prophylaxis. These infections are discussed in detail in Chapter 64 (p. 1249).
Gestational Diabetes
All pregnant women should be screened for gestational diabetes mellitus, whether by history, clinical factors, or routine laboratory testing. Although laboratory testing between 24 and 28 weeks’ gestation is the most sensitive approach, there may be pregnant women at low risk who are less likely to benefit from testing (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Gestational diabetes is discussed in Chapter 57 (p. 1136).

Selected Genetic Screening
Selected screening for certain genetic abnormalities should be offered to those at increased risk based on family history, ethnic or racial background, or age (American College of Obstetricians and Gynecologists, 2009c, 2011c, 2013h). These are discussed in greater detail in Chapters 13 (p. 275) and 14 (p. 294). Some examples include testing for Tay-Sachs disease for persons of Eastern European Jewish or French Canadian ancestry; β-thalassemia for those of Mediterranean Southeast Asian, Indian, Pakistani, or African ancestry; α-thalassemia for individuals of Southeast Asian or African ancestry; sickle-cell anemia for people of African, Mediterranean, Middle Eastern, Caribbean, Latin American, or Indian descent; and trisomy 21 for those with advanced maternal age.

NUTRITIONAL COUNSELING

Weight Gain Recommendations
For the first half of the 20th century, it was recommended that weight gain during pregnancy be limited to less than 20 lb or about 9 kg. It was believed that such restriction would prevent gestational hypertension and fetal macrosomia. By the 1970s, however, women were encouraged to gain at least 25 lb or 11 to 12 kg to prevent preterm birth and fetal-growth restriction, a recommendation supported by subsequent research (Ehrenberg, 2003). The Institute of Medicine and National Research Council (2009) revised its guidelines for weight gain in pregnancy and continues to stratify suggested weight gain ranges based on prepregnancy body mass index (BMI) (Table 9-5). BMI can easily be calculated with commonly available graphs (Fig. 48-1, p. 962). Of note, the new guidelines include a specific, relatively narrow range of recommended weight gains for obese women. Also, the same recommendations apply to adolescents, short women, and women of all racial and ethnic groups. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) have endorsed these guidelines.

As emphasized by Catalano (2007), when the Institute of Medicine guidelines were formulated, concern focused on low-birthweight newborns. Current emphasis now, however, is on the obesity epidemic. This likely explains renewed interest in lower weight gains during pregnancy. As discussed in Chapter 48 (p. 965), obesity is associated with significantly increased risks for gestational hypertension, preeclampsia, gestational diabetes, macrosomia, cesarean delivery, and other complications. The risk appears “dose related” to prenatal weight gain. In a population-based cohort of more than 120,000 obese pregnant women, Kiel and associates (2007) found that those who gained less than 15 pounds had the lowest rates of preeclampsia, large-for-gestational age neonates, and cesarean delivery. Among 100,000 women with normal prepregnancy BMI, DeVader and colleagues (2007) found that those who gained less than 25 pounds during pregnancy had a lower risk for preeclampsia, failed induction, cephalopelvic disproportion, cesarean delivery, and large-for-gestational age infants. This cohort, however, had an increased risk for small-for-gestational age newborns.

There is irrefutable evidence that maternal weight gain during pregnancy influences birthweight. Martin and coworkers (2009) studied this using birth certificate data for 2006. As shown in Figure 9-4, 60 percent of pregnant women gained 26 lb or more. Maternal weight gain had a positive correlation with birthweight. Moreover, women with the greatest risk—14 percent—for delivering an infant weighing < 2500 g were those with weight gain < 16 lb. Nearly 20 percent of births to women with such low weight gains were preterm.

*Empirical recommendations for weight gain in twin pregnancies include: normal BMI, 37–54 lb; overweight women, 31–50 lb; and obese women, 25–42 lb. BMI = body mass index. Modified from the Institute of Medicine and National Research Council, 2009.*
Meaningful studies of nutrition in human pregnancy are exceedingly difficult to design because experimental dietary deficiency is not ethical. In those instances in which severe nutritional deficiencies have been induced as a consequence of social, economic, or political disaster, coincidental events have often created many variables, the effects of which are not amenable to quantification. Some past experiences suggest, however, that in otherwise healthy women, a state of near starvation is required to establish clear differences in pregnancy outcome.

During the severe European winter of 1944 to 1945, nutritional deprivation of known intensity prevailed in a well-circumscribed area of The Netherlands occupied by the German military (Kyle, 2006). At the lowest point during this Dutch Hunger Winter, rations reached 450 kcal/day, with generalized rather than selective malnutrition. Smith (1947) analyzed the outcomes of pregnancies that were in progress during this 6-month famine. Median infant birthweights decreased approximately 250 g and rose again after food became available. This indicated that birthweight can be influenced significantly by starvation during later pregnancy. The perinatal mortality rate, however, was not altered, nor was the incidence of malformations significantly increased. Interestingly, the frequency of pregnancy “toxemia” declined.

Evidence of impaired brain development has been obtained in some animal fetuses whose mothers had been subjected to intense dietary deprivation. Subsequent intellectual development was studied by Stein and associates (1972) in young male adults whose mothers had been starved during pregnancy in the Hunger Winter. The comprehensive study was made possible because all males at age 19 underwent compulsory examination for military service. It was concluded that severe dietary deprivation during pregnancy caused no detectable effects on subsequent mental performance.
Several studies of the long-term consequences to this cohort of children born to nutritionally deprived women have been performed and have been reviewed by Kyle and Pichard (2006). Progeny deprived in mid to late pregnancy were lighter, shorter, and thinner at birth, and they had a higher incidence of subsequent diminished glucose tolerance, hypertension, reactive airway disease, dyslipidemia, and coronary artery disease. Early pregnancy deprivation was associated with increased obesity in adult women but not men. Early starvation was also linked to increased central nervous system anomalies, schizophrenia, and schizophrenia-spectrum personality disorders.

These observations, as well as others, have led to the concept of *fetal programming* by which adult morbidity and mortality are related to fetal health. Known widely as the *Barker hypothesis*, as promulgated by Barker and colleagues (1989), this concept is discussed in Chapter 44 (p. 876).

### Weight Retention after Pregnancy

Not all the weight gained during pregnancy is lost during and immediately after delivery (Hytten, 1991). Schauberger and coworkers (1992) studied prenatal and postpartum weights in 795 women. Their average weight gain was 28.6 lb or 4.8 kg. As shown in Figure 9-5, most maternal weight loss was at delivery—approximately 12 lb or 5.5 kg—and in the ensuing 2 weeks—approximately 9 lb or 4 kg. An additional 5.5 lb or 2.5 kg was lost between 2 weeks and 6 months postpartum. Thus, average total weight loss resulted in an average retained pregnancy weight of 3 lb or 1.4 kg. Overall, the more weight that was gained during pregnancy, the more that was lost postpartum. Interestingly, there is no relationship between prepregnancy BMI or prenatal weight gain and weight retention (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Accruing weight with age—rather than parity—is considered the main factor affecting weight gain over time.

![Figure 9-5](image) Cumulative weight loss from last antepartum visit to 6 months postpartum.
*Significantly different from 2-week weight loss; **Significantly different from 6-week weight loss
Recommended Dietary Allowances

Periodically, the Institute of Medicine (2006, 2011) publishes recommended dietary allowances, including those for pregnant or lactating women. The latest recommendations are summarized in Table 9-6. Certain prenatal vitamin–mineral supplements may lead to intakes well in excess of the recommended allowances. Moreover, the use of excessive supplements, which often are self-prescribed, has led to concern regarding nutrient toxicities during pregnancy. Those with potentially toxic effects include iron, zinc, selenium, and vitamins A, B<sub>6</sub>, C, and D. In particular, excessive vitamin A—more than 10,000 IU per day—may be teratogenic (Chap. 12, p. 252). Vitamin and mineral intake more than twice the recommended daily dietary allowance shown in Table 9-6 should be avoided.

TABLE 9-6. Recommended Daily Dietary Allowances for Adolescent and Adult Pregnant and Lactating Women
**Calories**

As shown in Figure 9-6, pregnancy requires an additional 80,000 kcal, mostly during the last 20
weeks. To meet this demand, a caloric increase of 100 to 300 kcal per day is recommended during pregnancy (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). This intake increase, however, should not be divided equally during the course of pregnancy. The Institute of Medicine (2006) recommends adding 0, 340, and 452 kcal/day to the estimated nonpregnant energy requirements in the first, second, and third trimesters, respectively. Calories are necessary for energy. Whenever caloric intake is inadequate, protein is metabolized rather than being spared for its vital role in fetal growth and development. Total physiological requirements during pregnancy are not necessarily the sum of ordinary nonpregnant requirements plus those specific to pregnancy. For example, the additional energy required during pregnancy may be compensated in whole or in part by reduced physical activity (Hytten, 1991).

**FIGURE 9-6** Cumulative kilocalories required for pregnancy. (Redrawn from Chamberlain, 1998, with permission.)

### Protein
To the basic protein needs of the nonpregnant woman are added the demands for growth and remodeling of the fetus, placenta, uterus, and breasts, as well as increased maternal blood volume (Chap. 4, p. 53). During the second half of pregnancy, approximately 1000 g of protein are deposited, amounting to 5 to 6 g/day (Hytten, 1971). Most amino-acid levels in maternal plasma fall markedly, including ornithine, glycine, taurine, and proline (Hytten, 1991). Exceptions during pregnancy are glutamic acid and alanine, the concentrations of which rise.

Preferably, most protein should be supplied from animal sources, such as meat, milk, eggs, cheese, poultry, and fish. These furnish amino acids in optimal combinations. Milk and dairy products have long been considered nearly ideal sources of nutrients, especially protein and calcium, for pregnant or lactating women. Ingestion of specific fish and potential methylmercury toxicity are discussed on page 183.

### Minerals

#### Iron
The intakes recommended by the Institute of Medicine (2006) for various minerals are presented in Table 9-6. With the exception of iron and iodine, practically all diets that supply sufficient calories for appropriate weight gain will contain enough minerals to prevent deficiency.

The reasons for substantively increased iron requirements during pregnancy are discussed in Chapter 4 (p. 55). Of the approximately 300 mg of iron transferred to the fetus and placenta and the 500 mg incorporated into the expanding maternal hemoglobin mass, nearly all is used after midpregnancy. During that time, iron requirements imposed by pregnancy and maternal excretion total approximately 7 mg per day (Pritchard, 1970). Few women have sufficient iron stores or dietary iron intake to supply this amount. Thus, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) endorse the recommendation by the National Academy of Sciences that at least 27 mg of elemental iron supplement be given daily to pregnant women. This amount is contained in most prenatal vitamins.

Scott and coworkers (1970) established that as little as 30 mg of elemental iron, supplied as ferrous gluconate, sulfate, or fumarate and taken daily throughout the latter half of pregnancy, provides sufficient iron to meet pregnancy requirements and to protect preexisting iron stores. This amount will also provide for iron requirements of lactation. The pregnant woman may benefit from 60 to 100 mg of elemental iron per day if she is large, has twin fetuses, begins supplementation late in pregnancy, takes iron irregularly, or has a somewhat depressed hemoglobin level. The woman who is overtly anemic from iron deficiency responds well to oral supplementation with iron salts (Chap. 56, p. 1102).

Because iron requirements are slight during the first 4 months of pregnancy, it is not necessary to provide supplemental iron during this time. Withholding iron supplementation during the first trimester of pregnancy also avoids the risk of aggravating nausea and vomiting (Gill, 2009). Ingestion of iron at bedtime or on an empty stomach aids absorption and appears to minimize the possibility of an adverse gastrointestinal reaction.

Since 1997, the Food and Drug Administration (FDA) has required that iron preparations containing 30 mg or more of elemental iron per tablet be packaged as individual doses, such as in blister packages. This regulation is targeted at preventing accidental iron poisoning in children.

Iodine

The recommended daily iodine allowance is 220 μg (Table 9-6). The use of iodized salt and bread products is recommended during pregnancy to offset the increased fetal requirements and maternal renal losses of iodine. Despite this, iodine intake has declined substantially in the last 15 years, and in some areas, it is probably inadequate (Chap. 58, p. 1155). Interest in increasing dietary iodine was heightened by reports linking subclinical maternal hypothyroidism to adverse pregnancy outcomes and possible neurodevelopmental defects in children (Casey, 2005; Haddow, 1999). Severe maternal iodine deficiency predisposes offspring to endemic cretinism, characterized by multiple severe neurological defects. In parts of China and Africa where this condition is common, iodide supplementation very early in pregnancy prevents some cretinism cases (Cao, 1994). To obviate this, many prenatal supplements now contain various quantities of iodine.

Calcium

As discussed in Chapter 4 (p. 54), the pregnant woman retains approximately 30 g of calcium. Most of this is deposited in the fetus late in pregnancy (Pitkin, 1985). This amount of calcium represents only approximately 2.5 percent of total maternal calcium, most of which is in bone and
can readily be mobilized for fetal growth. Moreover, Heaney and Skillman (1971) demonstrated increased calcium absorption by the intestine and progressive retention throughout pregnancy. Efforts to prevent preeclampsia using routine calcium supplementation have not proven efficacious (Chap. 40, p. 748).

**Zinc**

Severe zinc deficiency in a given person may lead to poor appetite, suboptimal growth, and impaired wound healing. During pregnancy, the recommended daily intake is approximately 12 mg. But, the safe level of zinc supplementation for pregnant women has not been clearly established. Goldenberg and colleagues (1995) randomly assigned 580 indigent women to daily 25-mg zinc supplementation or placebo beginning at midpregnancy. Plasma zinc levels were significantly higher in women who received supplements. Infants born to zinc-supplemented women were slightly larger—mean increase 125 g—and had a slightly larger head circumference—mean 4 mm. Later, Osendarp and associates (2001) randomly assigned 420 women in Bangladesh to receive either daily 30-mg zinc supplementation or placebo from 12 to 16 weeks’ gestation until delivery. Supplementation did not improve birthweight. However, low-birthweight infants of mothers who received zinc had reduced risks of acute diarrhea, dysentery, and impetigo. In a follow-up study of these infants at 13 months, zinc supplementation did not benefit their developmental outcome (Hamadani, 2002).

**Magnesium**

Deficiency of this mineral as a consequence of pregnancy has not been recognized. Undoubtedly, during prolonged illness with no magnesium intake, the plasma level might become critically low, as it would in the absence of pregnancy. We have observed magnesium deficiency during pregnancies in some with previous intestinal bypass surgery. Sibai and coworkers (1989) randomly assigned 400 normotensive primigravid women to 365-mg elemental magnesium supplementation or placebo tablets from 13 to 24 weeks’ gestation. Supplementation did not improve any measures of pregnancy outcome.

**Trace Metals**

Copper, selenium, chromium, and manganese all have important roles in certain enzyme functions. In general, most are provided by an average diet. A severe geochemical selenium deficiency has been identified in a large area of China. Deficiency is manifested by a frequently fatal cardiomyopathy in young children and reproductive-aged women. Conversely, selenium toxicity resulting from oversupplementation also has been observed. There is no reported need to supplement selenium in American women.

**Potassium**

The concentration of potassium in maternal plasma decreases by approximately 0.5 mEq/L by midpregnancy (Brown, 1986). Potassium deficiency develops in the same circumstances as in nonpregnant individuals.

**Fluoride**

There is no evidence that supplemental fluoride during pregnancy is beneficial (Institute of Medicine, 1990). Maheshwari and colleagues (1983) found that fluoride metabolism is not altered appreciably during pregnancy. Horowitz and Heifetz (1967) concluded that there were no
additional benefits from maternal ingestion of fluoridated water if the offspring ingested such water from birth. Sa Roriz Fonteles and associates (2005) studied microdrill biopsies of deciduous teeth and concluded that prenatal fluoride provided no additional fluoride uptake compared with postnatal fluoride alone. Supplemental fluoride ingested by lactating women does not increase the fluoride concentration in breast milk (Ekstrand, 1981).

**Vitamins**

The increased requirements for most vitamins during pregnancy shown in Table 9-6 usually are supplied by any general diet that provides adequate calories and protein. The exception is folic acid during times of unusual requirements, such as pregnancy complicated by protracted vomiting, hemolytic anemia, or multiple fetuses. That said, in impoverished countries, routine multivitamin supplementation reduced the incidence of low-birthweight and growth-restricted fetuses, but did not alter preterm delivery or perinatal mortality rates (Fawzi, 2007).

**Folic Acid**

The Centers for Disease Control and Prevention (2004) estimated that the number of pregnancies affected by neural-tube defects has decreased from 4000 pregnancies per year to approximately 3000 per year since mandatory fortification of cereal products with folic acid in 1998. Perhaps more than half of all neural-tube defects can be prevented with daily intake of 400 μg of folic acid throughout the periconceptional period. Putting 140 μg of folic acid into each 100 g of grain products may increase the folic acid intake of the average American woman of childbearing age by 100 μg per day. Because nutritional sources alone are insufficient, however, folic acid supplementation is still recommended (American College of Obstetricians and Gynecologists 2013f). Likewise, the United States Preventive Services Task Force (2009) has issued a Level-A recommendation that all women planning or capable of pregnancy take a daily supplement containing 0.4 to 0.8 mg of folic acid. Using data from 15 international registries, Botto and associates (2006) demonstrated a significant reduction in neural-tube defect rates only in countries with folic acid fortification programs. There was no rate decrease in areas with supplementation recommendations alone.

A woman with a prior child with a neural-tube defect can reduce the 2- to 5-percent recurrence risk by more than 70 percent with daily 4-mg folic acid supplements the month before conception and during the first trimester. As emphasized by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012), this dose should be consumed as a separate supplement and not as multivitamin tablets. This practice avoids excessive intake of fat-soluble vitamins. Unfortunately, surveys continue to suggest that many women, especially among minorities, remain unaware of the recommendations regarding folic acid supplementation (Perlow, 2001; Rinsky-Eng, 2002). This important relationship between folic acid deficiency and neural-tube defects is further discussed in Chapter 14 (p. 284).

**Vitamin A**

Although essential, this vitamin has been associated with congenital malformations when taken in higher doses (> 10,000 IU per day) during pregnancy. These malformations are similar to those produced by the vitamin A derivative isotretinoin—Accutane—which is one of the most potent teratogens (Chap. 12, p. 251). Beta-carotene, the precursor of vitamin A found in fruits and vegetables, has not been shown to produce vitamin A toxicity. Most prenatal vitamins contain vitamin A in doses considerably below the teratogenic threshold. Dietary intake of vitamin A in
the United States appears to be adequate, and additional supplementation is not routinely recommended.

Vitamin A deficiency is an endemic nutritional problem in the developing world. It is estimated that 6 million pregnant women suffer from night blindness secondary to vitamin A deficiency (West, 2003). In a study from India, Radhika and coworkers (2002) found overt deficiency manifested as night blindness in 3 percent of 736 women in their third trimester. Another 27 percent had subclinical vitamin A deficiency defined as a serum retinol concentration below 20 μg/dL. Vitamin A deficiency, whether overt or subclinical, was associated with an increased risk of maternal anemia and spontaneous preterm birth.

**Vitamin B<sub>12</sub>**

Maternal plasma vitamin B<sub>12</sub> levels decrease in normal pregnancy mostly as a result of reduced plasma levels of their carrier proteins—transcobalamins. Vitamin B<sub>12</sub> occurs naturally only in foods of animal origin, and strict vegetarians may give birth to infants whose B<sub>12</sub> stores are low. Likewise, because breast milk of a vegetarian mother contains little vitamin B<sub>12</sub>, the deficiency may become profound in the breast-fed infant (Higginbottom, 1978). Excessive ingestion of vitamin C also can lead to a functional deficiency of vitamin B<sub>12</sub>. Although its role is still controversial, low levels of vitamin B<sub>12</sub> preconceptionally, similar to folate, may increase the risk of neural-tube defects (Molloy, 2009; Thompson, 2009).

**Vitamin B<sub>6</sub>—Pyridoxine**

Limited clinical trials in pregnant women have failed to demonstrate any benefits of vitamin B<sub>6</sub> supplements (Thaver, 2006). For women at high risk for inadequate nutrition—for example, substance abusers, adolescents, and those with multifetal gestations—a daily 2-mg supplement is recommended. As discussed on page 187 and in Chapter 54 (p. 1072), vitamin B<sub>6</sub>, when combined with the antihistamine doxylamine, is helpful in many cases of nausea and vomiting of pregnancy (Boskovic, 2003; Staroselsky, 2007).

**Vitamin C**

The recommended dietary allowance for vitamin C during pregnancy is 80 to 85 mg/day—approximately 20 percent more than when nonpregnant (see Table 9-6). A reasonable diet should readily provide this amount. The maternal plasma level declines during pregnancy, whereas the cord-blood level is higher, a phenomenon observed with most water-soluble vitamins.

**Vitamin D**

This is a fat-soluble vitamin that, after being metabolized to its active form, increases the efficiency of intestinal calcium absorption and promotes bone mineralization and growth. Unlike most vitamins that are obtained exclusively from dietary intake, vitamin D is also synthesized endogenously with exposure to sunlight. There is increasing recognition that vitamin D deficiency is common during pregnancy. This is especially true in high-risk groups such as women with limited sun exposure, ethnic minorities—particularly those with darker skin, and vegetarians (Bodnar, 2007). Such maternal deficiency can cause disordered skeletal homeostasis, congenital rickets, and fractures in the newborn (American College of Obstetricians and Gynecologists 2011d). The Food and Nutrition Board of the Institute of Medicine (2011) established that an adequate intake of vitamin D during pregnancy and lactation was 15 μg per day (600 IU per day).
In women suspected of having vitamin D deficiency, serum levels of 25-hydroxyvitamin D can be obtained. Even then, the optimal levels in pregnancy have not been established (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012).

**Pragmatic Nutritional Surveillance**

Although researchers continue to study the ideal nutritional regimen for the pregnant woman and her fetus, basic tenets for the clinician include:

1. In general, advise the pregnant woman to eat what she wants in amounts she desires and salted to taste.
2. Ensure that food is amply available for socioeconomically deprived women.
3. Monitor weight gain, with a goal of approximately 25 to 35 lb in women with a normal BMI.
4. Explore food intake by dietary recall periodically to discover the occasional nutritionally errant diet.
5. Give tablets of simple iron salts that provide at least 27 mg of elemental iron daily. Give folate supplementation before and in the early weeks of pregnancy. Provide iodine supplementation in areas of known dietary insufficiency.
6. Recheck the hematocrit or hemoglobin concentration at 28 to 32 weeks’ gestation to detect significant decreases.

**COMMON CONCERNS**

**Employment**

More than half of the children in the United States are born to working mothers. Federal law prohibits employers from excluding women from job categories on the basis that they are or might become pregnant (Annas, 1991). The Family and Medical Leave Act requires that covered employers must grant up to 12 workweeks of unpaid leave to an employee for the birth and care of a newborn child. In the absence of complications, most women can continue to work until the onset of labor (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012).

Some types of work, however, may increase pregnancy complication risks. Mozurkewich and colleagues (2000) reviewed 29 studies that involved more than 160,000 pregnancies. With physically demanding work, women had a 20- to 60-percent increase in rates of preterm birth, fetal-growth restriction, or gestational hypertension. In a prospective study of more than 900 healthy nulliparas, Higgins and associates (2002) found that women who worked had a fivefold risk of preeclampsia. Newman and coworkers (2001) reported outcomes in 2929 women with singleton pregnancies studied by the Maternal-Fetal Medicine Units Network. Occupational fatigue—estimated by the number of hours standing, intensity of physical and mental demands, and environmental stressors—was associated with an increased risk of preterm premature membrane rupture. For women reporting the highest degrees of fatigue, the risk was 7.4 percent.

Thus, any occupation that subjects the pregnant woman to severe physical strain should be avoided. Ideally, no work or play should be continued to the extent that undue fatigue develops. Adequate periods of rest should be provided. It seems prudent to advise women with previous
pregnancy complications that are at risk to recur—for example, preterm birth—to minimize physical work.

**Exercise**

In general, pregnant women do not need to limit exercise, provided they do not become excessively fatigued or risk injury. Clapp and associates (2000) randomly assigned 46 pregnant women who did not exercise regularly to either no exercise or to weight-bearing exercise beginning at 8 weeks’ gestation. Exercise consisted of treadmill running, step aerobics, or stair stepper use for 20 minutes three to five times each week. They did this throughout pregnancy at an intensity level between 55 and 60 percent of the preconceptional maximum aerobic capacity. Both placental size and birthweight were significantly greater in the exercise group. Duncombe and coworkers (2006) reported similar findings in 148 women. In contrast, Magann and colleagues (2002) prospectively analyzed exercise behavior in 750 healthy women and found that working women who exercised had smaller infants and more dysfunctional labors, and they had more frequent upper respiratory infections.

The American College of Obstetricians and Gynecologists (2009b) advises a thorough clinical evaluation before recommending an exercise program. In the absence of contraindications listed in Table 9-7, pregnant women should be encouraged to engage in regular, moderate-intensity physical activity for 30 minutes or more day. Each activity should be reviewed individually for its potential risk. Pregnant women should refrain from activities with a high risk of falling or abdominal trauma. Similarly, scuba diving is avoided because the fetus is at increased risk for decompression sickness.

</tbody>
</table>
• Poorly controlled hypertension
• Orthopedic limitations
• Poorly controlled seizure disorder
• Poorly controlled hyperthyroidism
• Heavy smoker

In the setting of certain pregnancy complications, it is wise to abstain from exercise and even limit physical activity. For example, some women with pregnancy-associated hypertensive disorders, preterm labor, placenta previa, or severe cardiac or pulmonary disease may gain from being sedentary. Also, those with multiple or suspected growth-restricted fetuses may be served by greater rest.

### Seafood Consumption

Fish are an excellent source of protein, are low in saturated fats, and contain omega-3 fatty acids. Because nearly all fish and shellfish contain trace amounts of mercury, pregnant and lactating women are advised to avoid specific types of fish with potentially high methylmercury levels. These include shark, swordfish, king mackerel, and tile fish. It is further recommended that pregnant women ingest no more than 12 ounces or two servings of canned tuna per week and no more than 6 ounces of albacore or “white” tuna (United States Environmental Protection Agency, 2004). If the mercury content of locally caught fish is unknown, then overall fish consumption should be limited to 6 ounces per week (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). The Avon Longitudinal Study of Parents and Children, however, reported beneficial effects on pregnancy outcomes in women who consumed 340 g or more of seafood weekly (Hibbeln, 2007).

### Lead Screening

Maternal lead exposure has been associated with several adverse maternal and fetal outcomes across a range of maternal blood lead levels (Bellinger, 2005). These include gestational hypertension, spontaneous abortion, low birthweight, and neurodevelopmental impairments in exposed fetuses (American College of Obstetricians and Gynecologists, 2012b). The exposure levels at which these risks increase remains unclear. But, recognizing that such exposure remains a significant health issue for reproductive-aged women, the Centers for Disease Control and Prevention (2010a) has issued guidelines for screening and managing exposed pregnant and lactating women. These guidelines, which have been endorsed by the American College of Obstetricians and Gynecologists (2012b), recommend blood lead testing only if a risk factor is identified (Table 9-8). If the levels are > 5 μg/dL, then counseling is completed, and the lead source is sought and removed. Subsequent blood levels should be obtained. Blood lead levels ≥ 45 μg/dL are consistent with lead poisoning, and women in this group may be candidates for chelation therapy. Such pregnancies should be managed in consultation with lead poisoning treatment experts. National and state resources are available at the CDC website:
TABLE 9-8. Risk Factors for Lead Exposure in Pregnant and Lactating Women

- Recent immigration from or residency in areas of high ambient lead contamination
- Living near a point source of lead
- Working with lead or living with someone who does
- Using lead-glazed ceramic pottery
- Using nonfood substances (pica)
- Using alternative or complementary medicines, herbs, or therapies
- Using imported cosmetics or certain food products
- Renovating or remodeling older homes without implementing lead hazard controls
- Consuming lead-contaminated drinking water
- Having a prior lead-exposure history or evidence of an elevated body burden of lead
- Living with someone identified with an elevated lead level

Adapted from Centers for Disease Control and Prevention, 2010a.

Automobile and Air Travel

The American College of Obstetricians and Gynecologists (2010) has formulated guidelines for automobile passenger restraints use during pregnancy (Chap. 47, p. 951). Women should be encouraged to wear properly positioned three-point restraints throughout pregnancy while riding in automobiles. The lap portion of the restraining belt should be placed under the abdomen and across her upper thighs. The belt should be comfortably snug. The shoulder belt also should be firmly positioned between the breasts. Available information suggests that airbags should not be disabled for the pregnant woman.

In general, air travel in a properly pressurized aircraft has no harmful effect on pregnancy (Aerospace Medical Association, 2003). Thus, in the absence of obstetrical or medical complications, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2009a, 2012) have concluded that pregnant women can safely fly up to 36 weeks’ gestation. It is recommended that pregnant women observe the same precautions for air travel as the general population. These include seatbelt use while seated and periodic lower extremity movement and at least hourly ambulation to lower venous thromboembolism risks. Significant risks with travel, especially international travel, are infectious disease acquisition and development of complications remote from adequate resources (Ryan, 2002).

Coitus

In healthy pregnant women, sexual intercourse usually is not harmful. Whenever abortion, placenta previa, or preterm labor threatens, however, coitus should be avoided. Nearly 10,000 women enrolled in a prospective investigation by the Vaginal Infection and Prematurity Study Group were interviewed regarding sexual activity (Read, 1993). They reported a decreased frequency of sexual intercourse with advancing gestation. By 36 weeks, 72 percent had intercourse less than
once weekly. According to Bartellas and colleagues (2000), the decline is attributed to decreased desire in 58 percent and fear of harm to the pregnancy in 48 percent.

Intercourse late in pregnancy specifically has not been found to be harmful. Grudzinskas and coworkers (1979) found no association between gestational age at delivery and coital frequency during the last 4 weeks of pregnancy. Sayle and colleagues (2001) found no increased—and actually a decreased—risk of delivery within 2 weeks of intercourse. Tan and associates (2007) studied women scheduled for nonurgent labor induction and found that spontaneous labor ensued at equal rates in groups either participating in or abstaining from intercourse.

Oral-vaginal intercourse is occasionally hazardous. Aronson and Nelson (1967) described a fatal air embolism late in pregnancy as a result of air blown into the vagina during cunnilingus. Other near-fatal cases have been described (Bernhardt, 1988).

Dental Care

Examination of the teeth should be included in the prenatal examination, and good dental hygiene is encouraged. Indeed, periodontal disease has been linked to preterm labor. Unfortunately, although its treatment improves dental health, it has not prevented preterm birth (Michalowicz, 2006). Dental caries are not aggravated by pregnancy. Importantly, pregnancy is not a contraindication to dental treatment including dental radiographs (Giglio, 2009).

Immunization

Current recommendations for immunization during pregnancy are summarized in Table 9-9. Well-publicized concerns regarding a causal link between childhood exposure to the thimerosal preservative in some vaccines and neuropsychological disorders has led to some parental prohibition. Although controversy continues, these associations have proven groundless (Sugarman, 2007; Thompson, 2007; Tozzi, 2009). Thus, many vaccines may be used in pregnancy. The American College of Obstetricians and Gynecologists (2013c) stresses the importance of integrating an effective vaccine strategy into the care of both obstetrical and gynecological patients. The College further emphasizes that information on the safety of vaccines given during pregnancy is subject to change and recommendations can be found from the Centers for Disease Control and Prevention website at: www.cdc.gov/vaccines.

Influenza                    | All pregnant women,                                    | One dose IM every year                                                        | Inactivated virus vaccine                                                                  |
regardless of trimester during flu season (October–May)

Rabies Indications for prophylaxis not altered by pregnancy; each case considered individually

Human papillomavirus Not recommended

Hepatitis B Preexposure and postexposure for women at risk of infection

Hepatitis A Preexposure and postexposure if at risk (international travel)

Public health authorities to be consulted for indications, dosage, and route of administration

Three-dose series IM at 0, 1, and 6 months

Killed-virus vaccine

Quadrivalent or bivalent vaccines; both are inactivated virus. No teratogenic effects have been observed with either Used with hepatitis B immune globulin for some exposures. Exposed newborn needs birth-dose vaccination and immune globulin as soon as possible. All infants should receive birth dose of vaccine

Inactivated virus

Inactivated Bacterial Vaccines

Pneumococcus Indications not altered by pregnancy. Recommended for women with asplenia; metabolic, renal, cardiac, immunosuppressed

Polyvalent polysaccharide vaccine; safety in the first trimester has not been evaluated

In adults, one dose only; consider repeat dose in 6 years for high-risk women

### Standard Immune Globulins

| Disease:  | Type: Postexposure prophylaxis and those at high risk | Dosage: 0.02 mL/kg IM in one dose | Immune globulin should be given as soon as possible and within 2 weeks of exposure; infants born to women who acquired varicella in pregnancy should be observed for 14 days following birth. |
The frequency of pertussis infection has substantially increased in the United States. This resulted in updated recommendations for use of the three-agent Tdap vaccine—tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Centers for Disease Control and Prevention 2013a). Young infants are at increased risk for death from pertussis and are entirely dependent on passive immunization from maternal antibodies until the vaccine series is initiated at 2 months of age. As demonstrated by Healy and coworkers (2013), maternal antipertussis antibodies are relatively short-lived, and Tdap administration before pregnancy—or even in the first half of the current pregnancy—is not likely to provide a high level of newborn antibody protection. The Advisory Committee on Immunization Practices, therefore, has recommended that a dose of Tdap be given to women during each pregnancy, optimally between 27 and 36 weeks’ gestation to maximize passive antibody transfer to the fetus (Centers for Disease Control and Prevention 2013a). The American College of Obstetricians and Gynecologists supports this recommendation (2012j).

All women who will be pregnant during influenza season should be offered vaccination, regardless of gestational age. Those with underlying medical conditions that increase the risk for complications should be provided the vaccine before flu season starts (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Zaman and colleagues (2008) showed that prenatal maternal vaccination reduced the infant influenza incidence in the first 6 months of life by 63 percent in infants born to these treated women. Moreover, it reduced all febrile respiratory illnesses in these infants by a third.

Women who are susceptible to rubella during pregnancy should receive MMR—measles, mumps, rubella—vaccination postpartum. Although this vaccine is not recommended during pregnancy, congenital rubella syndrome has never resulted from its inadvertent use. There is no contraindication to MMR vaccination while breast feeding (Centers for Disease Control and Prevention, 2011).

**Biological Warfare and Vaccines**

The ongoing threat of bioterrorism requires familiarity with smallpox and anthrax vaccines during pregnancy. The smallpox vaccine is made with live attenuated vaccinia virus, which is related to smallpox and cowpox viruses. Fetal vaccinia infection is rare, but it may result in abortion, stillbirth, or neonatal death. Thus, in nonemergency circumstances, vaccination is contraindicated...
during pregnancy and in women who might become pregnant within 28 days of vaccination (Centers for Disease Control and Prevention, 2013c). But, if vaccination is inadvertently administered in early pregnancy, this is not an indication for termination (Suarez, 2002). If the pregnant woman is at risk because of exposure to smallpox—either as a direct victim of a bioterrorist attack or as a close contact of an individual case—the risks from clinical smallpox substantially outweigh any potential risk from vaccination.

Anthrax vaccination has been limited principally to individuals who are occupationally exposed, such as special veterinarians, laboratory workers, and military personnel. The vaccine contains no live bacteria and thus would not be expected to pose significant fetal risk. Wiesen and Littell (2002) studied the reproductive outcomes of 385 women in the United States Army who became pregnant after vaccination and reported no adverse effects on fertility or pregnancy outcome. Smallpox, anthrax, and other infections related to bioterrorism are discussed in Chapter 64 (p. 1258).

### Caffeine

Whether adverse pregnancy outcomes are related to caffeine consumption is somewhat controversial. As summarized from Chapter 18 (p. 353), heavy intake of coffee each day—about five cups or 500 mg of caffeine—slightly increases the abortion risk. Studies of “moderate” intake—less than 200 mg daily—did not report increased risk.

It is unclear if caffeine consumption is associated with preterm birth or impaired fetal growth. Clausson and coworkers (2002) found no association between moderate caffeine consumption of less than 500 mg daily and low birthweight, fetal-growth restriction, or preterm delivery. Bech and associates (2007) randomly assigned more than 1200 pregnant women who drank at least three cups of coffee per day to caffeinated versus decaffeinated coffee. They found no difference in birthweight or gestational age at delivery between groups. The CARE Study Group (2008) however, evaluated 2635 low-risk pregnancies and reported a 1.4-fold risk for fetal-growth restriction among those whose daily caffeine consumption was > 200 mg compared with those who consumed < 100 mg daily. The American College of Obstetricians and Gynecologists (2013d) has concluded that moderate consumption of caffeine—less than 200 mg per day—does not appear to be associated with miscarriage or preterm birth, but that the relationship between caffeine consumption and fetal-growth restriction remains unsettled. The American Dietetic Association (2008) recommends that caffeine intake during pregnancy be limited to less than 300 mg daily, or approximately three 5-oz cups of percolated coffee.

### Nausea and Vomiting

These are common complaints during the first half of pregnancy. Nausea and vomiting of varying severity usually commence between the first and second missed menstrual period and continue until 14 to 16 weeks’ gestation. Although nausea and vomiting tend to be worse in the morning—thus erroneously termed morning sickness—both symptoms frequently continue throughout the day. Lacroix and coworkers (2000) found that nausea and vomiting were reported by three fourths of pregnant women and lasted an average of 35 days. Half had relief by 14 weeks, and 90 percent by 22 weeks. In 80 percent of these women, nausea lasted all day.

Treatment of pregnancy-associated nausea and vomiting seldom provides complete relief, but symptoms can be minimized. Eating small meals at more frequent intervals but stopping short of satiation is valuable. Borrelli and colleagues (2005) performed a systematic literature search and
reported that the herbal remedy ginger was likely effective. Mild symptoms usually respond to vitamin B<sub>6</sub> given along with doxylamine, but some women require phenothiazine or H<sub>1</sub>-receptor blocking antiemetics (American College of Obstetricians and Gynecologists, 2013e). In some hyperemesis gravidarum develops—vomiting so severe that dehydration, electrolyte and acid-base disturbances, and starvation ketosis become serious problems. Its management and that of less severe nausea are described in Chapter 54 (p. 1072).

### Backache

Low back pain to some extent is reported by nearly 70 percent of pregnant women (Wang, 2004). Minor degrees follow excessive strain or significant bending, lifting, or walking. It can be reduced by squatting rather than bending when reaching down, by using a pillow back support when sitting, and by avoiding high-heeled shoes. Back pain complaints increase with progressing gestation and are more prevalent in obese women and those with a history of low back pain. In some cases, troublesome pain may persist for years after the pregnancy (Norén, 2002).

Severe back pain should not be attributed simply to pregnancy until a thorough orthopedic examination has been conducted. Severe pain also has other uncommon causes, such as pregnancy-associated osteoporosis, disc disease, vertebral osteoarthritis, or septic arthritis (Smith, 2008). More commonly, muscular spasm and tenderness are classified clinically as acute strain or fibrositis. Although evidence-based clinical research directing care in pregnancy is limited, such low back pain usually responds well to analgesics, heat, and rest. Tylenol may be used chronically as needed. Nonsteroidal antiinflammatory drugs may also be beneficial but are used only in short courses to avoid fetal effects (Chap. 12, p. 247). Muscle relaxants that include cyclobenzaprine (Flexeril) or baclofen may be added when needed. Once acute pain is improved, stabilizing and strengthening exercises provided by physical therapy improve spine and hip stability, which is essential for the increased load of pregnancy. For some, a sacroiliac joint stabilizing support belt may be beneficial. There may also be a role for chiropractic manipulation in selected women. George and associates (2013) randomized 169 women with low back pain at 24 to 28 weeks’ gestation to standard obstetrical care or standard care plus multimodal therapy—a combination of manual chiropractic therapy, exercises, and patient education. The patients who received the multimodal therapy experienced significantly less pain, less disability, and greater global improvement in daily activities.

### Varicosities and Hemorrhoids

Venous leg varicosities have a congenital predisposition and accrue with advancing age. They can be aggravated by factors that cause increased lower extremity venous pressures. As discussed in Chapter 4 (p. 60), femoral venous pressures in the supine pregnant woman increase from 8 mm Hg early to 24 mm Hg at term. Thus, susceptible women develop leg varicosities that typically worsen as pregnancy advances, especially with prolonged standing. Symptoms vary from cosmetic blemishes and mild discomfort at the end of the day to severe discomfort that requires prolonged rest with feet elevation. Treatment is generally limited to periodic rest with leg elevation, elastic stockings, or both. Surgical correction during pregnancy generally is not advised, although rarely the symptoms may be so severe that injection, ligation, or even stripping of the veins is necessary.

Vulvar varicosities frequently coexist with leg varicosities, but they may appear without other venous pathology. Uncommonly, they become massive and almost incapacitating. If these large varicosities rupture, blood loss may be severe. Treatment is with specially fitted pantyhose that
will also minimize lower extremity varicosities. With particularly bothersome vulvar varicosities, a foam rubber pad suspended across the vulva by a belt can be used to exert pressure on the dilated veins.

Hemorrhoids are rectal vein varicosities and may first appear during pregnancy as pelvic venous pressures increase. Commonly, they are recurrences of previously encountered hemorrhoids. Pain and swelling usually are relieved by topically applied anesthetics, warm soaks, and stool-softening agents. With thrombosis of an external hemorrhoid, there can be considerable pain. This may be relieved by incision and removal of the clot under local analgesia.

Heartburn
This symptom is one of the most common complaints of pregnant women and is caused by gastric content reflux into the lower esophagus. The increased frequency of regurgitation during pregnancy most likely results from upward displacement and compression of the stomach by the uterus, combined with relaxation of the lower esophageal sphincter (Chap. 4, p. 66). In most pregnant women, symptoms are mild and are relieved by a regimen of more frequent but smaller meals and avoidance of bending over or lying flat. Antacids may provide considerable relief. Aluminum hydroxide, magnesium trisilicate, or magnesium hydroxide alone or in combination are given. Management for symptoms that do not respond to these simple measures is discussed in Chapter 54 (p. 1072).

Pica and Ptyalism
The craving of pregnant women for strange foods is termed pica. At times, nonfoods such as ice—pagophagia, starch—amylophagia, or clay—geophagia may predominate. This desire has been considered by some to be triggered by severe iron deficiency. Although such cravings usually abate after iron deficiency correction, not all pregnant women with pica are iron deficient. Indeed, if strange “foods” dominate the diet, iron deficiency will be aggravated or will develop eventually.

Patel and coworkers (2004) from the University of Alabama at Birmingham prospectively completed a dietary inventory on more than 3000 women during the second trimester. The prevalence of pica was 4 percent. The most common nonfood items ingested were starch in 64 percent, dirt in 14 percent, sourdough in 9 percent, and ice in 5 percent. The prevalence of anemia was 15 percent in women with pica compared with 6 percent in those without it. Interestingly, the rate of spontaneous preterm birth before 35 weeks was twice as high in women with pica.

Women during pregnancy are occasionally distressed by profuse salivation—ptyalism. Although usually unexplained, ptyalism sometimes appears to follow salivary gland stimulation by the ingestion of starch.

Sleeping and Fatigue
Beginning early in pregnancy, many women experience fatigue and need increased amounts of sleep. This likely is due to the soporific effect of progesterone but may be compounded in the first trimester by nausea and vomiting and in the latter stages of pregnancy by general discomforts, urinary frequency, and dyspnea. Moreover, sleep efficiency appears to progressively diminish as pregnancy advances. Wilson and associates (2011) performed overnight polysomnography in 27 women in the third trimester, in 21 women in the first trimester, and in 24 nonpregnant control
Women. Women in the third trimester had poorer sleep efficiency, more awakenings, and less of both stage 4 (deep) and rapid-eye movement sleep. Women in the first trimester were also affected but to a lesser extent. Subjective assessments of sleep quality have yielded similar findings. Facco and colleagues (2010) prospectively evaluated 189 healthy nulliparous women with a sleep survey completed once before midpregnancy and again in the third trimester. They found that women in the third trimester had significantly shorter sleep durations and were more likely to snore and meet criteria for restless leg syndrome. Most women experience some degree of sleep disturbance by the third trimester. Daytime naps and mild sedatives at bedtime such as diphenhydramine (Benadryl) can be helpful.

Leukorrhea

Pregnant women commonly develop increased vaginal discharge that in many instances is not pathological. Increased mucus secretion by cervical glands in response to hyperestrogenemia is undoubtedly a contributing factor. Occasionally, troublesome leukorrhea is the result of vulvovaginal infection. In the adult woman, most of these are bacterial vaginosis, candidiasis, or trichomoniasis, which are reviewed in Chapter 65 (p. 1276).

Cord Blood Banking

Since the first successful cord blood transplantation in 1988, more than 25,000 umbilical cord blood transplantations have been performed to treat hemopoietic cancers and various genetic conditions (Butler, 2011). There are two types of cord blood banks. Public banks promote allogeneic donation, for use by a related or unrelated recipient, similar to blood product donation. Private banks were initially developed to store stem cells for future autologous use and charged fees for initial processing and annual storage. The American College of Obstetricians and Gynecologists (2012d) has concluded that if a woman requests information on umbilical cord banking, information regarding advantages and disadvantages of public versus private banking should be explained. Some states have passed laws that require physicians to inform patients about cord blood banking options. Importantly, few transplants have been performed by using cord blood stored in the absence of a known indication in the recipient (Thornley, 2009). The likelihood that cord blood would be used for the child or family member of the donor couple is considered remote and estimated to be about 1 in 2700 individuals (American College of Obstetricians and Gynecologists, 2008). It is recommended that directed donation be considered when an immediate family member carries the diagnosis of a specific condition known to be treatable by hemopoietic transplantation.

REFERENCES

A great hallmark in obstetrical history began in the second half of the 20th century with the ability to image the pregnant uterus and its contents. Beginning with sonographic imaging and continuing through computed tomographic and magnetic resonance imaging, obstetrical practice was revolutionized and gave birth to the specialty of fetal medicine. Today’s practitioner can hardly imagine obstetrical care without these technical advances, which have become commonplace and regarded almost as a sixth sense.

Sonography in prenatal care includes first- and second-trimester fetal anatomic evaluation and specialized studies performed to characterize abnormalities. With improvements in resolution and image display, anomalies are increasingly diagnosed in the first trimester. Applications for three-dimensional sonography and Doppler continue to expand. A sonographic examination performed with the exacting recommended standards of the American Institute of Ultrasound in Medicine (2013a) offers vital information regarding fetal anatomy, physiology, growth, and well-being. Indeed, a National Institute of Child Health and Human Development (NICHD) workshop concluded that “every fetus deserves to have a physical examination” (Reddy, 2008).
The real-time image on the ultrasound screen is produced by sound waves that are reflected back from fluid and tissue interfaces of the fetus, amnionic fluid, and placenta. Sector array transducers used in obstetrics contain groups of piezoelectric crystals working simultaneously in arrays. These crystals convert electrical energy into sound waves, which are emitted in synchronized pulses. Sound waves pass through tissue layers and are reflected back to the transducer when they encounter an interface between tissues of different densities. Dense tissue such as bone produces high-velocity reflected waves, which are displayed as bright echoes on the screen. Conversely, fluid generates few reflected waves and appears dark—or anechoic. Digital images generated at 50 to more than 100 frames per second undergo postprocessing that yields the appearance of real-time imaging.

_Ultrasound_ refers to sound waves traveling at a frequency above 20,000 hertz (cycles per second). Higher-frequency transducers yield better image resolution, whereas lower frequencies penetrate tissue more effectively. Transducers use wide-bandwidth technology to perform over a range of frequencies. In the second trimester, a 4- to 6-megahertz abdominal transducer is often in close enough proximity to the fetus to provide precise images. By the third trimester, however, a lower frequency 2- to 5-megahertz transducer may be needed for penetration, but can lead to compromised resolution. This explains why resolution is often poor when imaging obese patients and why low-frequency transducers are needed to reach the fetus through maternal tissues. In early pregnancy, a 5- to 10-megahertz vaginal transducer may provide excellent resolution, because the early fetus is close to the transducer.

**Fetal Safety**

Sonography should be performed only for a valid medical indication, using the lowest possible exposure setting to gain necessary information—the ALARA principle—as low as reasonably achievable. It should be performed only by those trained to recognize medically important conditions such as fetal anomalies, artifacts that may mimic pathology, and techniques to avoid ultrasound exposure beyond what is considered safe for the fetus (American Institute of Ultrasound in Medicine, 2008a, 2013a). Prolonged ultrasound exposure may affect brain cell migration in fetal mice (Rakic, 2006). However, no causal relationship has been demonstrated between diagnostic ultrasound and recognized adverse effects in human pregnancy (American Institute of Ultrasound in Medicine, 2010).

All sonography machines are required to display two indices: the _thermal index_ and the _mechanical index_. The thermal index is a measure of the relative probability that the examination may raise the temperature, potentially enough to induce injury. That said, it is extremely unlikely that fetal damage could occur using commercially available ultrasound equipment in routine practice. The potential for temperature elevation is higher with longer examination time and is greater near bone than in soft tissue. Also, theoretical risks are greater during organogenesis than later in gestation. The thermal index is higher with pulsed Doppler applications than with routine B-mode scanning (p. 219). In the first trimester, if pulsed Doppler is needed for a clinical indication, the thermal index should be ≤ 1.0, and exposure time should be kept as short as possible, usually no longer than 5 to 10 minutes (American Institute of Ultrasound in Medicine 2011; Salvesen, 2011). To document the embryonic or fetal heart rate, M-mode imaging should be used instead of pulsed Doppler imaging (American Institute of Ultrasound in Medicine, 2013a).

The mechanical index is a measure of likelihood of adverse effects related to rarefractional pressure, such as cavitation—which is relevant only in tissues that contain air. Microbubble ultrasound contrast agents are not used in pregnancy for this reason. No adverse effects have been reported in mammalian tissues that do not contain gas bodies over the range of diagnostically
relevant exposures. Because fetuses cannot contain gas bodies, they are not considered at risk (American Institute of Ultrasound in Medicine, 2008b).

The use of sonography for any nonmedical purpose, such as “keepsake fetal imaging,” is considered contrary to responsible medical practice and is not condoned by the Food and Drug Administration (Rados, 2007), the American Institute of Ultrasound in Medicine (2012, 2013a), or the International Society of Ultrasound in Obstetrics and Gynecology (2011).

Operator Safety

The reported prevalence of work-related musculoskeletal discomfort or injury among sonographers and sonologists is as high as 70 to 80 percent (Janga, 2012; Magnavita, 1999; Pike, 1997). According to the National Institute for Occupational Safety and Health, the main risk factors for injury during transabdominal ultrasound are awkward posture, sustained static forces, and various pinch grips while maneuvering the transducer (Centers for Disease Control and Prevention, 2006). Another possible contributory factor is maternal habitus—as more force may be employed when imaging obese patients.

The following guidelines may help avert injury:

1. Position the patient on the examination table close to you, so that your elbow is close to your body, with less than 30 degrees shoulder abduction, keeping your thumb facing up.
2. Adjust the table or chair height so that your forearm is parallel to the floor.
3. If seated, use a chair with back support, support your feet, and keep ankles in neutral position.
   - Do not lean toward the patient or monitor.
4. Face the monitor squarely and position it so that it is viewed at a neutral angle, such as 15 degrees downward.
5. Avoid reaching, bending, or twisting while scanning.
6. Frequent breaks may avoid muscle strain. Stretching and strengthening exercises can be helpful.

First-Trimester Sonography

Indications for sonography before 14 weeks’ gestation are listed in Table 10-1. Early pregnancy can be evaluated using transabdominal or transvaginal sonography, or both. The components listed in Table 10-2 should be assessed. The crown-rump length (CRL) is the most accurate biometric predictor of gestational age (Appendix, p. 1294). The CRL should be obtained in a sagittal plane and include neither the yolk sac nor a limb bud. If carefully performed, it has a variance of only 3 to 5 days.

Modified from the American Institute of Ultrasound in Medicine, 2013a.

First-trimester sonography can reliably diagnose anembryonic gestation, embryonic demise, ectopic pregnancy, and gestational trophoblastic disease. Multifetal gestation can be identified early, and this is the optimal time to determine chorionicity (Chap. 45, p. 896). The first trimester is also the ideal time to evaluate the uterus, adnexa, and cul-de-sac. Cervical length and the relationship of the placenta to the cervical os are best evaluated in the second trimester.

An intrauterine gestational sac is reliably visualized with transvaginal sonography by 5 weeks, and an embryo with cardiac activity by 6 weeks. The embryo should be visible transvaginally once the mean sac diameter has reached 20 mm—otherwise the gestation is anembryonic (Chap. 18, p. 355). Cardiac motion is usually visible with transvaginal imaging when the embryo length has reached 5 mm. If an embryo less than 7 mm is not identified to have cardiac activity, a subsequent examination is recommended in 1 week (American Institute of Ultrasound in Medicine, 2013a). A
Parkland hospital, first-trimester demise is diagnosed if the embryo has reached 10 mm without cardiac motion, taking into consideration the standard error of the ultrasound measurements.

**Nuchal Translucency (NT)**

Nuchal translucency evaluation, a component of first-trimester aneuploidy screening, has had a major impact on the number of pregnancies receiving late first-trimester ultrasound examination. It represents the maximum thickness of the subcutaneous translucent area between the skin and soft tissue overlying the fetal spine at the back of the neck (Fig. 14-5, p. 290). It is measured in the sagittal plane between 11 and 14 weeks using precise criteria (Table 10-3). When the nuchal translucency is increased, the risk for fetal aneuploidy and various structural anomalies—including heart defects—is significantly elevated. Aneuploidy screening using nuchal translucency measurement in conjunction with assessment of maternal serum human chorionic gonadotropin and pregnancy-associated plasma protein A levels is discussed in Chapter 14 (p. 290).

**TABLE 10-3. Guidelines for Nuchal Translucency (NT) Measurement**

| The margins of NT edges must be clear enough for proper caliper placement |
| The fetus must be in the midsagittal plane |
| The image must be magnified so that it is filled by the fetal head, neck, and upper thorax |
| The fetal neck must be in a neutral position, not flexed and not hyperextended |
| The amnion must be seen as separate from the NT line |
| Electronic calipers must be used to perform the measurement |
| The + calipers must be placed on the inner borders of the nuchal space with none of the horizontal crossbar itself protruding into the space |
| The calipers must be placed perpendicular to the long axis of the fetus |
| The measurement must be obtained at the widest space of the NT |

**First-Trimester Fetal Anomaly Detection**

Assessment for selected fetal abnormalities in an at-risk pregnancy is another indication for first-trimester sonography (see Table 10-1). Research in this area has focused on anatomy visible at 11 to 14 weeks, to coincide with sonography performed as part of aneuploidy screening (Chap. 14, p. 289). With current technology, it is not realistic to expect that all major abnormalities detectable in the second trimester may be visualized in the first trimester. A study of systematic anatomy evaluation between 11 and 14 weeks in more than 40,000 pregnancies yielded a detection rate of approximately 40 percent for nonchromosomal abnormalities (Syngelaki, 2011). This detection rate is nearly identical to that from a review of more than 60,000 pregnancies from 15 studies and is also comparable with other reports (Pilalis, 2012; Syngelaki, 2011). Identification varies considerably according to the specific abnormality. For example, reported detection rates are extremely high for anencephaly, alobar holoprosencephaly, and ventral wall defects. However, only one-third of major cardiac anomalies have been identified, with no detected cases of microcephaly, agenesis of the corpus callosum, cerebellar abnormalities, congenital pulmonary airway malformations, or bowel obstruction (Syngelaki, 2011). Thus, as first-trimester sonography is unreliable for detection of many major abnormalities, it should not replace second-trimester
Second- and Third-Trimester Sonography

The many indications for second- and third-trimester sonography are listed in Table 10-4. There are three types of examinations: standard, specialized, and limited.

Adapted from the American Institute of Ultrasound in Medicine, 2013a.
1. Standard sonographic examination is the most commonly performed. Components are listed in Table 10-2. The fetal anatomical structures that should be evaluated during the examination, which are listed in Table 10-5, may be adequately assessed after approximately 18 weeks. When examining twins or other multiples, documentation also includes the number of chorions and amnions, comparison of fetal sizes, estimation of amniotic fluid volume within each sac, and fetal sex determination (Chap. 45, p. 912).

2. There are several types of specialized examinations. The targeted examination is a detailed anatomical survey performed when an abnormality is suspected on the basis of history, screening test result, or abnormal findings from a standard examination (American Institute of Ultrasound in Medicine, 2013a). A targeted examination is performed and interpreted by an experienced operator. It includes the anatomical structures listed in Table 10-5, along with additional views of the brain and cranium, neck, profile, lungs and diaphragm, cardiac anatomy, liver, shape and curvature of the spine, hands and feet, and any placental abnormalities. The physician performing the examination further determines whether other examination components will be needed on a case-by-case basis (American College of Obstetricians and Gynecologists, 2011). Other specialized examinations include fetal echocardiography and Doppler evaluation (discussed below), biophysical profile (Chap. 17, p. 341), and additional biometric measurements.

3. A limited examination is performed to address a specific clinical question. Examples include amniotic fluid volume assessment, placental location, or evaluation of fetal presentation or viability. In most cases, a limited examination is appropriate only when a prior standard or targeted examination has previously been performed (American Institute of Ultrasound in Medicine, 2009, 2013a).

**Fetal Biometry**

Equipment software derives the estimated gestational age from the crown-rump length. Formulas are similarly used to calculate estimated gestational age and fetal weight from measurements of the biparietal diameter, head and abdominal circumference, and femur length (Fig. 10-1). The estimates are most accurate when multiple parameters are used and when nomograms derived from fetuses of similar ethnic or racial background living at similar altitude are selected. Even the best models may over- or underestimate fetal weight by as much as 15 percent (American Institute of Ultrasound in Medicine, 2013a). Various nomograms for other fetal structures, including the cerebellum diameter, ear length, interocular and binocular distances, thoracic circumference, and kidney, long bones, and feet lengths, may be used to address specific questions regarding organ system abnormalities or syndromes. These nomograms may be found in the Appendix (p. 1298).
A. Transthalamic view. A transverse (axial) image of the head is obtained at the level of the cavum septum pellucidum (arrows) and thalami (asterisks). The biparietal diameter is measured perpendicular to the sagittal midline, from the outer edge of the skull in the near-field to the inner edge of the skull in the far-field. By convention, the near-field is that which is closer to the sonographic transducer. The head circumference is measured
circumferentially around the outer border of the skull. **B. Femur length.** The femur is measured perpendicular to the femoral shaft, from each diaphyseal end, excluding the epiphysis. **C. Abdominal circumference.** This is a transverse measurement at the level of the stomach (S). The J-shaped structure (arrowheads) indicates the confluence of the umbilical vein and the right portal vein. Ideally, only one rib is visible on each side of the abdomen, indicating that the image was not taken at an oblique angle.

In the second trimester, the biparietal diameter (BPD) most accurately reflects the gestational age, with a variation of 7 to 10 days. The BPD is measured in the **transthalamic view**, at the level of the thalami and cavum septum pellucidum (CSP), from the outer edge of the skull in the near field to the inner edge of the skull in the far field (see Fig. 10-1A). The head circumference (HC) is also measured in the transthalamic view, either by placing an ellipse around the outer edge of the skull, or by measuring the occipital-frontal diameter (OFD) and calculating the circumference from the BPD and OFD. The **cephalic index**, which is the BPD divided by the OFD, is normally approximately 70 to 86 percent. If the head shape is flattened—**dolichocephaly**, or rounded—**brachycephaly**, the HC is more reliable than the BPD. Dolichocephaly and brachycephaly may be normal variants or may be secondary to positional changes or oligohydramnios. However, dolichocephaly can occur with neural-tube defects, and brachycephaly may be seen in fetuses with Down syndrome (Chap. 13, p. 262). Whenever the skull shape is abnormal, craniosynostosis and other craniofacial abnormalities are a consideration.

The femur length (FL) correlates well with both BPD and gestational age. It is measured with the beam perpendicular to the long axis of the shaft, excluding the epiphysis. For gestational age estimation, it has a variation of 7 to 11 days in the second trimester (see Fig. 10-1B). A mildly foreshortened femur—one that is 90 percent or less than that expected for gestational age—has been used as a minor marker for Down syndrome (Chap. 14, p. 292). A femur length that is dramatically foreshortened prompts an evaluation for a skeletal dysplasia, as discussed on page 217. In general, the normal range for the FL to abdominal circumference (AC) ratio is 20 to 24 percent. A FL/AC < 16 percent suggests a lethal skeletal dysplasia, particularly if other skeletal abnormalities are present (Rahemtullah, 1997; Ramus, 1998).

The abdominal circumference has the greatest variation, up to 2 to 3 weeks, for gestational age estimation. The AC is measured around the outer border of the skin. This is a transverse image at the level of the stomach and the confluence of the umbilical vein with the portal sinus (see Fig. 10-1C). Of the biometric parameters, AC is most affected by fetal growth. As discussed in Chapter 44 (p. 875), a small abdominal circumference has been used as an early indicator of fetal-growth restriction (Baschat, 2011).

Variability of the estimated gestational age and of fetal weight increases with advancing gestation. Individual measurements are least accurate in the third trimester. Although estimates are improved by averaging multiple parameters, if one parameter differs significantly from the others, consideration is given to excluding it from the calculation. The outlier could result from poor visibility, but it could also indicate a fetal abnormality or growth problem. Reference tables such as the one in the Appendix (p. 1296) are used to estimate fetal weight percentiles. Menstrual dates are generally considered confirmed if an estimated gestational age (EGA) based on a sonographic first-trimester crown-rump length is within 1 week or if the EGA from biometry at 14 to 20 weeks is within 10 days (American College of Obstetricians and Gynecologists, 2011). In the third trimester, the accuracy of sonography is only within 3 to 4 weeks. Sonographic evaluation performed to monitor fetal growth should typically be performed at least 2 to 4 weeks after a prior examination (American Institute of Ultrasound in Medicine, 2013a).
Amnionic Fluid

Amnionic fluid volume evaluation is a component of every second- or third-trimester sonogram. Oligohydramnios indicates that the volume is below normal range, and subjective crowding of the fetus is often noted. Hydramnios—also called polyhydramnios—is defined as amnionic fluid volume above normal (Fig. 11-3, p. 234). Although it is considered acceptable for an experienced examiner to assess the amnionic fluid volume qualitatively, fluid is usually assessed semiquantitatively (American Institute of Ultrasound in Medicine, 2013a). Measurements include either the single deepest vertical fluid pocket or the sum of the deepest vertical pockets from each of four equal uterine quadrants—the amnionic fluid index (Phelan, 1987). Reference ranges have been established for both measurements from 16 weeks’ gestation onward (Fig. 11-1, p. 233). The single deepest vertical pocket is normally between 2 and 8 cm, and the amnionic fluid index normally ranges between 8 and 24 cm. Amnionic fluid volume is discussed further in Chapter 11 (p. 232).

Fetal Anatomical Evaluation

An important goal of second- and third-trimester sonography is to systematically evaluate fetal anatomy and determine whether specific anatomical components appear normal or abnormal. If a single ultrasound examination is planned for the purpose of evaluating fetal anatomy, the American College of Obstetricians and Gynecologists (2011) recommends that it be performed at 18 to 20 weeks. At this gestational age range, complex organs such as the fetal brain and heart can be imaged clearly enough to visualize many major malformations. Technical factors such as maternal habitus, abdominal wall scarring, fetal size, and fetal position may limit adequate visualization, and these limitations should be noted in the report. If imaging is suboptimal, a follow-up examination may be helpful. If an abnormality is identified or suspected during a standard examination of fetal anatomy, specialized sonography is indicated.

Second-Trimester Fetal Anomaly Detection. The sensitivity of sonography for detecting fetal anomalies varies according to factors such as gestational age, maternal habitus, fetal position, equipment features, examination type, operator skill, and the specific abnormality in question. For example, maternal obesity has been associated with a 20-percent reduction in the fetal anomaly detection rate, regardless of examination type (Dashe, 2009).

Imaging technological advances have contributed to dramatic improvements in anomaly detection. In a review of more than 925,000 pregnancies evaluated between 1978 and 1997, Levi (2002) identified an overall anomaly detection rate of 40 percent. The single largest trial, the EUROFETUS study, included 170,800 pregnancies and identified 55 percent with severe malformations before 24 weeks (Grandjean, 1999). The most recent data are available from a network of population-based registries from 21 European countries, termed EUROCAT, found at www.eurocat-network.eu.

Between 2006 and 2010, EUROCAT prenatal detection rates for selected anomalies were as follows: anencephaly, 97 percent; spina bifida, 84 percent; hydrocephaly, 77 percent; cleft lip, 54 percent; hypoplastic left heart, 73 percent; diaphragmatic hernia, 59 percent; gastroschisis, 94 percent; omphalocele, 84 percent; bilateral renal agenesis, 91 percent; posterior urethral valves, 81 percent; limb-reduction defects, 52 percent; and clubfoot, 43 percent (EUROCAT, 2012). Importantly, however, the overall anomaly detection rate, excluding aneuploidy, was only 34 percent. This reflects inclusion of anomalies with minimal or no sonographic detection, such as microcephaly, anotia, choanal atresia, cleft palate, bile duct atresia, Hirschsprung disease, anal atresia, and congenital skin disorders. These are mentioned because clinicians tend to focus on
abnormalities amenable to sonographic detection, whereas families may find those not readily detectable no less devastating. Every sonographic examination should include a frank discussion of examination limitations.

The sensitivity of specialized sonography in experienced centers is considered to be at least 80 percent (American College of Obstetricians and Gynecologists, 2011). Most anomalous infants—approximately 75 percent—occur in pregnancies that are otherwise low-risk, that is, without an indication for specialized sonography. Thus, the quality of a standard screening sonogram greatly affects overall anomaly detection from a population perspective (Dashe, 2009; Levi, 2002). Practice guidelines and standards established by organizations such as the American Institute of Ultrasound in Medicine (2013a) and the International Society of Ultrasound in Obstetrics and Gynecology (Salomon, 2011) have undoubtedly contributed to improvements in anomaly detection rates.

NORMAL AND ABNORMAL FETAL ANATOMY

Many fetal anomalies and syndromes may be characterized with targeted sonography. Selected abnormalities of the anatomical components in Table 10-5 are discussed below. This list is not intended to be comprehensive but covers abnormalities that are relatively common and may be detectable with standard sonography, as well as those that are potentially amenable to fetal therapy. Sonographic features of chromosomal abnormalities are reviewed in Chapters 13 and 14, and fetal therapy is discussed in Chapter 16.

Brain and Spine

Standard sonographic evaluation of the fetal brain includes three transverse (axial) views. The transthalamic view is used to measure the BPD and HC and includes the midline falx, cavum septum pellucidum (CSP), and thalami (see Fig. 10-1A). The CSP is the space between the two laminae that separate the frontal horns. Inability to visualize a normal CSP may indicate a midline brain abnormality such as agenesis of the corpus callosum, lobar holoprosencephaly, or septo-optic dysplasia (de Morsier syndrome). The transventricular view includes the lateral ventricles, which contain the echogenic choroid plexus (Fig. 10-2). The ventricles are measured at their atrium, which is the confluence of their temporal and occipital horns. The transcerebellar view is obtained by angling the transducer back through the posterior fossa (Fig. 10-3). In this view, the cerebellum and cisterna magna are measured, and between 15 and about 20 weeks, the nuchal skinfold thickness may be measured (Chap. 14, p. 289). From 15 until 22 weeks, the cerebellar diameter in millimeters is roughly equivalent to the gestational age in weeks (Goldstein, 1987). The cisterna magna normally measures between 2 and 10 mm. Effacement of the cisterna magna is present in the Chiari II malformation, discussed on page 202.
FIGURE 10-2 The transventricular view depicts the lateral ventricles, which contain the echogenic choroid plexus (CP). The lateral ventricle is measured at the atrium (arrows), which is the confluence of the temporal and occipital horns. A normal measurement is between 5 and 10 mm throughout the second and third trimesters. The atria measured 6 mm in this 21-week fetus.

FIGURE 10-3 Transcerebellar view of the posterior fossa, demonstrating measurement of the cerebellum (+), cisterna magna (X), and nuchal fold thickness (bracket). Care is taken not to angle obliquely down the spine, which may artificially increase the nuchal fold measurement.
Imaging of the spine includes evaluation of the cervical, thoracic, lumbar, and sacral regions (Fig. 10-4). Representative spinal images for record keeping are often obtained in the sagittal or coronal plane. However, real-time imaging should include evaluation of each spinal segment in the transverse plane, as this is more sensitive for abnormality detection. Transverse images demonstrate three ossification centers. The anterior ossification center is the vertebral body, and the posterior paired ossification centers represent the junction of vertebral laminae and pedicles. Ossification of the spine proceeds in a cranial-caudal fashion, such that ossification of the upper sacrum (S1-S2) is not generally visible sonographically before 16 weeks’ gestation. Ossification of the entire sacrum may not be visible until 21 weeks (De Biasio, 2003). Thus, detection of some spinal abnormalities may be challenging in the early second trimester.

Examples of spinal abnormalities include spina bifida, caudal regression sequence, and sacrococcygeal teratoma. More subtle spinal abnormalities may be visible. These include diastematomyelia, which is a longitudinal cleft or splitting of the spinal cord itself, and hemivertebrae—a component of the vertebral, anal, cardiac, tracheo-esophageal fistula, renal, limb (VACTERL) association.

If a brain or spinal abnormality is identified, specialized sonography is indicated. The International Society of Ultrasound in Obstetrics and Gynecology (2007) has published guidelines for a “fetal neurosonogram.” Fetal magnetic resonance (MR) imaging may be helpful in further characterizing central nervous system (CNS) abnormalities (p. 223).

**Neural-Tube Defects**
These result from incomplete closure of the neural tube by the embryonic age of 26 to 28 days.
They are the second most common class of malformations after cardiac anomalies. Their prevalence was previously considered to be 1.4 to 2 per 1000 births. However, birth defect registries in the United States and Europe now report a prevalence of only 0.9 per 1000. In the United Kingdom, the prevalence is 1.3 per 1000 (Dolk, 2010). Neural-tube defects can be prevented with folic acid supplementation (Chap. 9, p. 181), and their prenatal diagnosis is discussed in Chapter 14 (p. 283). When isolated, neural-tube defect inheritance is multifactorial, and the defect recurrence risk without periconceptional folic acid supplementation is 3 to 5 percent.

Anencephaly is characterized by absence of the cranium and telencephalic structures, with the skullbase and orbits covered only by angiomatous stroma. Acrania is absence of the cranium, with protrusion of disorganized brain tissue. Both are generally grouped together, and anencephaly is considered to be the final stage of acrania (Bronshtein, 1991; McGahan, 2003). These lethal anomalies can be diagnosed in the late first trimester, and with adequate visualization, virtually all cases may be diagnosed in the second trimester (Fig. 10-5). An inability to view the biparietal diameter should raise suspicion. Hydramnios from impaired fetal swallowing is common in the third trimester.
FIGURE 10-5 Anencephaly/acrania. A. Acrania. This 11-week fetus has absence of the cranium, with protrusion of a disorganized mass of brain tissue that resembles a “shower cap” (arrows) and a characteristic triangular facial appearance. B. Anencephaly. This sagittal image shows the absence of forebrain and cranium above the skull base and orbit. The long white arrow points to the fetal orbit, and the short white arrow indicates the nose.
Cephalocele is the herniation of meninges through a cranial defect, typically located in the midline occipital region (Fig. 10-6). When brain tissue herniates through the skull defect, the anomaly is termed an encephalocele. Associated hydrocephalus and microcephaly are common. Surviving infants—those with smaller defects—have a high incidence of neurological deficits and developmental impairment. Cephalocele is an important feature of the autosomal recessive Meckel-Gruber syndrome, which includes cystic renal dysplasia and polydactyly. A cephalocele not located in the occipital midline raises suspicion for amnionic-band sequence (Chap. 6, p. 121).

![Figure 10-6 Encephalocele](image)

**FIGURE 10-6** Encephalocele. This transverse image depicts a large defect in the occipital region of the cranium (arrows) through which meninges and brain tissue have herniated.

Spina bifida is a defect in the vertebrae, typically the dorsal arch, with exposure of the meninges and spinal cord. The birth prevalence is approximately 1 per 2000 (Cragan, 2009; Dolk, 2010). Most cases are open spina bifida—the defect includes the skin and soft tissues. Herniation of a meningeal sac containing neural elements is termed a myelomeningocele (Fig. 10-7). When only a meningeal sac is present, the defect is a meningocele. Although the sac may be easier to image in the sagittal plane, transverse images more readily demonstrate separation or splaying of the lateral processes.
As discussed in Chapter 14 (p. 285), spina bifida may be reliably diagnosed with second-trimester sonography, often because of two characteristic cranial findings. These are scalloping of the frontal bones—the lemon sign (Fig. 14-4, p. 287), and anterior curvature of the cerebellum with effacement of the cisterna magna—the banana sign (Fig. 14-5) (Nicolaides, 1986). These findings are manifestations of the Chiari II malformation (also called Arnold-Chiari malformation), which occurs when downward displacement of the spinal cord pulls a portion of the cerebellum through the foramen magnum and into the upper cervical canal. Ventriculomegaly is another frequent sonographic finding, particularly after midgestation, and more than 80 percent of infants with open spina bifida require ventriculoperitoneal shunt placement. A small biparietal diameter is often present as well. Children with spina bifida require multidisciplinary care to address problems related to the defect, shunt, swallowing, bladder and bowel function, and ambulation. They are also at increased risk for latex allergy. Fetal surgery for myelomeningocele is discussed in Chapter 16 (p. 325).

**Ventriculomegaly**

This distention of the cerebral ventricles by cerebrospinal fluid (CSF) is a nonspecific marker of abnormal brain development (Pilu, 2011). The atrium normally measures between 5 and 10 mm from 15 weeks until term (see Fig. 10-2). Mild ventriculomegaly is diagnosed when the atrial width measures 10 to 15 mm, and overt or severe ventriculomegaly when it exceeds 15 mm (Fig. 10-8). CSF is produced by the choroid plexus, which is an epithelium-lined capillary core and loose connective tissue found in the ventricles. A dangling choroid plexus characteristically is found with severe ventriculomegaly.
Ventriculomegaly may be caused by various genetic and environmental insults, and prognosis is determined by etiology, degree, and rate of progression. In general, the larger the atrium, the greater the likelihood of abnormal outcome (Gaglioti, 2009; Joó, 2008). The finding of an enlarged ventricle may be due to another central nervous system abnormality—such as Dandy-Walker malformation or holoprosencephaly, due to an obstructive process—such as aqueductal stenosis, or secondary to a destructive process—such as porencephaly or an intracranial teratoma. Initial evaluation includes a specialized examination of fetal anatomy, fetal karyotyping, and testing for congenital infections such as cytomegalovirus and toxoplasmosis (Chap. 64, p. 1245).

Even when ventriculomegaly is mild and appears isolated, counseling may be a challenge because of the wide variability in prognosis. Devaseelan and colleagues (2010) conducted a systematic review of nearly 1500 pregnancies with apparently isolated mild ventriculomegaly. They found that 1 to 2 percent of cases were associated with congenital infection, 5 percent with aneuploidy, and 12 percent with neurological abnormality in the absence of infection or aneuploidy. Neurological abnormality was significantly more common if ventriculomegaly progressed, but asymmetry of ventricular size did not affect prognosis. As abnormalities associated with mild ventriculomegaly may not be detectable sonographically, fetal MR imaging may be considered.

Agenesis of the Corpus Callosum
The corpus callosum is the major fiber bundle connecting reciprocal regions of the cerebral hemispheres. With complete agenesis of the corpus callosum, a normal cavum septum pellucidum cannot be visualized sonographically, and the frontal horns are displaced laterally. Also, there is mild enlargement of the atria posteriorly—such that the ventricle has a characteristic “teardrop” appearance (Fig. 10-9). Callosal dysgenesis can also occur, in which absence involves only the
caudal portions—the body and splenium—and is consequently more difficult to detect prenatally.

![FIGURE 10-9](image) Agenesis of the corpus callosum. This image demonstrates a “teardrop” shaped ventricle with mild ventriculomegaly (dotted line) and laterally displaced frontal horns (arrow). A normal cavum septum pellucidum cannot be visualized.

In population-based studies, prevalence of agenesis of the corpus callosum is 1 in 5000 births (Glass, 2008; Szabo, 2011). In a recent review of apparently isolated cases of agenesis, fetal MR imaging identified additional brain abnormalities in more than 20 percent (Sotiriadis, 2012). If the anomaly was still considered isolated following MR imaging, normal developmental outcome was reported in 75 percent of cases, and severe disability in 12 percent. Agenesis of the corpus callosum is associated with other CNS and non-CNS anomalies, aneuploidy, and many genetic syndromes—more than 200—and thus genetic counseling can be challenging.

**Holoprosencephaly**

In early normal brain development, the prosencephalon or forebrain divides into the telencephalon and diencephalon. With holoprosencephaly, the prosencephalon fails to divide completely into two separate cerebral hemispheres and into underlying diencephalic structures. Main forms of holoprosencephaly are a continuum that contains, with decreasing severity, *alobar, semilobar*, and *lobar* types. In the most severe form—*alobar holoprosencephaly*—a single monoventricle, with or without a covering mantle of cortex, surrounds the fused central thalami (Fig. 10-10). In *semilobar holoprosencephaly*, partial separation of the hemispheres occurs. *Lobar holoprosencephaly* is characterized by a variable degree of fusion of frontal structures. Lobar holoprosencephaly should be considered when a normal cavum septum pellucidum cannot be visualized.
FIGURE 10-10 Alobar holoprosencephaly. A. Transverse cranial image of a 26-week fetus with alobar holoprosencephaly, depicting fused thalami (*Th*) encircled by a monoventricle (*V*). The midline falx is absent. B. In this profile view of the face and head, a soft tissue mass—a proboscis (*arrow*), protrudes from the region of the forehead.

Differentiation into two cerebral hemispheres is induced by prechordal mesenchyme, which is
also responsible for differentiation of the midline face. Thus, holoprosencephaly may be associated with anomalies of the orbits and eyes—hypotelorism, cyclopia, or micro-ophthalmia; lips—median cleft; or nose—ethmocephaly, cebocephaly, or arhinia with proboscis (see Fig. 10-10).

The birth prevalence of holoprosencephaly is only 1 in 10,000 to 15,000. However, the abnormality has been identified in nearly 1 in 250 early abortuses, which attests to the extremely high in-utero lethality of this condition (Orioli, 2010; Yamada 2004). The alobar form accounts for 40 to 75 percent of cases, and approximately 30 to 40 percent have a numerical chromosomal abnormality, particularly trisomy 13 (Orioli, 2010; Solomon, 2010). Conversely, two thirds of trisomy 13 cases are found to have holoprosencephaly. Fetal karyotyping should be offered when this anomaly is identified.

**Dandy-Walker Malformation—Vermian Agenesis**

Originally described by Dandy and Blackfan (1914), this posterior fossa abnormality is characterized by agenesis of the cerebellar vermis, posterior fossa enlargement, and elevation of the tentorium. Sonographically, fluid in the enlarged cisterna magna visibly communicates with the fourth ventricle through the cerebellar vermis defect, with visible separation of the cerebellar hemispheres (Fig. 10-11). The birth prevalence is approximately 1 in 12,000 (Long, 2006). Associated anomalies and aneuploidy are very common in prenatal series. These include ventriculomegaly in 30 to 40 percent, other anomalies in approximately 50 percent, and aneuploidy in 40 percent (Ecker, 2000; Long, 2006). Dandy-Walker malformation is also associated with numerous genetic and sporadic syndromes, congenital viral infections, and teratogen exposure, all of which greatly affect the prognosis. Thus, the initial evaluation mirrors that for ventriculomegaly (p. 202).

![FIGURE 10-11](image) **Dandy-Walker malformation.** This transcerebellar image demonstrates agenesis of the cerebellar vermis. The cerebellar hemispheres (+) are widely separated by a fluid collection.
that connects the 4th ventricle (red asterisk) to the enlarged cisterna magna (CM).

Inferior vermian agenesis, also called Dandy-Walker variant, is a term used when only the inferior portion of the vermis is absent. But, even when vermian agenesis appears to be partial and relatively subtle, there is a high prevalence of associated anomalies and aneuploidy, and the prognosis is often poor (Ecker, 2000; Long, 2006).

**Sacrococcygeal Teratoma**

This germ cell tumor is one of the most common tumors in neonates, with a birth prevalence of approximately 1 per 28,000 (Derikx, 2006; Swamy, 2008). It is believed to arise from the totipotent cells along Hensen node, anterior to the coccyx. The American Academy of Pediatrics–Surgical Section classification for sacrococcygeal teratoma (SCT) includes four types. Type 1 is predominantly external with a minimal presacral component; type 2 is predominantly external but with a significant intrapelvic component; type 3 is predominantly internal but with abdominal extension; and type 4 is entirely internal with no external component (Altman, 1974). The tumor may be mature, immature, or malignant. Sonographically, SCT appears as a solid and/or cystic mass that arises from the anterior sacrum and usually extends inferiorly and externally as it grows (Fig. 10-12). Solid components often have varying echogenicity, appear disorganized, and may grow rapidly with advancing gestation. Internal pelvic components may be more challenging to visualize, and fetal MR imaging should be considered. Hydramnios is frequent, and hydrops may develop from high-output cardiac failure, either as a consequence of tumor vascularity or secondary to bleeding within the tumor and resultant anemia. Fetuses with tumors > 5 cm often require cesarean delivery, and classical hysterotomy may be needed (Gucciono, 2011). Fetal surgery for SCT is discussed in Chapter 16 (p. 327).

![FIGURE 10-12 Sacrococcygeal teratoma. Sonographically, this tumor appears as a solid and/or cystic mass that arises from the anterior sacrum and tends to extend inferiorly and externally as it](image-url)
Caudal Regression Sequence—Sacral Agenesis

This rare anomaly is characterized by absence of the sacral spine and often portions of the lumbar spine. It is approximately 25 times more common in pregnancies with pregestational diabetes (Garne, 2012). Sonographic findings include a spine that appears abnormally short, lacks the normal lumbosacral curvature, and terminates abruptly above the level of the iliac wings. Because the sacrum does not lie between the iliac wings, they are abnormally close together and may appear “shield-like.” There may be abnormal positioning of the lower extremities and lack of normal soft tissue development. Caudal regression should be differentiated from sirenomelia, which is a rare anomaly characterized by a single fused lower extremity in the midline.

Face and Neck

Normal fetal lips and nose are shown in Figure 10-13. A fetal profile is not a required component of standard examination but may be helpful in identifying cases of micrognathia—an abnormally small jaw (Fig. 10-14). Micrognathia should be considered in the evaluation of hydramnios (Chap. 11, p. 235). Use of the ex-utero intrapartum treatment (EXIT) procedure for severe micrognathia is discussed in Chapter 16 (p. 331).

FIGURE 10-13 Midline face. This view demonstrates the integrity of the upper lip.
FIGURE 10-14 Fetal profile. A. This image depicts a normal fetal profile. B. This fetus has severe micrognathia, which creates a severely recessed chin.

Facial Clefts

There are three main types of clefts. The first type, *cleft lip and palate*, always involves the lip, may also involve the hard palate, may be unilateral or bilateral, and has a birth prevalence of approximately 1 per 1000 (Cragan, 2009; Dolk, 2010). If isolated, the inheritance is multifactorial—with a recurrence risk of 3 to 5 percent for one prior affected child. If a cleft is visible in the upper lip, a transverse image at the level of the alveolar ridge may demonstrate that the defect also involves the primary palate (Fig. 10-15).
In a recent systematic review of low-risk pregnancies, cleft lip was identified sonographically in only about half of cases (Maarse, 2010). Approximately 40 percent of those detected in prenatal series are associated with other anomalies or syndromes, and aneuploidy is common (Maarse, 2011; Offerdal, 2008). The rate of associated anomalies is highest for bilateral defects that involve the palate. Using data from the Utah Birth Defect Network, Walker and associates (2001) identified aneuploidy in 1 percent with cleft lip alone, 5 percent with unilateral cleft lip and palate, and 13 percent with bilateral cleft lip and palate. It seems reasonable to offer fetal karyotyping when a cleft is identified.

The second type of cleft is isolated cleft palate. It begins at the uvula, may involve the soft palate, and occasionally involves the hard palate—but does not involve the lip. The birth prevalence is approximately 1 per 2000 (Dolk, 2010). Identification of isolated cleft palate has been described using specialized 2- and 3-dimensional sonography (Ramos, 2010; Wilhelm, 2010). However, it is not expected to be visualized during a standard ultrasound examination (Maarse, 2011; Offerdal, 2008).

A third type of cleft is median cleft lip, which is found in association with several conditions. These include agenesis of the primary palate, hypotelorism, and holoprosencephaly. Median clefts may also be associated with hypertelorism and frontonasal hyperplasia, formerly called the median cleft face syndrome.

Cystic Hygroma
This is a venolymphatic malformation in which fluid-filled sacs extend from the posterior neck (Fig. 10-16). Cystic hygromas may be diagnosed as early as the first trimester and vary widely in size. They are believed to develop when lymph from the head fails to drain into the jugular vein and accumulates instead in jugular lymphatic sacs. Their birth prevalence is approximately 1 in 5000, but given the high in-utero lethality of this condition, the incidence is much higher (Cragan, 2009).
Cystic hygromas. A. This 9-week fetus with a cystic hygroma (arrow) was later found to have Noonan syndrome. B. Massive multiseptated hygromas (arrowheads) in the setting of hydrops fetalis at 15 weeks.

Up to 70 percent of cystic hygromas are associated with aneuploidy. Of those diagnosed in the second trimester, approximately 75 percent of aneuploid cases are 45,X—Turner syndrome (Johnson, 1993; Shulman, 1992). When cystic hygromas are diagnosed in the first trimester, trisomy 21 and 45,X are both common, followed by trisomy 18 in frequency (Kharrat, 2006; Malone, 2005). In a review of more than 100 cystic hygroma cases from the First And Second Trimester Evaluation of Risk (FASTER) trial, trisomy 21 was the single most common aneuploidy (Malone, 2005). First-trimester fetuses with cystic hygromas were five times more likely to be aneuploid than the fetuses with an increased nuchal translucency.

In the absence of aneuploidy, cystic hygromas confer a significantly increased risk for other anomalies, particularly cardiac anomalies that are flow-related. These include hypoplastic left heart and coarctation of the aorta. Cystic hygromas also may be part of a genetic syndrome. One is Noonan syndrome, an autosomal dominant disorder that shares several features with Turner syndrome, including short stature, lymphedema, high-arched palate, and often pulmonary valve stenosis.

Large cystic hygromas are usually found with hydrops fetalis, rarely resolve, and carry a poor prognosis. Small hygromas may undergo spontaneous resolution, and provided that fetal karyotype and echocardiography results are normal, the prognosis may be good. The likelihood of a nonanomalous liveborn infant with normal karyotype following identification of first-trimester hygroma is approximately 1 in 6 (Kharrat, 2006; Malone, 2005).

Thorax
The lungs appear as homogeneous structures surrounding the heart and are best visualized after 20 to 25 weeks’ gestation. In the four-chamber view of the chest, they comprise approximately two thirds of the area, with the heart occupying the remaining third. The thoracic circumference is measured at the skin line in a transverse plane at the level of the four-chamber view. In cases of suspected pulmonary hypoplasia secondary to a small thorax, such as with severe skeletal dysplasia, comparison with a reference table may be helpful (Appendix, p. 1299). Various abnormalities may be seen sonographically as cystic or solid space-occupying lesions. Fetal therapy for thoracic abnormalities is discussed in Chapter 16 (p. 329).

**Congenital Diaphragmatic Hernia**

This is a defect in the diaphragm through which abdominal organs herniate into the thorax. It is left-sided in approximately 75 percent of cases, right-sided in 20 percent, and bilateral in 5 percent (Gallot, 2007). The prevalence of congenital diaphragmatic hernia (CDH) is approximately 1 per 3000 to 4000 births (Cragan, 2009; Dolk, 2010; Gallot, 2007). Associated anomalies and aneuploidy occur in 40 percent of cases (Gallot, 2007; Stege, 2003). Targeted sonography and fetal echocardiography should be performed, and fetal karyotyping should be offered. Given the association with genetic syndromes, chromosomal microarray analysis is a consideration (Chap. 13, p. 277). In population-based series, the presence of an associated abnormality reduces the overall survival rate of neonates with diaphragmatic hernia from approximately 50 percent to about 20 percent (Colvin, 2005; Gallot, 2007; Stege, 2003). In the absence of associated abnormalities, the major causes of mortality are pulmonary hypoplasia and pulmonary hypertension.

Sonographically, the most frequent finding with a left-sided defect is repositioning of the heart to the mid or right hemithorax. With this, the axis of the heart points toward the midline (Fig. 10-17). Associated findings include the stomach bubble or bowel peristalsis in the chest and a wedge-shaped mass—the liver—located anteriorly in the left hemithorax. Liver herniation complicates at least 50 percent of cases and is associated with a 30-percent reduction in the survival rate (Mullassery, 2010). With large lesions, impaired swallowing and mediastinal shift may result in hydramnios and hydrops, respectively.
Congenital diaphragmatic hernia. In this transverse view of the thorax, the heart is shifted to the far right side of the chest by a left-sided diaphragmatic hernia containing stomach (S), liver (L), and bowel (B).

Efforts to predict survival have focused on indicators such as the sonographic lung-to-head ratio, MR imaging measurements of lung volume, and the degree of liver herniation (Jani, 2012; Mayer, 2011; Metkus, 1996; Worley, 2009). These and fetal therapy for CDH are reviewed in Chapter 16 (p. 328).

**Congenital Cystic Adenomatoid Malformation**

This abnormality represents hamartomatous overgrowth of terminal bronchioles that communicates with the tracheobronchial tree. It is also called CPAM—congenital pulmonary airway malformation, based on an understanding that not all histopathologic types are cystic or adenomatoid (Azizkhan, 2008; Stocker, 1977, 2002). The prevalence is estimated to be 1 per 6000 to 8000 births, and the reported prevalence appears to be increasing with improved sonographic detection of milder cases (Burge, 2010; Duncombe, 2002).

Sonographically, congenital cystic adenomatoid malformation (CCAM) is a well-circumscribed thoracic mass that may appear solid and echogenic or may have one or multiple variably sized cysts (Fig. 10-18). It usually involves one lobe and has blood supply from the pulmonary artery, with drainage into the pulmonary veins. When the mass is large, hydrops and pulmonary hypoplasia may result. Lesions with cysts $\geq 5$ mm are generally termed macrocystic, and lesions with cysts $< 5$ mm are termed microcystic (Adzick, 1985).
In a review of 645 CCAM cases without hydrops, the overall survival rate was above 95 percent, and 30 percent of cases demonstrated apparent prenatal resolution. In the 5 percent complicated by hydrops, there typically were very large lesions with mediastinal shift, and the prognosis was poor without fetal therapy (Cavoretto, 2008). A subset of CCAMs demonstrate rapid growth between 18 and 26 weeks’ gestation, and a measurement called the CCAM volume ratio, discussed in Chapter 16 (p. 323), has been used to quantify size and hydrops risk. Corticosteroid therapy has been used for large microcystic lesions to forestall growth and potentially ameliorate hydrops (Curran, 2010). If a large dominant cyst is present, thoracoamnionic shunt placement may lead to hydrops resolution (Wilson, 2006). Fetal therapy for CCAM/CPAN is discussed in Chapter 16 (p. 323).

**Extralobar Pulmonary Sequestration**

Also called *bronchopulmonary sequestration*, this abnormality is an accessory lung bud “sequestered” from the tracheobronchial tree, that is, a mass of nonfunctioning lung tissue. Most cases diagnosed prenatally are *extralobar*, which means they are enveloped in their own pleura. Overall, however, most sequestrations present in adulthood and are *intralobar*—within the pleura of another lobe. Extralobar pulmonary sequestration (ELS) is considered significantly less common than CCAM, and no precise prevalence has been reported. Lesions have a left-sided predominance and most often involve the left lower lobe. Approximately 10 to 20 percent of cases are located below the diaphragm, and associated anomalies have been reported in about 10 percent of cases (Yildirim, 2008).
Sonographically, ELS presents as a homogeneous, echogenic thoracic mass. Thus, it may resemble a microcystic CCAM. However, the blood supply to an ELS is from the systemic circulation—from the aorta rather than the pulmonary artery. In approximately 5 to 10 percent of cases, a large ipsilateral pleural effusion develops, and this may result in pulmonary hypoplasia or hydrops without treatment (Chap. 16, p. 329). Hydrops may also result from mediastinal shift or high-output cardiac failure due to the left-to-right shunt imposed by the mass (Chap. 15, p. 316). In the absence of a pleural effusion, the reported survival rate exceeds 95 percent, and 40 percent of cases demonstrate apparent prenatal resolution (Cavoretto, 2008).

**Congenital High Airway Obstruction Sequence (CHAOS)**

This rare anomaly usually results from laryngeal or tracheal atresia. The normal egress of lung fluid is obstructed, and the tracheobronchial tree and lungs become massively distended. Sonographically, the lungs appear brightly echogenic, and the bronchi are dilated with fluid (Fig. 10-19). Flattening and eversion of the diaphragm is common, as is compression of the heart. Venous return is impaired and ascites develops, typically followed by hydrops (Chap. 15, p. 316). In one series, associated anomalies were reported in three of 12 cases (Roybal, 2010). This anomaly is a feature of the autosomal recessive Fraser syndrome. In some cases, spontaneous perforation of the obstructed airway can occur, potentially conferring a better prognosis. The EXIT procedure has also been used to treat this anomaly, as discussed in Chapter 16 (p. 331).

**FIGURE 10-19** Congenital high airway obstruction sequence (CHAOS). The lungs appear brightly echogenic, and one is marked by an “L.” The bronchi, one of which is noted by an arrow, are dilated with fluid. Flattening and eversion of the diaphragm is common, as is ascites (asterisks).
Cardiac malformations are the most common class of congenital anomalies, with an overall prevalence of 8 per 1000 births (Cragan, 2009). Almost 90 percent of cardiac defects are multifactorial or polygenic in origin; another 1 to 2 percent result from a single-gene disorder or gene-deletion syndrome; and 1 to 2 percent are from exposure to a teratogen such as isotretinoin, hydantoin, or maternal diabetes. Based on data from population-based registries, approximately 1 in 8 liveborn and stillborn neonates with a congenital heart defect has a chromosomal abnormality (Dolk, 2010; Hartman, 2011). The most frequent chromosomal abnormality found in those with a heart defect is trisomy 21. This accounts for more than half of cases and is followed by trisomy 18, 22q11.2 microdeletion, trisomy 13, and monosomy X (Hartman, 2011). Approximately 50 to 70 percent of aneuploid fetuses have extracardiac anomalies that are identifiable sonographically. Fetal karyotyping should be offered, and 22q11.2 microdeletion testing should be offered for conotruncal defects.

Traditionally, detection of congenital cardiac anomalies has been more challenging than anomalies of other organ systems. In recent series, routine second-trimester sonography identified approximately 40 percent of those with major cardiac anomalies before 22 weeks, and specialized sonography identified 80 percent (Romosan, 2009; Trivedi, 2012). There is evidence that prenatal detection of selected cardiac anomalies may improve neonatal survival rates. This may be particularly so with ductal-dependent anomalies—those requiring prostaglandin infusion after birth to keep the ductus arteriosus open (Franklin, 2002; Mahle, 2001; Tworetsky, 2001).

**Basic Cardiac Examination**

Standard cardiac assessment includes a four-chamber view (Fig. 10-20), evaluation of rate and rhythm, and evaluation of the left and right ventricular outflow tracts (Fig. 10-21) (American Institute of Ultrasound in Medicine, 2013a). Evaluation of the cardiac outflow tracts may aid in detection of abnormalities not initially appreciated in the four-chamber view. These may include tetralogy of Fallot, transposition of the great vessels, or truncus arteriosus.
FIGURE 10-20 The four-chamber view. A. Diagram demonstrating measurement of the cardiac
axis from the four-chamber view of the fetal heart. B. Sonogram of the four-chamber view at 22 weeks demonstrates the normal symmetry of the atria and ventricles, normal position of the mitral and tricuspid valves, pulmonary veins entering the left atrium, and descending aorta (Ao). L = left; LA = left atrium; LV = left ventricle; R = right; RA = right atrium; RV = right ventricle.

Superior and inferior vena cava views. Ao = aorta; IVC = inferior vena cava; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle;
SVC superior vena cava.

**Four-Chamber View.** This is a transverse image of the fetal thorax at a level immediately above the diaphragm. It allows evaluation of cardiac size, position in the thorax, cardiac axis, atria and ventricles, foramen ovale, atrial septum primum, interventricular septum, and atrioventricular valves (see Fig. 10-20). The atria and ventricles should be similar in size, and the apex of the heart should form a 45-degree angle with the left anterior chest wall. Abnormalities of cardiac axis are frequently encountered with structural cardiac anomalies and occur in more than a third (Shipp, 1995). Smith and coworkers (1995) found that 75 percent of fetuses with congenital heart anomalies had an axis angle that exceeded 75 degrees.

**Fetal Echocardiography**

This is a specialized examination of fetal cardiac structure and function designed to identify and characterize abnormalities. Guidelines for its performance have been developed collaboratively by the American Institute of Ultrasound in Medicine (2013b), American College of Obstetrics and Gynecology, Society of Maternal-Fetal Medicine, American Society of Echocardiography, and American College of Radiology. Echocardiography indications include suspected fetal cardiac anomaly, extracardiac anomaly, or chromosomal abnormality; fetal arrhythmia; hydrops; increased nuchal translucency; monochorionic twin gestation; first-degree relative to the fetus with a congenital cardiac defect; in vitro fertilization; maternal anti-Ro or anti-La antibodies; exposure to a medication associated with increased cardiac malformation risks; and maternal metabolic disease associated with cardiac defects—such as pregestational diabetes or phenylketonuria (American Institute of Ultrasound in Medicine, 2013a). Components of the examination are listed in Table 10-6, and examples of the nine required gray-scale imaging views are shown in Figure 10-21. Examples of selected cardiac anomalies are reviewed below.

Superior and inferior vena cavae

**Color Doppler evaluation**
- Systemic veins (vena cavae and ductus venosus\(^a\))
- Pulmonary veins
- Foramen ovale
- Atrioventricular valves\(^a\)
- Atrial and ventricular septae
- Aortic and pulmonary valves\(^a\)
- Ductus arteriosus
- Aortic arch
- Umbilical artery and vein (optional)\(^a\)

**Cardiac rate and rhythm assessment**

\(^a\)Pulsed-wave Doppler sonography should be used as an adjunct to evaluate these structures. Cardiac biometry and functional assessment are optional but should be considered for suspected structural/functional abnormalities.

Adapted from the American Institute of Ultrasound in Medicine, 2013b.

**Ventricular Septal Defect.** This is the single most common congenital cardiac anomaly and occurs in approximately 1 per 300 births (Cragan, 2009; Dolk, 2010). Even with adequate visualization, the prenatal detection rate of ventricular septal defect (VSD) is low. A defect may be appreciated in the membranous or muscular portion of the interventricular septum in the four-chamber view, and color Doppler demonstrates flow through the defect. Imaging of the left ventricular outflow tract may demonstrate discontinuity of the interventricular septum as it becomes the wall of the aorta (Fig. 10-22). Fetal VSD is associated with aneuploidy, particularly with coexistent other congenital abnormalities, and fetal karyotyping should be offered. That said, the prognosis for an isolated defect is good—more than a third of prenatally diagnosed VSDs close in utero, and another third close in the first year of life (Axt-Fliedner, 2006; Paladini, 2002).
Ventricular septal defect.

A. In this four-chamber view of a 22-week fetus, a defect (arrow) is noted in the superior (membranous) portion of the interventricular septum. B. The left-ventricular outflow tract view of the same fetus demonstrates a break (arrow) in continuity between the interventricular septum and the anterior wall of the aorta.

Endocardial Cushion Defect. This is also called an atrioventricular (AV) septal defect or AV canal defect. It develops in approximately 1 per 2500 births and is associated with trisomy 21 in more than half of cases (Cragan, 2009; Dolk, 2010). The endocardial cushions are the crux of the heart, and defects jointly involve the atrial septum primum, interventricular septum, and medial leaflets of the mitral and tricuspid valves (Fig. 10-23). In addition to trisomy 21 and other aneuploidies, an endocardial cushion defect may develop with heterotaxy syndrome. In this condition, which is also called atrial isomerism, the heart and/or abdominal organs are on the incorrect side. Endocardial cushion defects associated with heterotaxy are more likely to have conduction system abnormalities resulting in third-degree AV block. As discussed in Chapter 16 (p. 322), this confers a poor prognosis.
Endocardial cushion defect. A. During ventricular systole, the lateral leaflets of the mitral and tricuspid valves come together in the midline. But the atrioventricular valve plane is abnormal, a common atrium (A) is observed, and there is a visible defect (arrow) in the interventricular septum. B. During diastolic filling, opening of the atrioventricular valves more clearly demonstrates the absence of their medial leaflets.

**Hypoplastic Left Heart Syndrome.** This anomaly occurs in approximately 1 per 4000 births (Cragan, 2009; Dolk, 2010). Postnatal treatment consists of a three-stage palliative repair or a cardiac transplantation. Once considered a lethal prognosis, it is now estimated that 70 percent of infants may survive to adulthood (Feinstein, 2012). Morbidity remains high, and developmental delays are common. Sonographically, the left side of the heart may appear so small that it is difficult to appreciate a ventricular chamber. There may be no visible inflow or outflow and may be reversal of flow in the ductus arteriosus. Fetal therapy for hypoplastic left heart is discussed in Chapter 16 (p. 331).

**Tetralogy of Fallot.** This anomaly occurs in approximately 1 per 3500 births (Cragan, 2009; Dolk, 2010). It is characterized by four components: ventricular septal defect, an overriding aorta, pulmonary valve abnormality, and right ventricular hypertrophy. The last does not present before birth. Due to the location of the ventricular septal defect, it is often not visible in the four-chamber view, which may appear normal. The prognosis following postnatal repair is usually excellent, and 20-year survival rates exceed 95 percent (Knott-Craig, 1998). Cases with pulmonary atresia have a more complicated course, however. There is also a variant in which the pulmonary valve is absent. Affected fetuses are at risk for hydrops and for tracheomalacia from compression of the trachea by the enlarged pulmonary artery.

**Cardiac Rhabdomyoma.** This is the most common cardiac tumor. Approximately 50 percent of cases are associated with tuberous sclerosis, an autosomal dominant disease with multiorgan system manifestations caused by mutations in the hamartin (TSC1) and tuberin (TSC2) genes. Cardiac rhabdomyomas appear as well-circumscribed echogenic masses, usually within the ventricles or outflow tracts. There may be one or multiple; they may increase in size during
gestation; and occasionally, inflow or outflow obstruction may result. In the absence of obstruction or very large size, the prognosis is relatively good from a cardiac standpoint. These tumors are largest in the neonatal period and tend to regress as children grow. It is problematic, however, that other findings of neurofibromatosis, including growth of benign tumors in the brain, kidney, and skin, may not be apparent prenatally or may develop later in gestation. If a fetal rhabdomyoma is identified, in the absence of a family history, evaluation of the parents for clinical manifestations of neurofibromatosis should be considered. Fetal MR imaging may be considered to evaluate CNS anatomy (p. 223).

M-Mode
Motion-mode or M-mode imaging is a linear display of cardiac cycle events, with time on the x-axis and motion on the y-axis. It is used frequently to measure fetal heart rate (Fig. 10-24). If there is an abnormality of heart rate or rhythm, M-mode imaging permits separate evaluation of atrial and ventricular waveforms. Thus, it is particularly useful for characterizing arrhythmias and their response to treatment, which is discussed in Chapter 16 (p. 321). M-mode can also be used to assess ventricular function and atrial and ventricular outputs.

FIGURE 10-24 M-mode, or motion mode, is a linear display of the events of the cardiac cycle, with time on the x-axis and motion on the y-axis. M-mode is used commonly to measure the fetal heart rate. In this image, there is normal concordance between atrial (A) and ventricular contractions (V). Movement of the tricuspid valve (T) is also shown. There is also a premature
atrial contraction (arrow) and a subsequent early ventricular contraction, followed by a compensatory pause.

Premature Atrial Contractions. Also called atrial extrasystoles, these are the most common fetal arrhythmia and a frequent finding. They represent cardiac conduction system immaturity and typically resolve later in gestation or in the neonatal period. Premature atrial contractions (PACs) may be conducted—and sound like an extra beat. However, they are more commonly blocked, and with handheld Doppler or fetoscope, they sound like a dropped beat. As shown in Figure 10-24, the dropped beat may be demonstrated with M-mode evaluation to be the compensatory pause that follows the premature contraction.

Premature atrial contractions are not associated with major structural cardiac abnormalities, although they sometimes occur with an atrial septal aneurysm. In case reports, they have been associated with maternal caffeine consumption and hydralazine (Lodeiro, 1989; Oei, 1989). In a small percentage of cases, about 2 percent, affected fetuses are later identified to have a supraventricular tachycardia (SVT) that requires urgent treatment (Copel, 2000). Given the importance of identifying SVT, pregnancies with fetal PACs are often followed with fetal heart rate assessment as often as every 1 to 2 weeks until ectopy resolution.

Abdominal Wall

The integrity of the abdominal wall at the level of the cord insertion is assessed during the standard examination (Fig. 10-25). Gastrochisis and omphalocele, collectively termed ventral wall defects, are relatively common fetal anomalies. As discussed in Chapter 14 (p. 285), both are associated with maternal serum alpha-fetoprotein elevation.

![Figure 10-25](image-url) Normal ventral wall. Transverse view of the abdomen in a second-trimester fetus with an intact anterior abdominal wall and normal cord insertion.
Gastroschisis
This is a full-thickness abdominal wall defect typically located to the right of the umbilical cord insertion. Bowel herniates through the defect into the amnionic cavity (Fig. 10-26). The prevalence is 1 per 2000 to 4000 pregnancies (Canfield, 2006; Dolk, 2010). Gastroschisis is the one major anomaly more common in fetuses of younger mothers, and the average maternal age is 20 years (Santiago-Muñoz, 2007). Bowel abnormalities such as jejunal atresia are found in 15 to 30 percent of cases. Gastroschisis is not associated with an increased risk for aneuploidy, and the survival rate approximates 90 percent (Kitchanan, 2000; Nembhard, 2001; Santiago-Muñoz, 2007).

FIGURE 10-26 Gastroschisis. This 18-week fetus has a full-thickness ventral wall defect to the right of the cord insertion (arrowhead), through which multiple small bowel loops (B) have herniated into the amnionic cavity.

Fetal-growth restriction develops with gastroschisis in 15 to 40 percent of cases (Nicholas, 2009; Puligandla, 2004; Santiago-Muñoz, 2007). Whereas Nicholas and colleagues (2009) reported an association between growth restriction and adverse outcome with gastroschisis, Santiago-Muñoz and associates (2007) found that such newborns did not have increased mortality rates or longer hospitalizations compared with those of normally grown neonates. In a series of 75 infants with gastroschisis, Ergün and coworkers (2005) reported that the only risk factor associated with longer hospitalization was delivery before 36 weeks.

Omphalocele
This anomaly complicates approximately 1 per 3000 to 5000 pregnancies (Canfield, 2006; Dolk, 2010). It forms when the lateral ectomesodermal folds fail to meet in the midline, leaving the abdominal contents covered only by a two-layered sac of amnion and peritoneum into which the
umbilical cord inserts (Fig. 10-27). In more than half of cases, omphalocele is associated with other major anomalies or aneuploidy. It also is a component of syndromes such as Beckwith–Wiedemann, cloacal extrophy, and pentalogy of Cantrell. Smaller defects confer an even greater risk for aneuploidy (De Veciana, 1994). Like other major anomalies, identification of an omphalocele mandates a complete anatomical evaluation, and fetal karyotyping is recommended.

**FIGURE 10-27** Omphalocele. Transverse view of the abdomen showing an omphalocele as a large abdominal wall defect with exteriorized liver covered by a thin membrane.

**Body Stalk Anomaly**

Also known as limb-body-wall complex or cyllosoma, this is a rare, lethal anomaly characterized by abnormal formation of the body wall. Typically, no abdominal wall is visible, and there is extrusion of the abdominal organs into the extraamnionic coelom. There is close approximation or fusion of the body to the placenta, and an extremely short umbilical cord. Acute-angle scoliosis is another feature. Amnionic bands are often identified.

**Gastrointestinal Tract**

The stomach is visible in nearly all fetuses after 14 weeks’ gestation. The liver, spleen, gallbladder, and bowel can be identified in many second- and third-trimester fetuses. If the stomach is not seen on an initial evaluation, the examination should be repeated, and targeted sonography should be considered. Nonvisualization of the stomach may be secondary to impaired swallowing. And, underlying causes may include esophageal atresia, a craniofacial abnormality, or a CNS or musculoskeletal abnormality such as arthrogryposis. Fetuses with oligohydramnios or with severe illness from various causes—such as hydrops, may also have impaired swallowing.
Bowel appearance changes with fetal maturation. Occasionally, it may appear bright or echogenic, which may indicate small amounts of swallowed intraamnionic blood, particularly in the setting of maternal serum alpha-fetoprotein elevation. Bowel that appears as bright as fetal bone confers a slightly increased risk for underlying gastrointestinal malformations, cystic fibrosis, trisomy 21, and congenital infection such as cytomegalovirus.

**Gastrointestinal Atresia**

Bowel atresia is characterized by obstruction and proximal bowel dilatation. In general, the more proximal the obstruction, the more likely it is to be associated with hydramnios. The hydramnios associated with proximal small bowel obstruction may be severe enough to result in maternal respiratory compromise or preterm labor. This may at times necessitate large-volume amniocentesis, also termed amnioreduction (Chap. 11, p. 236).

*Esophageal atresia* occurs in approximately 1 in 4000 births (Cragan, 2009; Pedersen, 2012). It may be suspected when the stomach cannot be visualized, and hydramnios is present. That said, in up to 90 percent of cases, a concomitant *tracheoesophageal fistula* allows fluid to enter the stomach, such that prenatal detection is problematic. More than half have associated anomalies and/or genetic syndromes. Specifically, multiple malformations are present in 30 percent, and aneuploidy are found in 10 percent, particularly trisomies 18 and 21 (Pedersen, 2012). Cardiac, urinary tract, and other gastrointestinal abnormalities are the most frequent. Approximately 10 percent of cases of esophageal atresia occur in the setting of the VACTERL association (p. 201) (Pedersen, 2012).

*Duodenal atresia* occurs in approximately 1 in 10,000 births (Best, 2012; Dolk, 2010). It is characterized by the sonographic *double-bubble sign*, which represents distention of the stomach and the first part of the duodenum (Fig. 10-28). This finding is usually not present before 22 to 24 weeks’ gestation and thus would not be expected to be identified during an 18-week standard sonographic examination. Demonstrating continuity between the stomach and proximal duodenum confirms that the second “bubble” is the proximal duodenum. Approximately 30 percent of affected fetuses have an associated chromosomal abnormality or genetic syndrome, particularly trisomy 21. In the absence of a genetic abnormality, a third of cases have associated anomalies, most commonly cardiac defects and other gastrointestinal abnormalities (Best, 2012). Obstructions in the more distal small bowel usually result in multiple dilated loops that may have increased peristaltic activity.

Large bowel obstructions and anal atresia are less readily diagnosed by sonography, because hydramnios is not a typical feature, and the bowel may not be significantly dilated. A transverse view through the pelvis may show an enlarged rectum as a fluid-filled structure between the bladder and the sacrum.
FIGURE 10-28 Duodenal atresia. The *double-bubble* sign represents distension of the stomach *(S)* and the first part of the duodenum *(D)*, as seen on this axial abdominal image. Demonstrating continuity between the stomach and proximal duodenum confirms that the second “bubble” is the proximal duodenum.

### Kidneys and Urinary Tract

The fetal kidneys are visible adjacent to the spine, frequently in the first trimester and routinely by 18 weeks’ gestation *(Fig. 10-29)*. The length of the kidney is about 20 mm at 20 weeks, increasing by approximately 1.1 mm each week thereafter (Chitty, 2003). With advancing gestation, the kidneys become relatively less echogenic, and a rim of perinephric fat aids visualization of their margins.
FIGURE 10-29 Normal fetal kidneys. The kidneys are visible adjacent to the fetal spine in this 29-week fetus. With advancing gestation, a rim of perinephric fat facilitates visualization of the margins of the kidney. A physiological amount of urine is visible in the renal pelves and is marked in one kidney by an arrow.

The placenta and membranes are the major sources of amnionic fluid early in pregnancy. However, after 18 weeks’ gestation, most of the fluid is produced by the kidneys (Chap. 11, p. 231). Fetal urine production increases from 5 mL/hr at 20 weeks to approximately 50 mL/hr at term (Rabinowitz, 1989). Unexplained oligohydramnios suggests a placental or urinary tract abnormality, whereas normal amnionic fluid volume in the second half of pregnancy suggests urinary tract patency with at least one functioning kidney.

**Renal Pelvis Dilatation**

This finding is present in 1 to 5 percent of fetuses. In 40 to 90 percent of cases, it is transient or physiological and does not represent an underlying abnormality (Ismaili, 2003; Nguyen, 2010). In approximately a third of cases, a urinary tract abnormality is confirmed in the neonatal period. Most frequently, this is either ureteropelvic junction (UPJ) obstruction or vesicoureteral reflux (VUR).

During evaluation, the renal pelvis is measured anterior-posterior in the transverse plane (Fig. 10-30). Although various thresholds have been defined, the pelvis is typically considered dilated if it exceeds 4 mm in the second trimester or 7 mm in the third trimester. Usually, the second-trimester threshold is used to identify pregnancies that warrant third-trimester evaluation.
FIGURE 10-30 Renal pelvis dilatation. This common finding is identified in 1 to 5 percent of pregnancies. **A.** In this 34-week fetus with mild renal pelvis dilatation, the anterior-posterior diameter of the renal pelvis measured 7 mm in the transverse plane. **B.** Sagittal image of the kidney in a 32-week fetus with severe renal pelvis dilatation secondary to ureteropelvic junction obstruction. One of the rounded calyces is marked (arrow).
Based on a meta-analysis of more than 100,000 screened pregnancies, the Society for Fetal Urology has categorized dilatation according to renal pelvis measurements and gestational age (Table 10-7) (Lee, 2006; Nguyen, 2010). The degree of renal pelvic dilatation correlates with the likelihood of underlying abnormality. Other findings that suggest pathology include calyceal dilatation, cortical thinning, or dilatation elsewhere along the urinary tract. Mild pyelectasis in the second trimester is associated with a slightly increased risk for Down syndrome (Chap. 14, p. 293).

*aSociety for Fetal Urology Classification. Modified from Lee, 2006; Nguyen, 2010.*

**Ureteropelvic Junction Obstruction.** This condition is the most common abnormality associated with renal pelvis dilatation. The birth prevalence approximates 1 per 1000 to 2000, and males are affected three times more often than females (Williams, 2007; Woodward, 2002). Obstruction is generally functional rather than anatomical, and it is bilateral in up to a fourth of cases. The likelihood of UPJ obstruction increases from 5 percent with mild renal pelvis dilatation to more than 50 percent with severe dilatation (Lee, 2006).

**Duplicated Renal Collecting System**

This occurs when the upper and lower poles of the kidney—called moieties—are each drained by a separate ureter (Fig. 10-31). Duplication is more common in females and is bilateral in 15 to 20 percent of cases (Whitten, 2001). It is recognized in approximately 1 per 4000 pregnancies (James, 1998; Vergani, 1998). Sonographically, an intervening tissue band separates two distinct renal pelves. These are typically cases in which hydronephrosis and/or ureteral dilatation develops, due to abnormal implantation of one or both ureters within the bladder—a relationship described by the Weigert-Meyer rule. The upper pole ureter often develops obstruction from a ureterocele within the bladder, whereas the lower pole ureter has a shortened intravesical segment that predisposes to vesicoureteral reflux (see Fig. 10-31). Thus, both moieties may become dilated from different etiologies, and both are at risk for loss of function. In the neonatal period, additional testing such as voiding cystourethrography will determine whether antimicrobial treatment is needed to minimize urinary infections and will assist with follow-up or surgical intervention.
FIGURE 10-31 Duplicated renal collecting system. The upper and lower moieties of the kidney are each drained by a separate ureter. **A.** Renal pelvis dilation is visible in both the upper (U) and lower (L) pole moieties, which are separated by an intervening band of renal tissue (arrowhead). **B.** The bladder, encircled by the highlighted umbilical arteries, contains a ureterocele (arrowhead).

**Renal Agenesis**
The prevalence of bilateral renal agenesis is approximately 1 per 8000 births, whereas that of
unilateral renal agenesis is 1 per 1000 births (Cragan, 2009; Dolt, 2010; Sheih, 1989; Wiesel, 2005). When a kidney is absent, the ipsilateral adrenal gland typically enlarges to fill the renal fossa, termed the *lying down adrenal sign* (Hoffman, 1992). In addition, color Doppler imaging of the descending aorta will demonstrate absence of the renal artery.

If renal agenesis is bilateral, no urine is produced. The resulting anhydramnios leads to pulmonary hypoplasia, limb contractures, and a distinctively compressed face. When this combination of abnormalities results from renal agenesis, it is called *Potter syndrome*, after Dr. Edith Potter who described it in 1946. When these abnormalities result from severely decreased amniotic fluid volume from another etiology, such as bilateral multicystic dysplastic kidney or autosomal recessive polycystic kidney disease, it is called *Potter sequence*.

**Multicystic Dysplastic Kidney**

This severe form of renal dysplasia results in a nonfunctioning kidney. The nephrons and collecting ducts do not form normally, such that primitive ducts are surrounded by fibromuscular tissue, and the ureter is atretic (Hains, 2009). Sonographically, the kidney contains numerous smooth-walled cysts of varying size that do not communicate with the renal pelvis and are surrounded by echogenic cortex (Fig. 10-32).

![FIGURE 10-32 Multicystic dysplastic kidneys. Coronal view of the fetal abdomen demonstrates markedly enlarged kidneys containing multiple cysts of varying sizes that do not communicate with a renal pelvis.](image)

Unilateral multicystic dysplastic kidney (MCDK) has a prevalence of 1 per 4000 births. It is associated with contralateral renal abnormalities in 30 to 40 percent of cases—most frequently vesicoureteral reflux or ureteropelvic junction obstruction (Schreuder, 2009). Nonrenal anomalies have been reported in 25 percent of cases, and cystic dysplasia may occur as a component of many genetic syndromes (Lazebnik, 1999; Schreuder, 2009). If MCDK is isolated and unilateral, the prognosis is generally good.
Bilateral MCDK develops in approximately 1 per 12,000 births. It is associated with severely decreased amnionic fluid volume from early in gestation. This leads to Potter sequence and a poor prognosis (Lazebnik, 1999).

**Polycystic Kidney Disease**

Of the hereditary polycystic diseases, only the infantile form of *autosomal recessive polycystic kidney disease (ARPKD)* may be reliably diagnosed prenatally. ARPKD is a chronic, progressive disease that involves the kidneys and liver. It results in cystic dilatation of the renal collecting ducts and congenital hepatic fibrosis (Turkbey, 2009). The carrier frequency of a disease-causing mutation in the *PKHD1* gene approximates 1 in 70, and the disease prevalence is 1 in 20,000 (Zerres, 1998). ARPKD has wide phenotypic variability. This ranges from lethal pulmonary hypoplasia at birth to presentation in late childhood or even adulthood with predominantly hepatic manifestations. Infantile polycystic kidney disease is characterized by abnormally large kidneys that fill and distend the fetal abdomen and have a solid, ground-glass texture. Severe oligohydramnios confers a poor prognosis.

As discussed in Chapter 53 (p. 1058), *autosomal dominant polycystic kidney disease (ADPKD)*, which is far more common, usually does not manifest until adulthood. Even so, some fetuses with ADPKD have mild renal enlargement, increased renal echogenicity, and normal amnionic fluid volume. The differential diagnosis for these findings includes several genetic syndromes, aneuploidy, or normal variant.

**Bladder Outlet Obstruction**

Distal obstruction of the urinary tract is more frequent in male fetuses, and the most common etiology is *posterior urethral valves*. Characteristically, there is dilatation of the bladder and proximal urethra, termed the “keyhole” sign, and the bladder wall is thick (Fig. 10-33). Oligohydramnios, particularly before midpregnancy, portends a poor prognosis because of pulmonary hypoplasia. Unfortunately, the outcome may be poor even with normal amnionic fluid volume. Evaluation includes a careful search for associated anomalies, which may occur in 40 percent of cases, and for aneuploidy, which has been reported in 5 to 8 percent (Hayden, 1988; Hobbins, 1984; Mann, 2010). If neither are present, affected male fetuses with severe oligohydramnios who have fetal urinary electrolytes suggesting a potentially favorable prognosis may be fetal therapy candidates. Evaluation and treatment of fetal bladder outlet obstruction is discussed in Chapter 16 (p. 330).
**Skeletal Abnormalities**

The 2010 revision of the Nosology and Classification of Genetic Skeletal Disorders includes an impressive 456 skeletal abnormalities in 40 groups that are defined by molecular, biochemical, and/or radiographic criteria (Warman, 2011). There are two types of skeletal dysplasias: osteochondrodysplasias—the generalized abnormal development of bone and/or cartilage, and dysostoses—which are abnormalities of individual bones, for example, polydactyly. In addition to these malformations, skeletal abnormalities include deformations, as with some cases of clubfoot, and disruptions such as limb-reduction defects.

**Skeletal Dysplasias**

The prevalence of skeletal dysplasias approximates 3 per 10,000 births. Two groups account for more than half of all cases: the fibroblast growth factor 3 (FGFR3) chondrodysplasia group and the osteogenesis imperfecta and decreased bone density group. Each has a prevalence of approximately 0.8 per 10,000 births (Stevenson, 2012).

Evaluation of a pregnancy with suspected skeletal dysplasia includes a survey of every long bone, as well as the hands and feet, skull size and shape, clavicles, scapulae, thorax, and spine. Reference tables are used to determine which long bones are affected and ascertain the degree of shortening (Appendix, p. 1299). Involvement of all long bones is termed micromelia, whereas predominant involvement of only the proximal, intermediate, or distal long bone segments is termed rhizomelia, mesomelia, and acromelia, respectively. The degree of ossification should be
noted, as should presence of bowing or fractures. Each of these may provide clues to narrow the differential diagnosis and occasionally suggest a specific skeletal dysplasia. Many, if not most, skeletal dysplasias have a genetic component, and knowledge of specific mutations has advanced rapidly (Warman, 2011).

Although precise characterization of a specific skeletal dysplasia may elude prenatal diagnosis, it is frequently possible to determine whether a skeletal dysplasia is lethal. Lethal dysplasias are frequently characterized by profound long bone shortening, with measurements below the 5th percentile and by femur length-to-abdominal circumference ratios < 16 percent (Appendix, p. 1299) (Rahemtullah, 1997; Ramus, 1998). Evidence of pulmonary hypoplasia includes a thoracic circumference < 80 percent of the abdominal circumference, thoracic circumference below the 2.5th percentile, and a cardiothoracic circumference ratio > 50 percent (Appendix, p. 1298). Affected pregnancies also may develop hydramnios and/or hydrops.

The FGFR3 chondrodysplasias include achondroplasia and thanatophoric dysplasia. Achondroplasia, also called heterozygous achondroplasia, is the most common nonlethal skeletal dysplasia. It is inherited in an autosomal dominant fashion, with 80 percent of cases resulting from a new mutation. An impressive 98 percent are due to one mutation in the FGFR3 gene. Achondroplasia is characterized by long bone shortening that is predominantly rhizomelic, an enlarged head with frontal bossing, depressed nasal bridge, exaggerated lumbar lordosis, and a trident configuration of the hands. Intelligence is typically normal. Sonographically, the femur and humerus measurements may not be below the 5th percentile until the early third trimester. Thus, this condition is usually not diagnosed until late in pregnancy. In homozygotes, which represent 25 percent of the offspring of heterozygous parents, the condition is characterized by much more severe long bone shortening and is lethal.

The other major class of FGFR3 dysplasias, thanatophoric dysplasia, is the most common lethal skeletal disorder. It is characterized by severe micromelia, and affected fetuses—particularly those with type II—may develop a characteristic cloverleaf skull deformity (kleeblattschädel) due to craniosynostosis. More than 99 percent of cases may be confirmed with genetic testing.

Osteogenesis imperfecta represents a group of skeletal dysplasias characterized by hypomineralization. There are multiple types, and more than 90 percent of cases are characterized by a mutation in the COL1A1 or COL1A2 gene. Type IIa, also called the perinatal form, is lethal. It is characterized by profound lack of skull ossification, such that gentle pressure on the maternal abdomen from the ultrasound transducer results in visible skull deformation (Fig. 10-34). Other features include multiple in-utero fractures and ribs that appear “beaded.” Inheritance is autosomal dominant, such that all cases result from either new mutations or gonadal mosaicism (Chap. 13, p. 269). Another skeletal dysplasia that results in severe hypomineralization is hypophosphatasia, which is inherited in an autosomal recessive fashion.
FIGURE 10-34 Osteogenesis imperfecta. Type IIa, which is lethal, is characterized by such profound lack of skull ossification that gentle pressure on the maternal abdomen from the ultrasound transducer results in visible deformation (flattening) of the skull (arrowheads).

Clubfoot—Talipes Equinovarus
This disorder is notable for a deformed talus and shortened Achilles tendon. The affected foot is abnormally fixed and positioned with equinus—downward pointing, varus—inward rotation, and forefoot adduction. Most cases are considered malformations, with a multifactorial genetic component. However, an association with environmental factors and with early amniocentesis suggests that deformation also plays a role (Tredwell, 2001). Sonographically, the footprint is visible in the same plane as the tibia and fibula (Fig. 10-35).
FIGURE 10-35 Foot position. A. Normal fetal lower leg, demonstrating normal position of the foot. B. With talipes equinovarus, the foot “print” is visible in the same plane as the tibia and fibula.

In population-based series, the prevalence of clubfoot is approximately 1 per 1000 births, with a male:female ratio of 2:1 (Carey, 2003; Pavone, 2012). Clubfoot is bilateral in approximately 50 percent of cases, and associated anomalies are present in at least 50 percent (Mammen, 2004; Sharma, 2011). Frequently associated anomalies include neural-tube defects, arthrogryposis, and myotonic dystrophy and other genetic syndromes. In the setting of associated anomalies, aneuploidy is present in approximately 30 percent, but it has been reported in less than 4 percent when clubfoot appears isolated (Lauson, 2010; Sharma, 2011). Thus, a careful search for associated anomalies is warranted, and fetal karyotyping may be considered.

Limb-Reduction Defects
Documentation of the arms and legs is a component of the standard examination. A limb-reduction defect is the absence of all or part of one or more extremities. Absence of an entire extremity is termed amelia. Phocomelia, associated with thalidomide exposure, is an absence of one or more long bones with the hands or feet attached to the trunk (Chap. 12, p. 252). Limb-reduction defects are associated with numerous genetic syndromes, such as Roberts syndrome, an autosomal recessive condition characterized by tetraphocomelia. A clubhand deformity, usually from an absent radius, is associated with trisomy 18 and is also a component of the thrombocytopenia-absent radius syndrome. Limb-reduction defects may occur in the setting of a disruption such as amnionic band sequence (Chap. 6, p. 121). They have also been associated with chorionic villus sampling when performed before 10 weeks’ gestation (Chap. 14, p. 300).

THREE- AND FOUR-DIMENSIONAL SONOGRAPHY
During the last two decades, three-dimensional (3-D) sonography has gone from a novelty to a standard feature of most modern ultrasound equipment (Fig. 10-36). 3-D sonography is not routinely used during a standard examination nor considered a required modality. However, it may be a component of various specialized evaluations.
Most 3-D scanning uses a special transducer developed for this purpose. After a region of interest is identified, a 3-D volume is acquired that may be rendered to display images of any plane—axial, sagittal, coronal, or even oblique—within that volume. Sequential “slices” can be generated, similar to computed tomographic (CT) or MR images. Technique applications include evaluation of intracranial anatomy in the sagittal plane, for example, the corpus callosum, and imaging of the palate and skeletal system (Benacerraf, 2006; Pili, 2008; Timor-Tritsch, 2000).

Unlike 2-D scanning, which appears to be in “real time,” 3-D imaging is static and obtained by processing a volume of stored images. There is also four-dimensional (4-D) sonography, also known as real-time 3-D sonography. This enhancement allows rapid reconstruction of the rendered images to convey the impression that the scanning is in real time. One application of 4-D imaging has been to improve visualization of cardiac anatomy. Postprocessing algorithms and techniques take advantage of real-time image volumes, with and without color Doppler mapping. An example is spatiotemporal image correlation—STIC, used to evaluate complex cardiac anatomy and function (DeVore, 2003; Espinoza, 2008). Addition of an inversion-mode algorithm may aid imaging of blood flow within the heart and great vessels and may even permit measurement of ventricular blood volume (Goncalves, 2004). Systematic approaches or protocols for using these new techniques to evaluate cardiac anatomy and physiology are under development (Espinoza, 2007; Turan, 2009).

For selected anomalies, such as those of the face and skeleton, 3-D sonography may provide additional useful information (Goncalves, 2005). That said, comparisons of 3-D with conventional 2-D sonography for the diagnosis of most congenital anomalies have not demonstrated an

FIGURE 10-36 Fetal face. Surface rendered three-dimensional image of a normal fetal face and hand at 32 weeks.
improvement in overall detection (Goncalves, 2006; Reddy, 2008). The American College of Obstetricians and Gynecologists (2011) currently recommends that 3-D ultrasound be used only as an adjunct to conventional sonography.

---

**DOPPLER**

When sound waves strike a moving target, the frequency of the waves reflected back is shifted proportionate to the velocity and direction of that moving target—a phenomenon known as the *Doppler shift*. Because the magnitude and direction of the frequency shift depend on the relative motion of the moving target, Doppler can be used to evaluate flow within blood vessels. The Doppler equation is shown in Figure 10-37.

![Doppler equation](image)

\[ f_d = 2f_0 \left( \frac{v \cos \theta}{c} \right) \]

**FIGURE 10-37** Doppler equation. Ultrasound emanating from the transducer with initial frequency \( f_0 \) strikes blood moving at velocity \( v \). Reflected frequency \( f_d \) is dependent on angle \( \theta \) between beam of sound and vessel.

An important component of the equation is the angle of insonation, abbreviated as theta (\( \theta \)), which is the angle between the sound waves from the transducer and flow within the vessel. Measurement error becomes large when \( \theta \) is not close to zero, in other words, when blood flow is not coming directly toward or away from the transducer. For this reason, ratios are often used to compare different waveform components, allowing cosine \( \theta \) to cancel out of the equation. **Figure 10-38** is a schematic of the Doppler waveform and describes the three ratios commonly used. The simplest is the *systolic-diastolic ratio (S/D ratio)*, which compares the maximal (or peak) systolic flow with end-diastolic flow to evaluate downstream impedance to flow.
Doppler systolic–diastolic waveform indices of blood flow velocity. S represents the peak systolic flow or velocity, and D indicates the end-diastolic flow or velocity. The mean, which is the time-average mean velocity, is calculated from computer-digitized waveforms.

Continuous wave Doppler equipment has two separate types of crystals—one transmits high-frequency sound waves, and another continuously captures signals. In M-mode imaging, continuous wave Doppler is used to evaluate motion through time, however, it cannot image individual vessels.

Pulsed-wave Doppler uses only one crystal, which transmits the signal and then waits until the returning signal is received before transmitting another one. It allows precise targeting and visualization of the vessel of interest. Pulsed-wave Doppler can be configured to allow color-flow mapping—such that blood flowing toward the transducer is displayed in red and that flowing away from the transducer appears in blue. Various combinations of pulsed-wave Doppler, color-flow Doppler, and real-time sonography are commercially available.

Umbilical Artery

As discussed in Chapter 17 (p. 344), umbilical artery Doppler has been subjected to more rigorous assessment than has any previous test of fetal health. The umbilical artery differs from other vessels in that it normally has forward flow throughout the cardiac cycle. Moreover, the amount of flow during diastole increases as gestation advances—a function of decreasing placental impedance. The S/D ratio normally decreases from approximately 4.0 at 20 weeks to 2.0 at term, and it is generally less than 3.0 after 30 weeks. Because of downstream impedance to flow, more end-diastolic flow is observed at the placental cord insertion than at the fetal ventral wall. Thus, abnormalities such as absent or reversed end-diastolic flow will appear first at the
fetal cord insertion site. The International Society of Ultrasound in Obstetrics and Gynecology recommends that umbilical artery Doppler measurements be made in a free loop of cord (Bhide, 2013). However, the Society for Maternal Fetal Medicine has recommended that assessment be performed close to the ventral wall insertion to optimize reproducibility (Berkley, 2012).

The waveform is considered abnormal if the $S/D$ ratio is above the 95th percentile for gestational age. In extreme cases of growth restriction, end-diastolic flow may become absent or even reversed (Fig. 10-39). Such reversal of end-diastolic flow has been associated with greater than 70-percent obliteration of the small muscular arteries in placental tertiary stem villi (Kingdom, 1997; Morrow, 1989).
FIGURE 10-39 Umbilical artery Doppler waveforms. A. Normal diastolic flow. B. Absence of
end-diastolic flow. C. Reversed end-diastolic flow.

Umbilical artery Doppler is a useful adjunct in the management of pregnancies complicated by fetal-growth restriction, and it has been associated with improved outcome in such cases (American College of Obstetricians and Gynecologists, 2013). It is not recommended for complications other than growth restriction. Similarly, it is not recommended as a screening tool for identifying pregnancies that will subsequently be complicated by growth restriction (Berkley, 2012). Abnormal umbilical artery Doppler findings should prompt a complete fetal evaluation if not already done, as such findings are associated with major fetal anomalies and aneuploidy (Wenstrom, 1991). The Society for Maternal Fetal Medicine has recommended that so long as fetal surveillance remains reassuring, pregnancies with fetal-growth restriction and absent end-diastolic flow in the umbilical artery may be managed expectantly until delivery at 34 weeks, and those with reversed end-diastolic flow managed expectantly until delivery at 32 weeks (Berkley, 2012).

Ductus Arteriosus

Doppler evaluation of the ductus arteriosus has been used primarily to monitor fetuses exposed to indomethacin and other nonsteroidal antiinflammatory agents (NSAIDs). Indomethacin, which is used by some for tocolysis, may cause ductal constriction or closure, particularly when used in the third trimester (Huhta, 1987). The resulting increased pulmonary flow may cause reactive hypertrophy of the pulmonary arterioles and eventual development of pulmonary hypertension. In a review of 12 randomized controlled trials involving more than 200 exposed pregnancies, Koren and colleagues (2006) reported that NSAIDs increased the odds of ductal constriction 15-fold. They also concluded that this was a low estimate because most of the pregnancies were exposed only briefly. Fortunately, ductal constriction is often reversible after NSAID discontinuation. Because ductal constriction is a potentially serious complication that should be avoided, the duration of NSAID administration is typically limited to less than 72 hours, and women taking NSAIDs are closely monitored so that these can be discontinued if ductal constriction is identified.

Uterine Artery

Uterine blood flow is estimated to increase from 50 mL/min early in gestation to 500 to 750 mL/min by term (Chap. 4, p. 47). The uterine artery Doppler waveform is characterized by high diastolic flow velocities and by highly turbulent flow. Increased resistance to flow and development of a diastolic notch are associated with later development of gestational hypertension, preeclampsia, and fetal-growth restriction. Zeeman and coworkers (2003) also found women with chronic hypertension who had increased uterine artery impedance at 16 to 20 weeks were at increased risk to develop superimposed preeclampsia. Even so, the predictive value of uterine artery Doppler testing is low, and screening is not recommended in either high-risk or low-risk pregnancies (Sciscione, 2009). The technique has not been standardized, frequency of assessment has not been established, and criteria for an abnormal test have not been determined. In a report from a workshop on prenatal imaging held by the NICHD, Reddy and associates (2008) concluded that perinatal benefits of uterine artery Doppler screening have not yet been demonstrated.

Middle Cerebral Artery
Doppler interrogation of the middle cerebral artery (MCA) has been investigated and applied clinically for fetal anemia detection and fetal-growth restriction evaluation. Anatomically, the path of the MCA is such that flow often approaches the transducer “head-on,” allowing for accurate determination of flow velocity (Fig. 10-40). The MCA is imaged in an axial view of the head at the base of the skull, ideally within 2 mm of the internal carotid artery origin. Velocity measurement is optimal when the insonating angle is close to zero, and no more than 30 degrees of angle correction should be used. In general, velocity assessment is not performed in other fetal vessels, because a larger insonating angle is needed and confers significant measurement error.

When fetal anemia is present, the *peak systolic velocity* is increased due to increased cardiac output and decreased blood viscosity (Segata, 2004). This has permitted the reliable, noninvasive detection of fetal anemia in cases of blood-group alloimmunization. More than a decade ago, Mari and colleagues (2000) demonstrated that an MCA peak systolic velocity threshold of 1.50 multiples of the median (MoM) could reliably identify fetuses with moderate or severe anemia. In most referral centers, MCA peak systolic velocity has replaced invasive testing with amniocentesis for fetal anemia detection (Chap. 15, p. 310).

MCA Doppler has also been studied as an adjunct in the evaluation of fetal-growth restriction. Fetal hypoxemia is believed to result in increased blood flow to the brain, heart, and adrenal glands, leading to increased end-diastolic flow in the MCA. This phenomenon, “brain-sparing,” is actually a misnomer, as it is not protective for the fetus but rather is associated with perinatal morbidity and mortality (Bahado-Singh, 1999; Cruz-Martinez, 2011). The utility of MCA Doppler to aid the timing of delivery is uncertain. It has *not* been evaluated in randomized trials nor
Ductus Venosus

The ductus venosus is imaged as it branches from the umbilical vein at approximately the level of the diaphragm. Fetal position poses more of a challenge in imaging the ductus venosus than it does with either the umbilical artery or the middle cerebral artery. The waveform is biphasic and normally has forward flow throughout the cardiac cycle. The first peak reflects ventricular systole, and the second is diastolic filling. These are followed by a nadir during atrial contraction—termed the a-wave.

It is believed that there is a progression of Doppler findings in preterm fetuses with growth restriction, such that umbilical artery Doppler abnormalities occur first, followed by those in the middle cerebral artery and then the ductus venosus. However, there is wide variability in manifestation of these abnormalities (Berkley, 2012). When severe fetal-growth restriction is present, cardiac dysfunction may lead to flow in the a-wave that is decreased, absent, and eventually reversed, along with pulsatile flow in the umbilical vein (Reddy, 2008).

Thus, ductus venosus abnormalities have potential to identify preterm growth-restricted fetuses that are at greatest risk for adverse outcomes (Baschat, 2003, 2004; Bilardo, 2004; Figueras, 2009). As noted by the Society for Maternal-Fetal Medicine, however, they have not been sufficiently evaluated in randomized trials (Berkley, 2012). The American College of Obstetricians and Gynecologists (2013) recently concluded that Doppler assessment of vessels other than the umbilical artery has not been shown to improve perinatal outcome and that its role in clinical practice remains uncertain.

MAGNETIC RESONANCE IMAGING

The fetus was first studied with MR imaging in the mid-1980s, when image acquisition was slow and motion artifact was problematic (Lowe, 1985). Since then, technological advances that allow fast-acquisition MR protocols have been developed. These newer protocols permit image acquisition in 1 second or less, which significantly reduces motion artifact and eliminates the need for sedation.

Image resolution with MR is often superior to that with sonography because it is not as hindered by bony interfaces, maternal obesity, oligohydramnios, or an engaged fetal head. MR may be a useful adjunct to sonography in evaluating and further characterizing suspected fetal abnormalities. MR imaging, however, is not portable, it is time-consuming, and its use is generally limited to referral centers with expertise in fetal imaging. It may be helpful in the evaluation of complex abnormalities of the fetal CNS, thorax, gastrointestinal system, genitourinary system, and musculoskeletal system. MR has also been used in the evaluation of maternal pelvic masses, placental invasion, and abnormalities of the pelvic floor and cervix.

The American College of Radiology and Society for Pediatric Radiology (2010) have developed a practice guideline for fetal MR imaging. This guideline acknowledges that sonography is the screening modality of choice. Moreover, it recommends that fetal MR imaging be used for problem solving to ideally contribute to prenatal diagnosis, counseling, treatment, and delivery planning. Specific indications for fetal MR imaging are listed in Table 10-8 and are
**TABLE 10-8. Fetal Conditions for Which Magnetic Resonance Imaging May Be Indicated**

**Brain and spine**
- Ventriculomegaly
- Agenesis of the corpus callosum
- Holoprosencephaly
- Posterior fossa abnormalities
- Cerebral cortical malformations
- Vascular malformations
- Hydranencephaly
- Infarctions
- Monochorionic twin pregnancy complications
- Neural-tube defects
- Sacrococcygeal teratoma
- Caudal regression sequence
- Sirenomelia
- Vertebral anomalies

**Skull, face, and neck**
- Venolymphatic malformations
- Hemangiomas
- Goiter
- Teratomas
- Facial clefts
- Other abnormalities with potential airway obstruction

**Thorax**
- Congenital cystic adenomatoid malformation
- Extralobar pulmonary sequestration
- Congenital diaphragmatic hernia
- Evaluation of pulmonary hypoplasia secondary to oligohydramnios, chest mass, or skeletal dysplasia

**Abdomen, pelvis, and retroperitoneum**
- Assess the size and location of tumors (such as sacrococcygeal teratoma, neuroblastoma, suprarenal or renal masses)
- Assess renal anomalies with oligohydramnios
- Diagnose bowel anomalies

**Complications of monochorionic twins**
- Determine vascular anatomy prior to laser treatment
- Assess morbidity after death of a monochorionic cotwin
- Evaluate conjoined twins
Fetal surgery assessment

- Fetal brain anatomy before and after surgical intervention
- Fetal anomalies for which surgery is planned

### Safety

MR imaging uses no ionizing radiation. Theoretical concerns include the effects of fluctuating electromagnetic fields and high sound-intensity levels. The strength of the magnetic field is measured in *tesla* ($T$), and all imaging studies during pregnancy are currently performed using 1.5 $T$ or less.

Human studies and tissue studies support the safety of fetal MR imaging. Repetitive exposure of human lung fibroblasts to a static 1.5-T magnetic field has not been found to affect cellular proliferation (Wiskirchen, 1999). Fetal heart rate patterns have been evaluated before and during MR imaging, with no significant differences observed (Vadeyar, 2000). Children exposed to MR as fetuses have not been found to have an increased incidence of disease or disability when tested at age 9 months or 3 years (Baker, 1994; Clements, 2000).

Glover and associates (1995) attempted to mimic the sound level experienced by the fetal ear by having an adult volunteer swallow a microphone while the stomach was filled with a liter of fluid to represent the amniotic sac. There was at least 30-dB attenuation in intensity from the body surface to the fluid-filled stomach, reducing the sound pressure from 120 dB to below 90 dB. This level is considerably less than the 135 dB experienced from vibroacoustic stimulation (*Chap. 17*, p. 341). Cochlear function testing has been performed in infants who were exposed to 1.5-T MR imaging as fetuses. Such testing has not demonstrated evidence of hearing impairment (Reeves, 2010).

The Expert Panel on MR Safety of the American College of Radiology (2013) has concluded that based on available evidence, there are no documented deleterious effects of MR imaging exposure on the developing fetus. Therefore, MR can be performed in pregnancy if the data are needed to care for the fetus or mother. Health-care providers who are pregnant may work in and around an MR unit, but it is recommended that they not remain in the MR scanner magnet room—known as Zone IV—while an examination is in progress (American College of Radiology, 2013).

Gadolinium-based MR contrast agents should be avoided during pregnancy because of the potential for dissociation of the chelate molecule in the amniotic fluid (American College of Radiology, 2013). These readily enter the fetal circulation and are excreted into the amniotic fluid via fetal urine. Here, they may remain for an indeterminate period before being reabsorbed. The longer the gadolinium-chelate molecule remains in a protected space such as the amniotic sac, the greater the potential for dissociation of the toxic gadolinium ion (American College of Radiology, 2013). In adults with renal disease, this contrast agent has been associated with development of nephrogenic systemic fibrosis, a potentially severe complication.

### Technique

All women complete a written MR safety screening questionnaire before the examination. This includes information regarding metallic implants, pacemakers, or other metal- or iron-containing
devices that may alter the study (American College of Radiology, 2013). Iron supplementation may cause artifact in the colon but does not usually affect the fetal resolution. In more than 2000 MR procedures in pregnancy performed at Parkland Hospital during the last 10 years, maternal anxiety secondary to claustrophobia and/or fear of the MR equipment has occurred in fewer than 1 percent of our patients. To reduce maternal anxiety in this small group, a single oral dose of diazepam, 5 to 10 mg, or lorazepam, 1 to 2 mg, is given.

Women are placed in the supine or left lateral decubitus position. A torso coil is used in most circumstances, with the occasional use of either the body or cardiac coil depending on maternal or fetal size and area of interest. A series of three-plane localizers are obtained relative to the maternal coronal, sagittal, and axial planes. The gravid uterus is imaged in the maternal axial plane (7-mm slices, 0 gap) with a T2-weighted fast acquisition. Typically, these may be a single-shot fast spin echo sequence (SSFSE), half-Fourier acquisition single-shot turbo spin echo (HASTE) or rapid acquisition with relaxation enhancement (RARE), depending on the brand of machine and manufacturer. Next, a fast T1-weighted acquisition such as spoiled gradient echo (SPGR) is performed (7-mm thickness, 0 gap). These acquisitions are particularly good for identifying fetal and maternal anatomy.

Orthogonal images of targeted fetal or maternal structures are then obtained. In these cases, 3- to 5-mm slice thickness, 0 gap T2-weighted acquisitions are performed in the coronal, sagittal, and axial planes. Depending on the anatomy and underlying suspected abnormality, T1-weighted images can be performed to evaluate for subacute hemorrhage, fat, or location of normal structures that appear bright on these sequences, such as liver and meconium in the colon (Brugger, 2006; Zaretsky, 2003b).

Short TI inversion recovery images (STIR) may provide differentiation in cases in which the water content of the abnormality is similar to the normal structure. An example is a thoracic mass compared with normal lung. Occasionally, fluid attenuated inversion recovery (FLAIR) images may be obtained for CNS abnormalities to evaluate the ventricular system and other CSF containing spaces. Diffusion-weighted imaging may be employed to evaluate for restricted diffusion and ischemia (Brugger, 2006; Zaretsky, 2003b). Our series also includes an axial brain 3- to 5-mm T2-weighted sequence to obtain head biometry for gestational age estimation using the biparietal diameter and head circumference (Reichel, 2003).

Fetal Anatomical Evaluation

Whenever a fetal abnormality has been identified, findings from the affected organ as well as other organ systems should be thoroughly characterized. Accordingly, a fetal anatomical survey is generally completed during each MR examination. In a recent prospective study, nearly 95 percent of the anatomical components recommended by the International Society of Ultrasound in Obstetrics and Gynecology were visible at 30 weeks (Millischer, 2013). The aorta and pulmonary artery were the structures most difficult to evaluate. Zaretsky and coworkers (2003a) similarly found that with the exclusion of cardiac structures, fetal anatomical evaluation was possible in 99 percent of cases.

Central Nervous System

With MR imaging, the brain can be visualized in the axial, coronal, and sagittal planes, without the near-field attenuation caused by the fetal skull during sonography. This makes MR a valuable adjunct in the evaluation of selected intracranial anomalies. Very fast T2-weighted images produce excellent tissue contrast, and CSF-containing structures are hyperintense or bright. This allows
exquisite detail of the posterior fossa, midline structures, and cerebral cortex. T1-weighted images are occasionally used to differentiate between fat and hemorrhage.

CNS biometry obtained with MR imaging has been found to be comparable with that obtained using sonography (Twickler, 2002). Nomograms have been published for multiple intracranial structures, including corpus callosum and cerebellar vermis lengths (Garel, 2004; Tilea, 2009).

Levine and colleagues (1999a) demonstrated that MR imaging accurately portrays cerebral gyration and sulcation patterns (Fig. 10-41). This is important because fetuses with a cerebral abnormality may have a significant lag in cortical development. Sonography permits limited evaluation of subtle migrational abnormalities, and MR imaging provides greater accuracy, particularly later in gestation.

FIGURE 10-41 Sagittal images of the fetal brain at 25 weeks (A) and at 37 weeks (B) demonstrate the normal increase in gyration and sulcation that occurs during fetal development. These images were obtained using a Half Fourier Acquisition Single Shot Turbo Spin Echo (HASTE) sequence.

**Indications.** There have been numerous studies of second-opinion MR examination for a cerebral abnormality detected or suspected sonographically (Benacerraf, 2007; Li, 2012). Levine and associates (1999b) found that MR imaging changed the diagnosis in 40 percent of cases and affected management in 15 percent. Simon and coworkers (2000) reported that MR-imaging
findings changed management in almost half of cases. Twickler and colleagues (2003) also reported that fetal CNS MR imaging changed the diagnosis in half of fetuses and altered clinical management in a third. Additional information was more likely to be gained when the examination was performed beyond 24 weeks’ gestation.

Ventriculomegaly is a common fetal MR imaging indication, if used to determine whether this finding is truly isolated or associated with other CNS dysmorphology (p. 202). For example, MR may demonstrate that severe ventriculomegaly is secondary to aqueductal stenosis, shown in Figure 10-42, or that it is actually hydranencephaly. In the case of mild ventriculomegaly, MR may identify agenesis of the corpus callosum or migrational abnormalities (Benacerraf, 2007; Li, 2012; Twickler, 2003).

**FIGURE 10-42** Aqueductal stenosis. **A.** An axial transventricular image at 22 weeks using a HASTE sequence demonstrates severe ventriculomegaly. **B.** A coronal image of the same fetus shows that the third ventricle (arrow) is dilated. **C.** An axial image at the level of the posterior fossa reveals that the fourth ventricle (arrowhead) appears normal, consistent with a diagnosis of aqueductal stenosis.

Another fetal MR imaging indication is the evaluation of possible intraventricular hemorrhage (IVH), such as shown in Figure 10-43. Fetal IVH risk factors may include an atypical appearance of ventriculomegaly, neonatal alloimmune thrombocytopenia, and a monochorionic multifetal gestation complicated by demise of one fetus or by severe twin-twin transfusion syndrome (Hu, 2006). If hemorrhage is identified, MR imaging characteristics may indicate which structures are involved and approximately when bleeding occurred.
Intraventricular hemorrhage. Axial images through the brain of a 24-week fetus. Arrows denote an area of abnormal signal in the left lateral ventricle. On the HASTE image (A), the irregularity is well delineated but of nonspecific low signal intensity. The T1-weighted image (B) demonstrates increased signal intensity within this area of concern, suggesting an intraventricular hemorrhage. Diffusion-weighted image (C) and Apparent Diffusion Coefficient map (D) demonstrate true restricted diffusion associated with the hemorrhage.

Thorax
Thoracic abnormalities are readily visualized with targeted sonography. MR imaging, however, may help delineate the location and size of space-occupying thoracic lesions and quantify remaining lung tissue volumes. MR imaging may aid in characterizing the type of cystic adenomatoid malformation and in visualizing the blood supply of extralobar pulmonary
sequestration (p. 208). With congenital diaphragmatic hernia, MR imaging may be used to verify and quantify the abdominal organs within the thorax. This includes the volume of herniated liver as well as compressed lung tissue volumes (Fig. 10-44) (Debus, 2013; Lee, 2011; Mehollin-Ray, 2012). MR imaging has also been used to identify other organ-system abnormalities in fetuses with diaphragmatic hernia. This may greatly clarify fetal prognosis (Kul, 2012). MR imaging similarly has been used for lung volume evaluation in cases of skeletal dysplasia and prolonged oligohydramnios secondary to renal disease or ruptured membranes (Messerschmidt, 2011; Zaretsky, 2005).

**FIGURE 10-44** Congenital diaphragmatic hernia A. A HASTE image of a 26-week fetus with congenital diaphragmatic hernia involving the liver (arrows). B. Coronal STIR image through a 33-week fetal chest demonstrates multiple loops of bowel filling the left chest (dashed lines).

**Abdomen**

When sonographic visualization is limited by oligohydramnios or maternal obesity, MR imaging may be useful (Caire, 2003). Hawkins and associates (2008) found that lack of signal in a contracted fetal bladder on T2-weighted sequences was associated with lethal renal abnormalities. Differences in signal characteristics between meconium in the fetal colon and urine in the bladder may permit characterization of cystic abdominal abnormalities (Farhataziz, 2005).

**Adjunct to Fetal Therapy**
As indications for fetal therapy have increased, MR imaging has become more routinely used to outline abnormalities preoperatively. At some centers, before laser ablation of placental anastomoses for twin-twin transfusion syndrome, MR imaging is performed to assess the brain for IVH or periventricular leukomalacia (Chap. 34, p. 656) (Hu, 2006; Kline-Fath, 2007). Because of its precision in visualizing brain and spine findings in cases of myelomeningocele, it is often used before fetal spina bifida surgery (Fig. 10-45). If fetal surgery is considered for sacrococcygeal teratomas, MR imaging may identify tumor extension into the fetal pelvis (Avni, 2002; Neubert, 2004). With a fetal neck mass for which an EXIT procedure is considered, MR imaging may help delineate the lesion extent and its effect on the oral cavity and hypopharynx (Hirose, 2003; Ogamo, 2005; Shiraishi, 2000). Finally, MR imaging has also been used when an EXIT procedure may be needed for severe micrognathia (MacArthur, 2012; Morris, 2009). Fetal therapy is discussed in Chapter 16 (p. 331).

**FIGURE 10-45** Myelomeningocele. A. A sagittal balanced TruFisp image at 32 weeks demonstrates herniation of the cerebellum into the cervical canal (arrow) and a small sacral neural-tube defect with a thin covering membrane (arrowhead). B. A sagittal TruFisp image of a different fetus demonstrates a neural-tube defect (arrowheads) and prominent myelomeningocele (arrows). B = fetal bladder.

**Placenta**
The clinical importance of identifying women with placenta accreta is discussed in Chapter 41 (p. 804). Sonography is generally used to identify placental invasion into the myometrium, however, MR evaluation has been used as an adjunct in indeterminate cases. Findings concerning for invasion include uterine bulging, dark intraplacental bands on T2-weighted images, and placental heterogeneity (Leyendecker, 2012). When used in a complementary role, MR imaging sensitivity for detection of placental invasion has been high, although the depth of invasion has been difficult to predict. Clinical risk factors and sonographic findings should be taken into account when interpreting MR placental images (Leyendecker, 2012). Identification of placenta percreta with bladder wall invasion has been a challenge, even when both sonography and MR imaging are used.

Emerging Concepts

As MR acquisition times improve and technology allows for better resolution of structures and movement, there are three potential directions that fetal imaging may proceed. One is volume acquisition and 3-D postprocessing. This would occur in a manner similar to spiral CT with multiple channel detectors, in which one large high-resolution image can be processed in any plane. Applying this to the fetal structure of interest would require faster acquisition times, the ability to correct for fetal motion, and improved field-of-view options—which are in development.

The second direction is real-time MR imaging for evaluation of the fetal heart and other moving structures. A feasibility study reviewed MR evaluations of the chest to ascertain specific fetal heart components (Gorincour, 2007). These authors found, among other things, that balanced fast imaging with steady-state precession (TruFISP) was helpful in defining atrial, ventricular, conotruncal, and venous relationships.

A third direction is further assessment of already established acquisitions of fetal physiological functions. This includes spectroscopy for brain maturity, which has been discussed in small series (Fenton, 2001; Kok, 2002). Other possibilities include diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) for fetal CNS evaluation (Chung, 2009; Garel, 2008). The latter has the added advantage of white matter tract imaging. These emerging technologies are still experimental and will require rigorous investigation before clinical application.

Amnionic fluid serves several roles during pregnancy. It creates a physical space for fetal movement, which is necessary for normal musculoskeletal development. It permits fetal swallowing—essential for gastrointestinal tract development, and fetal breathing—necessary for lung development. Amnionic fluid guards against umbilical cord compression and protects the fetus from trauma. It even has bacteriostatic properties. Amnionic fluid volume abnormalities may reflect a problem with fluid production or its circulation, such as underlying fetal or placental pathology. These volume extremes may be associated with increased risks for adverse pregnancy outcome.

**NORMAL AMNIONIC FLUID VOLUME**

Amnionic fluid volume increases from approximately 30 mL at 10 weeks to 200 mL by 16 weeks and reaches 800 mL by the mid-third trimester (Brace, 1989; Magann, 1997). This fluid is approximately 98-percent water. A full-term fetus contains roughly 2800 mL of water, and the placenta another 400 mL, such that the term uterus holds nearly 4 liters of water (Modena, 2004). Abnormally decreased fluid volume is termed *oligohydramnios*, whereas abnormally increased fluid volume is termed *hydramnios* or *polyhydramnios*.

**Physiology**

Early in pregnancy, the amnionic cavity is filled with fluid that is similar in composition to extracellular fluid. During the first half of pregnancy, transfer of water and other small molecules
takes place across the amnion—*transmembranous flow*, across the fetal vessels on placental surface—*intramembranous flow*, and across fetal skin. Fetal urine production begins between 8 and 11 weeks, but it does not become a major component of amnionic fluid until the second trimester. This latter observation explains why fetuses with lethal renal abnormalities may not manifest severe oligohydramnios until after 18 weeks. Water transport across the fetal skin continues until keratinization occurs at 22 to 25 weeks. This explains why extremely preterm infants can experience significant fluid loss across their skin.

With advancing gestation, four pathways play a major role in amnionic fluid volume regulation (Table 11-1). First, fetal urination is the primary amnionic fluid source by the second half of pregnancy. By term, fetal urine production may exceed 1 liter per day—such that the entire amnionic fluid volume is recirculated on a daily basis. Fetal urine osmolality is significantly hypotonic to that of maternal and fetal plasma and similar to that of amnionic fluid. Specifically, the osmolality of maternal and fetal plasma is approximately 280 mOsm/mL, whereas that of amnionic fluid is about 260 mOsm/L. This hypotonicity of fetal urine—and thus of amnionic fluid—accounts for significant *intramembranous* fluid transfer across and into fetal vessels on the placental surface, and thus into the fetus. This transfer reaches 400 mL per day and is a second regulator of fluid volume (Mann, 1996). In the setting of maternal dehydration, the resultant increase in maternal osmolality favors fluid transfer from the fetus to the mother, and then from the amnionic fluid compartment into the fetus (Moore, 2010).

An important third source of amnionic fluid regulation is the respiratory tract. Approximately 350 mL of lung fluid is produced daily late in gestation, and half of this is immediately swallowed. Last, fetal swallowing is the primary mechanism for amnionic fluid resorption and averages 500 to 1000 mL per day (Mann, 1996). Impaired swallowing, secondary to either a central nervous system abnormality or gastrointestinal tract obstruction, can result in an impressive degree of hydramnios. The other pathways—transmembranous flow and flow across the fetal skin—account for a far smaller proportion of fluid transport in the second half of pregnancy.

### Measurement

From a practical standpoint, the actual volume of amnionic fluid is rarely measured outside of the
research setting. That said, direct measurement and dye-dilution methods of fluid quantification have contributed to an understanding of normal physiology. These measurements have further been used to validate sonographic fluid assessment techniques. The dye-dilution method involves injection of a small quantity of a dye such as aminohippurate into the amnionic cavity under sonographic guidance. The amnionic fluid is then sampled to determine the dye concentration and hence to calculate the fluid volume in which it was diluted.

Brace and Wolf (1989) reviewed 12 studies done through the 1960s in which amnionic fluid volume was assessed using these measurement techniques. Although fluid volume increased across gestation, they found that the mean value did not change significantly between 22 and 39 weeks—it was approximately 750 mL. There was considerable variation at each week of gestation, particularly in the mid-third trimester. At this time, the 5th percentile was 300 mL, and the 95th percentile approximated 2000 mL. In contrast, Magann and colleagues (1997) used dye-dilution measurements and found that the amnionic fluid volume continues to increase with advancing gestation. Specifically, the average fluid volume was approximately 400 mL between 22 and 30 weeks, doubling thereafter to a mean of 800 mL. The volume remained at this level until 40 weeks and then declined by approximately 8 percent per week thereafter. The two reports differed in the regression methodology employed, and despite different conclusions, both identified a wide normal range at each week of gestation, particularly in the third trimester. This normal variation has also been identified using semiquantitative sonographic methods, described next.

**Sonographic Assessment**

Amnionic fluid volume evaluation is a component of every standard sonogram performed in the second or third trimester (Chap. 10, p. 199). Volume is typically assessed semiquantitatively, by measuring either a single pocket or the amnionic fluid index—AFI (Phelan, 1987). A qualitative or subjective estimate of amnionic fluid volume is also considered acceptable when performed by an experienced examiner (American College of Obstetricians and Gynecologists, 2011; American Institute of Ultrasound in Medicine, 2013). One limitation of subjective estimation, however, is that it does not permit a longitudinal assessment of trends in the amount or adequacy of fluid volume.

**Single Deepest Pocket**

This is also called the maximum vertical pocket. The ultrasound transducer is held perpendicular to the floor and parallel to the long axis of the pregnant woman. In the sagittal plane, the largest vertical pocket of fluid is identified. The fluid pocket may contain fetal parts or loops of umbilical cord, but these are not included in the measurement.

The normal range for single deepest pocket that is most commonly used is 2 to 8 cm, with values above and below this indicating hydramnios and oligohydramnios, respectively. These thresholds are based on data from Chamberlain and associates (1984) and correspond to the 3rd and 97th percentiles. This group also reported increased perinatal mortality rates among nonanomalous infants if the single deepest pocket was below the normal range. The fetal biophysical profile similarly uses a 2-cm single deepest vertical pocket threshold to indicate a normal amnionic fluid volume (American College of Obstetricians and Gynecologists, 2012). This is discussed in more detail in Chapter 17 (p. 341).

Other less commonly used thresholds to determine amnionic fluid volume adequacy involve measurement of a single pocket in both the vertical and transverse planes. Adequate fluid volume is defined as a $2 \times 1$ cm pocket, a $2 \times 2$ cm pocket, or a pocket that is at least 15 cm$^2$ (Gramellini,
When evaluating twin pregnancies and other multifetal gestations, a single deepest pocket of amnionic fluid is assessed in each gestational sac, again using a normal range of 2 to 8 cm (Hernandez, 2012; Society for Maternal-Fetal Medicine, 2013).

**Amnionic Fluid Index (AFI)**

This was described by Phelan and coworkers (1987) more than 25 years ago, and it remains one of the most commonly used methods of amnionic fluid volume assessment. As with the single deepest fluid pocket measurement, the ultrasound transducer is held perpendicular to the floor and parallel to the long axis of the pregnant woman. The uterus is divided into four equal quadrants—the right- and left-upper and lower quadrants, respectively. The AFI is the sum of the single deepest pocket from each quadrant. A fluid pocket may contain fetal parts or umbilical cord loops, but these are not included in the measurement. Color Doppler is generally used to verify that no umbilical cord is included in the measurement. This may result in greater consistency and in reduction of intraobserver variation (Callen, 2008; Hill, 2003). It has been reported, however, that color Doppler use results in a lower AFI measurement, thus potentially leading to overdiagnosis of oligohydramnios (Magann, 2001).

The intraobserver variability of the AFI is approximately 1 cm and the interobserver variability about 2 cm. There are larger variations when fluid volumes are above the normal range (Moore, 1990; Rutherford, 1987b). A useful guideline is that the AFI is approximately three times the single deepest pocket of fluid encountered (Hill, 2003).

**Normal AFI.** Determination of whether the AFI is normal—that is, the thresholds for defining oligohydramnios and hydramnios—may be based on either a static numerical cut-off or a gestational age-specific percentile reference range.

*The normal range for AFI that is most commonly used is 5 to 24 cm, with values above and below this indicating hydramnios and oligohydramnios, respectively.* Rutherford and colleagues (1987a) reported an increased risk for adverse pregnancy outcomes with indices outside of this range. Moore and Cayle (1990) published normal curves for AFI values based on a cross-sectional evaluation of nearly 800 uncomplicated pregnancies. As shown in Figure 11-1, the mean AFI was found to be between 12 and 15 cm from 16 weeks until 40 weeks. Other investigators have published nomograms with similar mean values (Hinh, 2005; Machado, 2007).
FIGURE 11-1 Amnionic fluid index (AFI) according to gestational-age-specific nomograms and threshold values. The blue curves represent the 2.5th, 50th, and 97.5th AFI percentile values, based on the nomogram by Moore (1990). Red and tan curves represent 50th percentile values for AFI from Machado (2007) and from Hinh and Ladinsky (2005), respectively. The light blue and yellow shaded bars indicate threshold values used to define hydramnios and oligohydramnios, respectively.

In the Moore (1990) nomogram, a threshold of 5 cm is < 2.5th percentile throughout the second and third trimesters. A value of 25 cm is > 95th percentile, but is not necessarily the 97.5th percentile, depending on gestational age. Using other published nomograms, a value of 25 cm exceeds the 97.5th percentile (Hinh, 2005; Machado, 2007). At this time, there is no consensus as to whether AFI nomogram use improves prediction of adverse outcome compared with use of a numerical threshold alone, and both are considered acceptable.

HYDRAMNIOS

This is an abnormally increased amnionic fluid volume, and it complicates 1 to 2 percent of pregnancies (Biggio, 1999; Dashe, 2000; Magann, 2007; Pri-Paz, 2012). Also termed polyhydramnios, hydramnios may be suspected if the uterine size exceeds that expected for gestational age. The uterus may feel tense, and palpating fetal small parts or auscultating fetal heart tones may be difficult. An extreme example is shown in Figure 11-2.
FIGURE 11-2 Severe hydramnios—5500 mL of amniotic fluid was measured at delivery.

Hydramnios may be further categorized according to degree. Such categorization has been primarily used in research studies to stratify risks. Several groups have termed hydramnios as mild if the AFI is 25 to 29.9 cm, moderate if 30 to 34.9 cm, and severe if 35 cm or more (Dashe, 2002; Lazebnik, 1999; Pri-Paz, 2012). Mild hydramnios is the most common, comprising approximately two thirds of cases. Moderate hydramnios accounts for about 20 percent, and severe hydramnios approximately 15 percent. Using the single deepest pocket of amniotic fluid, criteria for mild is 8 to 9.9 cm, moderate is 10 to 11.9 cm, and severe hydramnios, ≥ 12 cm. An example of severe hydramnios seen sonographically is shown in Figure 11-3. These definitions fit the general rule that the AFI is approximately three times the measurement of the single deepest fluid pocket (Hill, 2003). In general, severe hydramnios is far more likely to have an underlying etiology and to have consequences for the pregnancy than mild hydramnios—which is frequently idiopathic and benign.
**Etiology**

Common underlying causes of hydramnios include fetal congenital anomalies in approximately 15 percent and diabetes in 15 to 20 percent (Table 11-2). Congenital infection and red blood cell alloimmunization are less frequent reasons. Infections that may present with hydramnios include cytomegalovirus, toxoplasmosis, syphilis, and parvovirus (Chaps. 64 and 65). Hydramnios is often a component of *hydrops fetalis*, and several of the above etiologies—selected anomalies, infections, and alloimmunization—may result in a hydropic fetus and placenta. The underlying pathophysiology in such cases is complex but is frequently related to a high cardiac-output state. Severe fetal anemia is the classic example. Because the etiologies of hydramnios are so varied, hydramnios treatment also varies and is tailored in most cases to the underlying cause. These etiologies are discussed further in Chapter 15 (p. 315) and in other chapters covering specific topics.

**TABLE 11-2. Hydramnios: Prevalence and Associated Etiologies—Values in Percent**
Diabetes Mellitus
The amniotic fluid glucose concentration is higher in diabetic women than in those without diabetes, and the amniotic fluid index may correlate with the amniotic fluid glucose concentration (Dashe, 2000; Spellacy, 1973; Weiss, 1985). Such findings support the hypothesis that maternal hyperglycemia causes fetal hyperglycemia, with resulting fetal osmotic diuresis into the amniotic fluid compartment.

Congenital Anomalies
Various anomalies may be found in the setting of hydramnios, and some are more characteristically linked with it than others. Because of this association, identification of hydramnios is an indication for targeted sonography. Many of the anomalies described next are displayed sonographically in Chapter 10 (p. 200).

Severe central nervous system abnormalities, such as anencephaly, hydranencephaly, or holoprosencephaly, can result in hydramnios due to impaired fetal swallowing. Fetal neuromuscular disorders such as myotonic dystrophy also may lead to excessive amniotic fluid. Obstruction of the fetal upper gastrointestinal tract—esophageal or duodenal atresia—is often associated with hydramnios. Fetal neuromuscular disorders such as myotonic dystrophy also may lead to excessive amniotic fluid. Obstruction of the fetal upper gastrointestinal tract—esophageal or duodenal atresia—is often associated with hydramnios. Other obstructive causes include clefts, micrognathia, congenital high-airway obstruction sequence, and fetal neck masses. Severe fetal thoracic abnormalities, such as diaphragmatic hernia, cystic adenomatoid malformation, and pulmonary sequestration, may be associated with hydramnios due to mediastinal shift and impaired swallowing, occasionally with development of hydrops. A common fetal renal anomaly, ureteropelvic junction obstruction, may at times result in paradoxical hydramnios. And although rare, tumors such as fetal sacrococcygeal teratoma, fetal mesoblastic nephroma, and large placental chorioangiomas are frequently accompanied by abnormally increased amniotic fluid volume.

The degree of hydramnios is associated with the likelihood of an anomalous infant (Many, 1995; Pri-Paz, 2012). For example, at Parkland Hospital, the prevalence of an anomalous infant was approximately 8 percent with mild hydramnios, 12 percent with moderate hydramnios, and more than 30 percent with severe hydramnios (Dashe, 2002). If no abnormality was detected with

^aA significant correlation was identified between severity of hydramnios and likelihood of an anomalous infant.
targeted sonography, the likelihood of a major anomaly identified at birth was 1 to 2 percent if the
hydramnios was mild or moderate but exceeded 10 percent if hydramnios was severe. Dorleijn
and associates (2009) have also reported an increased risk for abnormalities detected in the first
year of life with apparent idiopathic hydramnios. The anomaly risk is particularly high with
hydramnios coexistent with fetal-growth restriction (Lazebnik, 1999). If a fetal abnormality is
encountered concurrent with hydramnios, amniocentesis should be considered, because the
aneuploidy risk is significantly increased (Dashe, 2002; Pri-Paz, 2012).

Although amnionic fluid volume abnormalities are associated with fetal malformations, the
converse is not usually the case. In the Spanish Collaborative Study of Congenital Malformation
that included more than 27,000 anomalous infants, only 4 percent were complicated by
hydramnios, and another 3 percent with oligohydramnios (Martinez-Frias, 1999).

Multifetal Gestation

Hydramnios is generally defined in multifetal gestations as a single deepest amnionic fluid pocket
measuring 8 cm or more. It may be further characterized as moderate if the single deepest pocket is
at least 10 cm and severe if this pocket is at least 12 cm. In monochorionic pregnancies,
hydramnios of one sac and oligohydramnios of the other are diagnostic criteria for twin-twin
transfusion syndrome, which is discussed in Chapter 45 (p. 904). In a review of nearly 2000 twin
gestations, Hernandez and coworkers (2012) identified hydramnios in 18 percent of both
monochorionic and dichorionic pregnancies. As in singletons, severe hydramnios was more
strongly associated with fetal abnormalities. In the absence of an abnormality, pregnancy risks
were not generally increased compared with twins with normal amnionic fluid volume.

Idiopathic Hydramnios

When there is no obvious cause of hydramnios it is considered idiopathic. As shown in Table 11-
2, this accounts for up to 70 percent of cases (Golan, 1993; Many, 1995; Panting-Kemp, 1999).
Pregnancies with idiopathic hydramnios have been reported to have at least twice the likelihood of
infant birthweight exceeding 4000 g (Lazebnik, 1999; Magann, 2010; Maymon, 1998). A rationale
for this association is that larger infants have higher urine output, by virtue of their increased
volume of distribution, and fetal urine is the largest contributor to amnionic fluid volume. Mild,
idiopathic hydramnios is most commonly a benign finding, and associated pregnancy outcomes are
usually good.

Complications

Unless hydramnios is severe or develops rapidly, maternal symptoms are infrequent. With chronic
hydramnios, fluid accumulates gradually, and a woman may tolerate excessive abdominal
distention with relatively little discomfort. Acute hydramnios, however, tends to develop earlier in
pregnancy. It may result in preterm labor before 28 weeks or in symptoms that become so
debilitating as to necessitate intervention.

Symptoms may arise from pressure exerted within the overdistended uterus and upon adjacent
organs. When distention is excessive, the mother may suffer dyspnea and orthopnea to such a
degree that she may be able to breathe comfortably only when upright (see Fig. 11-2). Edema may
develop as a consequence of major venous system compression by the enlarged uterus, and it tends
to be most pronounced in the lower extremities, vulva, and abdominal wall. Rarely, oliguria may
result from ureteral obstruction by the enlarged uterus (Chap. 53, p. 1064). Maternal complications
such as these are typically associated with severe hydramnios from an underlying etiology.
Maternal complications associated with hydramnios include placental abruption, uterine dysfunction, and postpartum hemorrhage. Placental abruption is fortunately infrequent. It may result from the rapid decompression of an overdistended uterus that follows fetal-membrane rupture or therapeutic amnioreduction. With prematurely ruptured membranes, a placental abruption occasionally occurs days or weeks after amniorrhesis. Uterine dysfunction consequent to overdistention may lead to postpartum atony and, in turn, postpartum hemorrhage.

**Pregnancy Outcomes**

Some outcomes that have been reported to be increased with hydramnios include cesarean delivery rate, birthweight > 4000 g, and importantly, perinatal mortality rate. The cesarean delivery rate is increased approximately threefold when hydramnios has been identified, and the perinatal mortality rate rises approximately fourfold (Biggio, 1999; Hill, 1987; Maymon, 1998). Pri-Paz and colleagues (2012) found that pregnancies with severe hydramnios were at particular risk, but reported no perinatal deaths with *idiopathic* hydramnios.

Risks appear to be compounded when a growth-restricted fetus is identified with hydramnios. Erez and associates (2005) reported that this combination was independently associated with a 20-fold increase in the perinatal mortality rate. The combination also has a recognized association with trisomy 18 (Sickler, 1997).

Considering that uterine distention from hydramnios may result in uterine size approaching that of a term gestation, preterm delivery is a logical concern. Somewhat surprisingly, studies of *idiopathic* hydramnios have generally found no association with preterm birth (Magann, 2010; Many, 1995; Panting-Kemp, 1999). Conversely, severe hydramnios and hydramnios concurrent with recognized fetal abnormalities have been linked with preterm birth (Many, 1995; Pri-Paz, 2012).

**Management**

As noted previously, hydramnios etiologies are varied, and treatment is directed in most situations to the underlying cause. Occasionally, severe hydramnios may result in early preterm labor or the development of maternal respiratory compromise. In such cases, large-volume amniocentesis—termed *amnioreduction*—may be needed. The needle insertion technique is the same as for amniocentesis, described in Chapter 14 (p. 297). However, either an evacuated container bottle or a larger syringe is connected to the needle via sterile intravenous tubing with a stopcock. In general, approximately 1000 to 1500 mL of fluid is slowly withdrawn during approximately 30 minutes, depending on the severity of hydramnios and gestational age. The goal is to restore amnionic fluid volume to upper normal range (p. 232). Hydramnios severe enough to necessitate amnioreduction almost invariably has an underlying etiology, and subsequent amnioreduction procedures may be required as often as weekly or even semiweekly. Importantly, amnioreduction is typically performed later in gestation and carries additional risks of membrane rupture, preterm labor or its exacerbation, and placental abruption.

**OLIGOHYDRAMNIOS**

This is an abnormally decreased amount of amnionic fluid. Oligohydramnios complicates
approximately 1 to 2 percent of pregnancies (Casey, 2000; Petrozella, 2011). Unlike hydramnios, which is often mild and confers a benign prognosis in the absence of an underlying etiology, oligohydramnios is a cause for concern. When no measurable pocket of amniotic fluid is identified, the term \textit{anhydramnios} may be used.

\textit{The sonographic diagnosis of oligohydramnios is usually based on an AFI \leq 5 cm or on a single deepest pocket of amniotic fluid \leq 2 cm} (American College of Obstetricians and Gynecologists, 2012). The diagnosis also may be based on an AFI below the 5th or 2.5\textperthousand percentile determined by a gestational-age-specific nomogram. Or, it may be based on subjective assessment of decreased amniotic fluid volume. In the Moore nomogram, a threshold of 5 cm is below the 2.5\textperthousand percentile throughout the second and third trimesters (see Fig. 11-1). When evaluating twin pregnancies for twin-twin transfusion syndrome, a single deepest pocket \leq 2 cm is used to define oligohydramnios (Society for Maternal-Fetal Medicine, 2013).

In general, no one criterion is considered superior to the others. As discussed subsequently, however, use of AFI rather than single deepest pocket will identify more pregnancies as having oligohydramnios, albeit without evidence of pregnancy outcome improvement (Nabhan, 2010).

\section*{Etiology}

Pregnancies complicated by oligohydramnios include those in which the amniotic fluid volume has been severely decreased since the early second trimester and those in which the fluid volume was normal until near-term or even full-term. The prognosis depends heavily on the underlying etiology and is variable. Whenever oligohydramnios is diagnosed, it becomes an important consideration in management decisions.

\subsection*{Early-Onset Oligohydramnios}

When amniotic fluid volume is abnormally decreased from the early second trimester, it may reflect a fetal abnormality that precludes normal urination, or it may represent a placental abnormality severe enough to impair perfusion. In either circumstance, the prognosis is poor. Second-trimester rupture of the fetal membranes may result in oligohydramnios—and should be excluded. More commonly, membrane rupture presents with fluid leakage, vaginal bleeding, or uterine contractions. With early-onset oligohydramnios, targeted sonography should be offered to assess for fetal abnormalities.

\subsection*{Oligohydramnios after Midpregnancy}

When amniotic fluid volume becomes abnormally decreased in the late second or in the third trimester, it more likely is associated with fetal-growth restriction, a placental abnormality, or a maternal complication such as preeclampsia or vascular disease (Table 11-3). In such cases, the underlying etiology is often presumed to be uteroplacental insufficiency, which can impair fetal growth and reduce fetal urine output. Exposure to selected medications has also been linked with oligohydramnios as discussed subsequently. Investigation of third-trimester oligohydramnios generally includes evaluation for membrane rupture and sonography to assess growth. Umbilical artery Doppler studies may be performed if growth restriction is identified (Chap. 10, p. 219).

\begin{table}[h]

\textbf{Preterm Birth} & 20\% \\
\textbf{Induced Labor} & 80\% \\
\textbf{Cesarean Section} & 20\% \\
\hline
\end{tabular}
\end{table}
Oligohydramnios is commonly encountered in postterm pregnancies as discussed in Chapter 43 (p. 865). Magann and coworkers (1997) found that amniotic fluid volume decreased by approximately 8 percent per week beyond 40 weeks. In postterm pregnancies, oligohydramnios has been associated with nonreassuring fetal heart rate patterns and adverse pregnancy outcomes (Leveno, 1984).

### Congenital Anomalies

By approximately 18 weeks, the fetal kidneys are the main contributor to amniotic fluid volume. Among those with fetal abnormalities, most cases of severely decreased amniotic fluid volume beginning early in gestation are secondary to genitourinary anomalies. Anomalies of other organ systems, aneuploidy, and other genetic syndromes also have the potential to cause oligohydramnios indirectly, either from fetal decompensation, fetal-growth restriction, or an accompanying placental abnormality. Overall, approximately 3 percent of newborns with congenital anomalies have oligohydramnios found during prenatal sonography (Martinez-Frias, 1999).

Selected renal abnormalities that lead to absent fetal urine production include bilateral renal agenesis, bilateral multicystic dysplastic kidney, unilateral renal agenesis with contralateral multicystic dysplastic kidney, and the infantile form of autosomal recessive polycystic kidney disease. Urinary abnormalities may also result in oligohydramnios because of fetal bladder outlet obstruction. Examples of this are posterior urethral valves, urethral atresia or stenosis, or the megacystis microcolon intestinal hypoperistalsis syndrome. Complex fetal genitourinary abnormalities such as persistent cloaca and sirenomelia similarly may result in lack of amniotic fluid. These renal abnormalities are also discussed and depicted in Chapter 10 (p. 216).

If there is bilateral renal agenesis, no urine is produced, and the resulting anhydramnios leads to limb contractures, a distinctively compressed face, and death from pulmonary hypoplasia (Fig. 11-...
When this combination of abnormalities results from renal agenesis, it is called Potter syndrome, after Dr. Edith Potter, who described it in 1946. When this constellation stems from another etiology of decreased amniotic fluid volume, it is generally called Potter sequence.

![FIGURE 11-4](image.png) Normal-sized lungs (*top*) are shown in comparison with hypoplastic lungs (*bottom*) of fetuses at the same gestational age. (From Newbould, 1994, with permission.)

If no amniotic fluid is visible beyond the mid-second trimester due to a genitourinary etiology, the prognosis is extremely poor unless fetal therapy is an option. Fetuses with bladder-outlet obstruction may be candidates for vesicoamnionic shunt placement (*Chap. 16, p. 330*).

**Medication**

Oligohydramnios has been associated with exposure to drugs that block the renin-angiotensin system. These include angiotensin-converting enzyme (ACE) inhibitors and nonsteroidal antiinflammatory drugs (NSAIDs). When taken in the second or third trimester, ACE inhibitors and angiotensin-receptor blockers may create fetal hypotension, renal hypoperfusion, and renal ischemia, with subsequent anuric renal failure (Guron, 2000; Pryde, 1993). These adverse outcomes appear to be more prevalent following exposure to angiotensin-receptor blockers, but both medication types are contraindicated in pregnancy (Bullo, 2012). NSAIDs have been associated with fetal ductus arteriosus constriction and with decreased fetal urine production. In
Pregnancy Outcomes

Oligohydramnios is associated with increased risk of adverse pregnancy outcomes. Casey and colleagues (2000) found that an AFI ≤ 5 cm complicated 2 percent of pregnancies undergoing sonography at Parkland Hospital after 34 weeks. Newborns from pregnancies with oligohydramnios were more likely than those with AFIs > 5 cm to have malformations. Even in the absence of malformations, higher rates of fetal stillbirth, growth restriction, nonreassuring heart rate pattern, and meconium aspiration syndrome were noted. Petrozella and associates (2011) similarly reported that with an AFI ≤ 5 cm identified between 24 and 34 weeks, there was increased risk for stillbirth, spontaneous or medically indicated preterm birth, heart rate pattern abnormalities, and growth restriction (see Table 11-3). In a metanalysis of 18 studies comprising more than 10,000 pregnancies, Chauhan and coworkers (1999) found that women with oligohydramnios had a twofold increased risk for cesarean delivery for fetal distress and a fivefold risk for an Apgar score < 7 at 5 minutes compared with pregnancies with normal AFI.

As noted earlier, there is evidence that if oligohydramnios is defined as an AFI ≤ 5 cm rather than a single deepest pocket ≤ 2 cm, more pregnancies will be classified as having oligohydramnios. However, this increased diagnostic frequency is not associated with improved pregnancy outcomes. Nabhan and Abdelmoula (2008) reviewed five randomized controlled trials involving more than 3200 pregnancies in which outcomes were compared according to which definition was used. The trials included both high-risk and low-risk pregnancies. There was no difference in the rates of cesarean delivery, neonatal intensive care unit admission, umbilical artery pH < 7.1, or Apgar score < 7 at 5 minutes. Using AFI criteria, however, twice as many pregnancies were diagnosed with oligohydramnios, along with a doubling of the labor induction rate, and a 50-percent increase in the cesarean delivery rate for fetal distress.

Pulmonary Hypoplasia

When decreased amnionic fluid is first identified before the mid-second trimester, particularly before 20 to 22 weeks, pulmonary hypoplasia is a significant concern. The underlying etiology is a major factor in the prognosis for such pregnancies. Severe oligohydramnios secondary to a renal abnormality generally has a lethal prognosis (see Fig. 11-4). If a placental hematoma or chronic abruption is severe enough to result in oligohydramnios—the chronic abruption-oligohydramnios sequence—it commonly also causes growth restriction (Chap. 41, p. 794). The prognosis for this constellation is similarly poor. Oligohydramnios that results from membrane rupture in the second trimester is reviewed in Chapter 42 (p. 848).

Management

As with hydramnios, management targets the underlying etiology when feasible. Initially, an evaluation for fetal anomalies and growth is essential. In a pregnancy complicated by oligohydramnios and fetal-growth restriction, close fetal surveillance is important because of associated morbidity and mortality. In many cases, evidence for fetal or maternal compromise will override potential complications from preterm delivery. But, oligohydramnios detected before 36 weeks in the presence of normal fetal anatomy and growth may be managed expectantly in
conjunction with increased fetal surveillance.

Amnioinfusion, as discussed in Chapter 24 (p. 494), may be used intrapartum in the setting of variable fetal heart rate decelerations. It is not considered treatment for oligohydramnios per se, although the decelerations are presumed secondary to umbilical cord compression resulting from lack of amnionic fluid. Amnioinfusion is not the standard of care for other etiologies of oligohydramnios and is not generally recommended.

“Borderline” Oligohydramnios

The term *borderline AFI* or *borderline oligohydramnios* is somewhat controversial. It usually refers to AFIs between 5 and 8 cm (Baron, 1995; Magann, 2011; Petrozella, 2011). Through the mid-third trimester, an AFI value of 8 cm is below the 5th percentile on the Moore nomogram (see Fig. 11-1). Petrozella and colleagues (2011) found that pregnancies between 24 and 34 weeks with an AFI between 5 and 8 cm were not more likely than those with an AFI above 8 cm to be complicated by maternal hypertension, stillbirth, or neonatal death. However, higher rates of preterm delivery, cesarean delivery for a nonreassuring fetal heart rate pattern, and fetal-growth restriction were found. Study results evaluating pregnancy outcomes with borderline AFI have been mixed. A recent review by Magann and associates (2011) concludes that there is insufficient evidence to support fetal testing or delivery in this setting.

Birth defects are common—2 to 3 percent of all newborns have a major congenital abnormality detectable at birth (Cragan, 2009; Dolk, 2010). By age 5, another 3 percent have been diagnosed with a malformation, and by age 18, another 8 to 10 percent have one or more apparent functional or developmental abnormalities. Importantly, nearly 70 percent of birth defects do not have an obvious etiology, and of those with an identified cause, it is far more likely to be genetic than teratogenic (Schardein, 2000; Wlodarczyk, 2011). The Food and Drug Administration (FDA) (2005b) estimates that less than 1 percent of all birth defects are caused by medications. Examples of medications considered teratogenic are shown in Table 12-1.

Although only a relatively small number of medications have proven harmful effects, there is significant concern surrounding medication use in pregnancy. This is because most pregnant women take medications and for most medications, available safety data are limited. In a review of more than 150,000 pregnancies, 40 percent of women were prescribed a medication other than multivitamins in the first trimester (Andrade, 2004). More recently, data from the National Birth Defects Prevention Study showed that women use an average of 2 to 3 medications per pregnancy and that 70 percent take medication in the first trimester (Mitchell, 2011).

Despite improvements in safety information, data are particularly limited for newer medications. For example, in a review of medications approved by the FDA between 2000 and 2010, the Teratogen Information System (TERIS) expert advisory board deemed the pregnancy risk “undetermined” for more than 95 percent (Adam, 2011).
The study of birth defects and their etiology is termed teratology. The word teratogen is derived from the Greek *teratos*, meaning monster. Pragmatically, a teratogen may be defined as any agent that acts during embryonic or fetal development to produce a permanent alteration of form or function. Thus, a teratogen may be a drug or other chemical substance, a physical or environmental factor such as heat or radiation, a maternal metabolite such as in phenylketonuria or diabetes, a genetic abnormality, or an infection. Tightly defined, a teratogen causes structural abnormalities, whereas a hadegen—after the god Hades—is an agent that interferes with normal maturation and function of an organ. A trophogen is an agent that alters growth. Substances in the latter two groups typically affect development in the fetal period or after birth, when exposures are often more difficult to document. In most circumstances, teratogen is used to refer to all three types of agents.

**Studies in Pregnant Women**

The study of medication safety—or teratogenicity—in pregnant women is fraught with complications. Animal studies are considered necessary but insufficient, which is a lesson learned from the safety of thalidomide in several animal species. Rarely are medications approved by the FDA with the specific indication for their use being pregnancy. Between 1996 and 2011, for example, the only medication approved specifically for pregnancy was hydroxyprogesterone caproate for recurrent preterm birth prevention.

Pregnant women are generally considered a special population and excluded from trials. An obvious reason is to protect the embryo and fetus from potentially harmful effects of a medication—its pharmacodynamic effect(s) on the body. Another reason is that pregnancy physiology affects the medication—its pharmacokinetics. Specifically, changes in volume of distribution, cardiac output, gastrointestinal absorption, hepatic metabolism, and renal clearance may each affect drug concentration and thus embryo-fetal exposure (Chap. 4, p. 51).

**Case Reports and Series**

Several major teratogens were first described by astute clinicians. Congenital rubella syndrome was identified in this way by Gregg (1941), an Australian ophthalmologist whose observations challenged the view that the uterine environment was impervious to noxious agents. Other teratogens identified through case series include thalidomide and alcohol (Jones, 1973; Lenz, 1962). Unfortunately, teratogens are less likely to come to attention through identification of clinical cases if the exposure is uncommon, if the defects are relatively nonspecific, or if abnormalities occur in only a small proportion of exposed infants. A major limitation of case series is that they lack a control group.

**Pregnancy Registries**

Potentially harmful agents may be monitored by clinicians who prospectively enroll exposed pregnancies in a registry. The FDA maintains a list of ongoing pregnancy registries on their website: [www.fda.gov](http://www.fda.gov). Included are medication groups used to treat asthma, autoimmune disease, cancer, epilepsy, human immunodeficiency virus (HIV) infection, and transplant rejection. Similar to case series, exposure registries are limited by lack of a control group. To compare the prevalence of an abnormality identified among exposed infants with that expected in the general population, investigators use a birth defect registry. One example is the Metropolitan Atlanta
Congenital Defects Program, which is an active surveillance program ongoing since 1967 for fetuses and infants with birth defects.

Case-Control Studies
In these studies, investigators retrospectively assess prenatal exposure to particular substances between affected infants and controls. Birth defect registries are ideal for ascertainment of cases. However, case-control studies have two inherent weaknesses. First, there is potential for recall bias, in which the mother of an affected infant may be more likely to recall exposure. Second, case-control studies can only evaluate associations, rather than causality, and are thus hypothesis-generating. For these reasons, Grimes and Schulz (2012) caution that unless odds ratios in case-control studies are above three- to fourfold, then observed findings may be incorrect.

The National Birth Defects Prevention Study. This population-based case-control study involves 10 states with active birth defects surveillance programs (www.nbdps.org). It represents an important collaborative effort by the Centers for Birth Defects Research and Prevention to evaluate medications as a cause of birth defects. Since 1997, each center has annually enrolled 300 or more cases—including live births, stillbirths, and terminated pregnancies that have one or more of 30 structural birth defects, along with 100 randomly selected controls. Clinical geneticists review each potential case, and standardized telephone interviews are conducted 6 weeks and 24 months after delivery to obtain information regarding medication exposure and medical risk factors (Mitchell, 2011). This large volume has considerable statistical power and permits identification of relatively small associations.

As of 2012, the National Birth Defects Prevention Study (NBDPS) had identified associations between individual birth defects and the following classes of medications: sulfonamides and nitrofurantoin, asthma medications, antiemetics, nonsteroidal antiinflammatory drugs, and opioids (Broussard, 2011; Crider, 2009; Hernandez, 2012; Lin, 2012; Munsie, 2011). For each, the authors discussed the possibility that the observed associations may have been due to chance alone or that the underlying medical disorder for which the drug was given may have caused the abnormality. Based on the degree of risk identified, if any of these medications is eventually deemed teratogenic, it would be considered a low-risk teratogen, as subsequently discussed. Thus, the American College of Obstetricians and Gynecologists (2013b) considers nitrofurantoin and sulfonamides appropriate for first-trimester use if no suitable alternative is available, and they remain the first-line agents for treatment and prevention of urinary infections beyond the first trimester (Chap. 53, p. 1052).

CRITERIA FOR DETERMINING TERATOGENICITY

The guidelines shown in Table 12-2, which were proposed by Shepard (1994) as a framework for discussion, have proven useful for more than 20 years. Although all criteria may not be required to establish teratogenicity, the following tenets must be considered (Shepard, 2002a):

- The defect has been completely characterized. This is preferably done by a geneticist or dysmorphologist because various genetic and environmental factors may produce similar anomalies. It is easiest to prove causation when a rare exposure produces a rare defect, when at least three cases with the same exposure have been identified, and when the defect is severe.
- The agent must cross the placenta. Although almost all drugs cross the placenta, transport must be
of sufficient quantity to directly influence embryonic or fetal development or to alter maternal or placental metabolism to exert an indirect effect. Placental transfer depends on maternal metabolism; on specific characteristics of the drug, such as protein binding and storage, molecular size, electrical charge, and lipid solubility; and on placental metabolism such as the cytochrome P<sub>450</sub> enzyme systems. In early pregnancy, the placenta also has a relatively thick membrane that slows diffusion.

- Exposure must occur during a critical developmental period:
  1. The preimplantation period is the 2 weeks from fertilization to implantation and is known as the “all or none” period. As the zygote undergoes cleavage, an insult damaging a large number of cells typically causes embryonic death. However, if only a few cells are injured, compensation may be possible, with normal development (Clayton-Smith, 1996). Based on animal data, insults that appreciably diminish the cell number in the inner cell mass may produce a dose-dependent diminution in body length or size (Iahnaccone, 1987).
  2. The embryonic period is from the second through the eighth week. It encompasses organogenesis and is thus the most crucial period with regard to structural malformations. Critical developmental periods for each organ system are illustrated in Figure 12-1.
  3. The fetal period, which is beyond 8 weeks, is characterized by continued maturation and functional development, and during this time, certain organs remain vulnerable. For example, brain development remains susceptible to environmental influences such as alcohol exposure throughout pregnancy.
- A biologically plausible association is supportive. Because birth defects and medication exposures are both common, they may be temporally but not causally related.
- Epidemiological findings must be consistent. Because initial evaluation of teratogen exposure is often retrospective, it may be hampered by recall bias, inadequate reporting, and incomplete assessment of the exposed population. Potential confounding factors include varying dosages, concomitant drug therapy, and maternal disease(s). Familial and environmental factors can also influence development of birth defects. Thus, an important criterion for teratogenicity is that two or more high-quality epidemiological studies report similar findings. Finally, a relative risk of 3.0 or greater is generally considered necessary to support the hypothesis, whereas a lesser risk is interpreted with caution (Khouri, 1992).
- The suspected teratogen causes a defect in animal studies. Human teratogenicity is more likely if an agent produces an adverse effect in different animal species. However, a major lesson was learned from the thalidomide tragedy in that its teratogenicity was not recognized because of reliance on animal data, in which thalidomide produced no defects in several animal species. Not until thousands of infants were affected by thalidomide embryopathy was it realized that this agent was a potent human teratogen.

### TABLE 12-2. Criteria for Determining Teratogenicity

<table>
<thead>
<tr>
<th>Essential Criteria:</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Careful delineation of clinical cases, particularly if there is a specific defect or syndrome</td>
</tr>
<tr>
<td>2. Proof that exposure occurred at critical time during development (see Fig. 12-1)</td>
</tr>
<tr>
<td>3. Consistent findings by at least two epidemiological studies with:</td>
</tr>
<tr>
<td>a. exclusion of bias,</td>
</tr>
<tr>
<td>b. adjustment for confounding variables,</td>
</tr>
</tbody>
</table>
c. adequate sample size (power),
d. prospective ascertainment if possible, and
e. relative risk (RR) of 3.0 or greater, some recommend RR of 6.0 or greater

or

For a rare environmental exposure associated with a rare defect, at least three reported cases. This is easiest if defect is severe

Ancillary Criteria:
4. The association is biologically plausible
5. Teratogenicity in experimental animals is important but not essential
6. The agent acts in an unaltered form in an experimental model

FIGURE 12-1 Timing of organogenesis during the embryonic period. (Redrawn from Sadler, 1990, with permission.)
Failure to employ these tenets and criteria has contributed to erroneous conclusions regarding the safety of some widely used drugs. The poster child for this is the medicolegal fiasco surrounding Bendectin. This antiemetic was a combination of doxylamine and pyridoxine that was both safe and effective for nausea and vomiting common in early pregnancy. More than 30 million women used this drug worldwide, and the 3-percent congenital anomaly rate among exposed fetuses was not different from the background rate (McKeigue, 1994). Despite evidence that the drug was not teratogenic, Bendectin was the target of numerous lawsuits, and the financial burden of defending these forced its withdrawal. As a consequence, hospitalizations for hyperemesis doubled (Koren, 1998). Ironically, the combination of doxylamine and pyridoxine has now been recently remarkeeted under the brand name Diclegis, which was FDA approved in 2013.

COUNSELING FOR TERATOGEN EXPOSURE

Questions regarding medication and illicit drug use should be part of routine preconceptional and prenatal care. Women who request counseling for prenatal drug exposure often have misinformation regarding their level of risk. Not uncommonly, they may underestimate the background risk for birth defects in the general population and exaggerate the potential risks associated with medication exposure. Koren and colleagues (1989) reported that a fourth of women exposed to nonteratogenic drugs thought they had a 25-percent risk for fetal anomalies. Misinformation may be amplified by inaccurate reports in the lay press. Knowledgeable counseling may allay anxiety considerably and in some situations may even avoid pregnancy termination.

The Food and Drug Administration Classification System

This system for evaluating drug safety in pregnancy was developed in 1979. It was designed to provide therapeutic guidance by using five categories—A, B, C, D, or X, shown in Table 12-3, to simplify risk-benefit information. In its present form, the system has important limitations, and these have been acknowledged by the FDA. One is that drugs in categories D and X, and some in category C, may pose similar risks but are in different categories because of different risk-benefit considerations. A higher letter grade does not necessarily confer an increased risk, and even drugs in the same category may have very different risks! And, despite the understanding that medications may affect human and animal development differently, the letter category is often based on animal data.

<table>
<thead>
<tr>
<th>TABLE 12-3. Food and Drug Administration Categories for Drugs and Medications</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Category A:</strong> Studies in pregnant women have not shown an increased risk for fetal abnormalities if administered during the first (second, third, or all) trimester(s) of pregnancy, and the possibility of fetal harm appears remote. Fewer than 1 percent of all medications are in this category. Examples include levothyroxine, potassium supplementation, and prenatal vitamins, when taken at recommended doses.</td>
</tr>
<tr>
<td><strong>Category B:</strong> Animal reproduction studies have been performed and have revealed no evidence of impaired fertility or harm to the fetus. Prescribing information should specify</td>
</tr>
<tr>
<td><strong>Category C:</strong> Animal reproduction studies have been performed, but there is inadequate evidence of no risk in humans or animals. Animal reproduction studies have shown an increased risk in animals but not in humans.</td>
</tr>
<tr>
<td><strong>Category D:</strong> Animal reproduction studies have shown an increased risk in animals or humans. The drug is not recommended for use during pregnancy unless clearly needed.</td>
</tr>
<tr>
<td><strong>Category X:</strong> Animal reproduction studies have shown an increased risk in humans and animals. The drug is contraindicated in pregnancy.</td>
</tr>
<tr>
<td><strong>Category:</strong></td>
</tr>
</tbody>
</table>
Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus during the first trimester of pregnancy, and there is no evidence of a risk in later trimesters. Examples include many antibiotics, such as penicillins, most cephalosporins, and macrolides.

**Category C:** Animal reproduction studies have shown that this medication is teratogenic (or embryocidal or has other adverse effect), and there are no adequate and well-controlled studies in pregnant women. Prescribing information should specify kind of animal and how dose compares with human dose.

There are no animal reproduction studies and no adequate and well-controlled studies in humans.

Approximately two thirds of all medications are in this category. It contains medications commonly used to treat potentially life-threatening medical conditions, such as albuterol, zidovudine, and calcium-channel blockers.

**Category D:** This medication can cause fetal harm when administered to a pregnant woman. If this drug is used during pregnancy or if a woman becomes pregnant while taking this medication, she should be apprised of the potential hazard to the fetus.

This category also contains medications used to treat potentially life-threatening medical conditions, for example: corticosteroids, azathioprine, carbamazepine, and lithium.

**Category X:** This medication is contraindicated in women who are or may become pregnant. It may cause fetal harm. If this drug is used during pregnancy or if a woman becomes pregnant while taking this medication, she should be apprised of the potential hazard to the fetus.

There are a few medications in this category that have never been shown to cause fetal harm but should be avoided nonetheless, such as the rubella vaccine.

From the foregoing, it follows that it may be insufficient or even inappropriate to rely on this classification to make complex therapeutic decisions in pregnant women. Rather than simplifying counseling, the letter classification shifts responsibility to the clinician, who must interpret category information in the context of medication dosage, route and timing of exposure, other medications used, and underlying medical condition(s).

Because of the limitations of its current classification, the FDA (2011b) has proposed a new system for labeling drugs for use by pregnant and lactating women. Letter categories A through X are to be replaced with: (1) a fetal risk summary, (2) a section on clinical considerations—including inadvertent exposure, (3) a section on prescribing decisions for pregnant and lactating women, and (4) a detailed discussion of human and animal data. It is anticipated that this evidence-based rating system may soon become available (Gee, 2014).

The FDA has also expanded the information available on its website: www.fda.gov. The website includes updated, detailed information regarding potentially harmful medications—in the
form of drug advisories, registries, and product information. It is an excellent resource for counseling. Current, accurate information is also available through online reproductive toxicity services such as Reprotox and TERIS.

### Presenting Risk Information

In addition to potential embryonic and fetal risks from drug exposure, counseling should include a discussion of the risks and/or genetic implications of the underlying condition for which the drug is given, as well as risks associated with not treating the condition. Even the manner in which information is presented affects perception. Jasper and associates (2001) found that women given negative information—such as a 2-percent chance of a malformed infant—are more likely to perceive an exaggerated risk than women given positive information—such as a 98-percent chance of a child without a malformation. Instead of citing an increased odds ratio, it may be helpful to provide the absolute risk for a particular defect or the attributable risk, which is the difference between prevalence in exposed and unexposed individuals (Conover, 2011). The association between oral corticosteroid medications and cleft lip sounds far more concerning when presented as a tripling or 200-percent increase in risk than when presented as an increase from 1 per 1000 to 3 per 1000, or a 99.7-percent likelihood of not developing a cleft following exposure.

With a few notable exceptions, most commonly prescribed drugs and medications can be used with relative safety during pregnancy. All women have an approximate 3-percent chance of having an infant with a birth defect. Although exposure to a confirmed teratogen may increase this risk, the magnitude of the increase is usually only 1 or 2 percent or at most, doubled or tripled. The concept of risk versus benefit is often central to counseling. Some untreated diseases pose a more serious threat to both mother and fetus than medication exposure risks.

There undoubtedly are a number of major teratogens. However, many drugs described in this chapter are low-risk teratogens, which are medications that produce defects in fewer than 10 per 1000 maternal exposures (Shepard, 2002a). Some examples include corticosteroids, lithium, trimethoprim, and methimazole. Because risks conferred by low-risk teratogens are so close to background, they may not be a major factor in deciding whether to discontinue treatment for an important condition (Shepard, 2002b). Obviously, clinicians and patients must carefully weigh risks and benefits in these instances.

### GENETIC AND PHYSIOLOGICAL SUSCEPTIBILITY TO TERATOGENS

Teratogens act by disturbing specific physiological processes, which may in turn lead to abnormal cellular differentiation, altered tissue growth, or cell death. Because pathophysiological processes may be induced in various cell types and tissues, exposure may result in multiple effects, and because different teratogens may disturb similar processes, they may produce similar phenotypic abnormalities. But even the most potent teratogen induces birth defects in only a fraction of exposed embryos. Despite the numerous factors that influence exposure, teratogens appear merely to have potential to cause birth defects. The reasons why some infants are affected and others are not remains largely unknown.

### Fetal Genome
In some cases, genetic composition has been linked to susceptibility to teratogenic effects of specific medications. For example, fetuses exposed to hydantoin are more likely to develop anomalies if homozygous for a gene mutation that results in abnormally low levels of epoxide hydrolase (Buehler, 1990). If activity of epoxide hydrolase enzyme is reduced, then hydantoin, carbamazepine, and phenobarbital are metabolized by microsomes to oxidative intermediates that accumulate in fetal tissues (Horning, 1974). These free oxide radicals have carcinogenic, mutagenic, and other toxic effects that are dose related and increase with multidrug therapy (Buehler, 1990; Lindhout, 1984).

**Disruption of Folic Acid Metabolism**

Fetal neural-tube defects, cardiac defects, and oral clefts can be a result of folic acid metabolic pathway disturbances. Folates are essential for methionine production, which is required for gene methylation and thus production of proteins, lipids, and myelin. Some anticonvulsants—phenytoin, carbamazepine, valproic acid, and phenobarbital—either impair folic acid absorption or act as folic acid antagonists. The resultant low periconceptional folic acid levels in some women with epilepsy may then cause fetal malformations (Dansky, 1987; Hiilesmaa, 1983). In one study of more than 5000 infants with birth defects, exposure to these folic acid antagonists was associated with a two- to threefold increased risk for oral clefts and cardiac abnormalities (Hernandez-Diaz, 2000).

Some congenital heart defects are related to interactions between folate-related genes and environmental or genetic factors. In a case-control study with more than 500 infants with a cardiac defect, maternal polymorphisms in three folate-related genes were found to increase the risk for cardiac anomalies when combined with maternal cigarette smoking, alcohol consumption, or obesity (Hobbs, 2010). Data from the National Down Syndrome Project demonstrated that trisomy 21 fetuses born to women not given periconceptional folic acid supplementation may be more likely to have endocardial cushion defects (Bean, 2011).

**Paternal Exposures**

In some cases, paternal exposures to drugs or environmental influences may increase the risk of adverse fetal outcome. Proposed mechanisms include induction of a gene mutation or chromosomal abnormality in sperm. Because of the 64 days in which male germ cells mature into functional spermatogonia, drug exposure during the 2 months before conception could cause gene mutations. It may be that epigenetic pathways suppress germ-cell apoptosis or interfere with imprinting (Cordier, 2008). Another possibility is that during intercourse the developing embryo is exposed to a teratogenic agent in seminal fluid.

There is some evidence to support these hypotheses. For example, ethyl alcohol, cyclophosphamide, lead, and certain opiates have been associated with an increased risk of behavioral defects in the offspring of exposed male rodents (Nelson, 1996). In humans, paternal environmental exposure to mercury, lead, solvents, pesticides, anesthetic gases, or hydrocarbons may be associated with early pregnancy loss (Savitz, 1994). In a 20-year study of Swedish university employees, paternal exposure to carcinogenic solvents resulted in offspring with more than a fourfold increase in neural-crest malformations (Magnusson, 2004). Other occupations associated with an increased risk for men to have anomalous offspring include janitors, woodworkers, firemen, printers, and painters (Olshan, 1991; Schnitzer, 1995). Risk attribution is limited because assessment of paternal exposure is often imprecise, and there is potential for
The number of medications and other substances strongly suspected or proven to be human teratogens is small, as shown in Table 12-1. With few exceptions, in every clinical situation potentially requiring therapy with a known teratogen, alternative drugs can be given with relative safety. As a general rule, because there are no adequate and well-controlled studies in pregnant women for most medications, and because animal reproduction studies are not always predictive of human response, any medication in pregnancy must be carefully considered and only used if clearly needed.

**Alcohol**

Ethyl alcohol is a potent and prevalent teratogen. Alcohol is one of the most frequent nongenetic causes of mental retardation as well as the leading cause of preventable birth defects in the United States. According to the Centers for Disease Control and Prevention (CDC)(2012), 8 percent of women report drinking alcohol during pregnancy, and the NBDPS identified a prevalence as high as 30 percent (Ethen, 2009). Between 1 and 2 percent of pregnant women admit to binge drinking.

The fetal effects of alcohol abuse have been recognized since the 1800s. Lemoine (1968) and Jones (1973) and their coworkers are credited with describing the spectrum of alcohol-related fetal defects known as *fetal alcohol syndrome* (Table 12-4). The Institute of Medicine (1996) has estimated that prevalence of the syndrome ranges from 0.6 to 3 per 1000 births.

**TABLE 12-4. Fetal Alcohol Syndrome and Alcohol-Related Birth Defects**

**Fetal Alcohol Syndrome Diagnostic Criteria—all required**

1. Dysmorphic facial features (all 3 are required)
   a. Small palpebral fissures
   b. Thin vermilion border
   c. Smooth philtrum
2. Prenatal and/or postnatal growth impairment
3. Central nervous system abnormalities (1 required)
   a. Structural: head size < 10th percentile, significant brain abnormality on imaging
   b. Neurological
   c. Functional: global cognitive or intellectual deficits, functional deficits in at least three domains

**Alcohol-Related Birth Defects**

1. Cardiac: atrial or ventricular septal defect, aberrant great vessels, conotruncal heart defects
2. Skeletal: radioulnar synostosis, vertebral segmentation defects, joint contractures, scoliosis
3. Renal: aplastic or hypoplastic kidneys, dysplastic kidneys, horseshoe kidney, ureteral duplication
4. Eyes: strabismus, ptosis, retinal vascular abnormalities, optic nerve hypoplasia
5. Ears: conductive or neurosensory hearing loss
6. Minor: hypoplastic nails, clinodactyly, pectus carinatum or excavatum, camptodactyly, “hockey stick” palmar creases, refractive errors, “railroad track” ears

Modified from Bertrand, 2005; Hoyme, 2005.

For every child with fetal alcohol syndrome, many more are born with neurobehavioral deficits from alcohol exposure (American College of Obstetricians and Gynecologist, 2013a). *Fetal alcohol spectrum disorder* is an umbrella term that includes the full range of prenatal alcohol damage that may not meet the criteria for fetal alcohol syndrome. Prevalence of this disorder is estimated to be as high as 1 percent of births in the United States (Centers for Disease Control 2012; Guerri, 2009).

**Clinical Characteristics**

Fetal alcohol syndrome has specific criteria, listed in Table 12-4, and which include dysmorphic facial features, pre- or postnatal growth impairment, and central nervous system abnormalities that may be structural, neurological, or functional (Bertrand, 2005). The distinctive facial features are shown in Figure 12-2. Other alcohol-related major and minor birth defects include cardiac and renal anomalies, orthopedic problems, and abnormalities of the eyes and ears. An association has also been reported between periconceptional alcohol use and omphalocele and gastroschisis (Richardson, 2011). There are no established criteria for prenatal diagnosis of fetal alcohol syndrome, although in some cases, major abnormalities or growth restriction may be suggestive (Paintner, 2012).

**FIGURE 12-2** Fetal alcohol syndrome. **A.** At 2½ years. **B.** At 12 years. Note persistence of short palpebral fissures, epicanthal folds, flat midface, hypoplastic philtrum, and thin upper vermilion border. (From Streissguth, 1985, with permission.)
Dose Effect
Fetal vulnerability to alcohol is modified by genetic factors, nutritional status, environmental factors, coexisting maternal disease, and maternal age (Abel, 1995). The minimum amount of alcohol required to produce adverse fetal consequences is unknown. Binge drinking, however, is believed to pose particularly high risk for alcohol-related birth defects and has also been linked to an increased risk for stillbirth (Centers for Disease Control, 2012; Maier, 2001; Strandberg-Larsen, 2008).

Anticonvulsant Medications
Pragmatically, no anticonvulsant drugs are considered truly “safe” in pregnancy. This is because most medications used to treat epilepsy have been proven or suspected to confer an increased risk for fetal malformations. The North American Antiepileptic Drug (NAAED) Pregnancy Registry was established to improve counseling information. Providers are encouraged to enroll pregnant women treated with antiepileptic medication through the FDA website or 1–888–233–2334.

Management of epilepsy in pregnancy, including risks associated with individual anticonvulsants, is discussed in Chapter 60 (p. 1190). Traditionally, women with epilepsy were informed that their risk for fetal malformations was increased two- to threefold. More recent data suggest that the risk may not be as great as once thought, particularly for newer agents. In a recent population-based study involving more than 800,000 pregnancies, exposure to newer anticonvulsants was associated with a 3-percent major malformation risk, compared with a 2-percent risk in unexposed fetuses (Molgaard-Nielsen, 2011). Similarly, the United Kingdom Epilepsy and Pregnancy Registry reported a 3-percent risk for major malformations in pregnancies treated with a single anticonvulsant—monotherapy. This is the same malformation rate as for those with untreated epilepsy (Morrow, 2006). There is one important exception to these findings. Women treated with valproic acid are at significantly increased risk for malformations as subsequently discussed.

The most frequently reported anomalies are orofacial clefts, cardiac malformations, and neural-tube defects (Food and Drug Administration, 2009). Several older anticonvulsants produce a constellation of malformations similar to the fetal hydantoin syndrome (Fig. 12-3). Of agents in current use, valproic acid confers the greatest risk. The NAAED Pregnancy Registry reported that major malformations occurred in 9 percent of fetuses with first-trimester valproate exposure and included a 4-percent risk for neural-tube defects (Hernandez-Diaz, 2012). Moreover, children with in utero exposure to valproic acid are reported to have significantly lower intelligence quotient (IQ) scores at age 3 years compared with scores of those exposed to phenytoin, carbamazepine, or lamotrigine (Meador, 2009). Of the newer agents, topiramate has recently been reported by the NAAED Pregnancy Registry and the NBDPS to confer a risk for orofacial clefts at least fivefold higher than in unexposed pregnancies (Food and Drug Administration, 2011c; Margulis, 2012). Regardless of the anticonvulsant medication used, specialized sonography should be considered.
**Angiotensin-Converting Enzyme Inhibitors and Angiotensin-Receptor Blocking Drugs**

Angiotensin-converting enzyme (ACE) inhibitors are considered fetotoxic and result in ACE inhibitor fetopathy. Normal renal development depends on the fetal renal-angiotensin system. ACE-inhibitor medication causes fetal hypotension and renal hypoperfusion, with subsequent ischemia and anuria (Guron, 2000; Pryde, 1993). Reduced perfusion may cause fetal-growth restriction and calvarium maldevelopment, whereas oligohydramnios may result in pulmonary hypoplasia and limb contractures (Barr, 1991). Because angiotensin-receptor blockers have a
similar mechanism of action, concerns regarding fetotoxicity have been generalized to include this entire medication class.

The possible embryotoxicity of these two drug classes is less certain. Cooper and colleagues (2006) reported that first-trimester ACE-inhibitor exposure was associated with a two- to threefold increased risk for cardiac and central nervous system abnormalities, but these observations have not been corroborated. It is reasonable to offer specialized sonography for pregnancies with first-trimester exposure. Given the many therapeutic options for treating hypertension during pregnancy, discussed in Chapter 50 (p. 1006), it is recommended that ACE inhibitors and angiotensin receptor-blocking drugs be avoided.

### Antifungal Medications

From this class of drugs, fluconazole has been associated with a pattern of congenital malformations resembling the autosomal recessive Antley-Bixler syndrome. Abnormalities include oral clefts, abnormal facies, and cardiac, skull, long-bone, and joint abnormalities. Such findings have been reported only with chronic, high-dose treatment in the first trimester—at doses of 400 to 800 mg daily. In a recent population-based cohort of more than 7000 pregnancies with first-trimester exposure to low-dose fluconazole, a threefold increased risk for tetralogy of Fallot was identified (Molgaard-Nielsen, 2013). However, risks for other birth defects were not increased. The FDA (2011e) lists fluconazole as pregnancy category D, but it states that a single 150-mg dose to treat vulvovaginal candidiasis does not appear to be teratogenic.

### Antiinflammatory Agents

#### Nonsteroidal Antiinflammatory Drugs

This drug class includes both aspirin and traditional “NSAIDs” such as ibuprofen and indomethacin. They exert their effects by inhibiting prostaglandin synthesis. At least 20 percent of pregnant women report use of these drugs in the first trimester. But, based on data from the NBDPS, such exposure does not appear to be a major risk factor for birth defects (Hernandez, 2012). Aspirin is not considered to increase the overall risk for congenital malformations (Kozer, 2002). Low-dose aspirin, 100 mg daily or lower, does not confer an increased risk for constriction of the ductus arteriosus or for adverse infant outcomes (Di Sessa, 1994; Grab, 2000). As with other NSAIDs, however, high-dose aspirin use should be avoided, particularly in the third trimester.

Importantly, NSAIDs may cause adverse fetal effects when taken in late pregnancy (Parilla, 2004; Rebordosa, 2008). Indomethacin may cause constriction of the fetal ductus arteriosus, resulting in pulmonary hypertension. The drug may also decrease fetal urine production and thereby reduce amniotic fluid volume. This is presumed due to an increase in vasopressin levels and vasopressin responsiveness (Rasanen, 1995; van der Heijden, 1994; Walker, 1994). Fetal ductal constriction is more likely when the drug is taken in the third trimester for longer than 72 hours’ duration. In a study of 60 exposed pregnancies, ductal constriction developed in 50 percent and was significantly more likely after 30 weeks (Vermillion, 1997). Fortunately, ductal flow velocity returned to normal in all fetuses following discontinuation of therapy. Other NSAIDs are assumed to confer similar risks.

Leflunomide
This is a pyrimidine-synthesis inhibitor used to treat rheumatoid arthritis (Chap. 59, p. 1177). It is considered contraindicated in pregnancy because when given at or below human-equivalent doses in several animal species, it is associated with multiple abnormalities. These include hydrocephalus, eye anomalies, skeletal abnormalities, and embryo death (sanofi-aventis, 2012). The active metabolite of leflunomide is detectable in plasma for up to 2 years following its discontinuation. Women of childbearing potential who discontinue this medication should consider cholestryramine treatment/washout, followed by verification that serum levels are undetectable on two tests performed 14 days apart. Guidelines are also available for cholestryramine treatment/washout for men who discontinue leflunomide and who are contemplating fatherhood (Brent, 2001).

Antimicrobial Drugs

Medications used to treat infections are among those most commonly administered during pregnancy. Over the years, experience has accrued regarding their general safety. With a few exceptions cited below, most of the commonly used antimicrobial agents are considered safe for the embryo/fetus.

Aminoglycosides

Preterm infants treated with gentamicin or streptomycin have developed nephrotoxicity and ototoxicity. Despite theoretical concern for potential fetal toxicity, no adverse effects have been demonstrated, and no congenital defects resulting from prenatal exposure have been identified.

Chloramphenicol

This antimicrobial is not considered teratogenic and is no longer routinely used in the United States. More than 50 years ago, a constellation of findings termed the gray baby syndrome was described in neonates who received the medication. Preterm infants were unable to conjugate and excrete the drug and manifested abdominal distention, respiratory abnormalities, an ashen-gray color, and vascular collapse (Weiss, 1960). Chloramphenicol was subsequently avoided in late pregnancy due to theoretical concerns.

Nitrofurantoin

As discussed on page 241, the NBDPS found an association between first-trimester nitrofurantoin exposure and selected birth defects. These include a fourfold increased risk for hypoplastic left heart syndrome and microphthalmia/anophthalmia and a twofold increased risk for clefts and atrial septal defects (Crider, 2009). For postexposure counseling purposes, the absolute risk of these defects remains quite low. For example, a fourfold increased incidence of hypoplastic left heart would result in a prevalence of less than 1 per 1000 exposed infants (Texas Department of State Health Services, 2012). Nitrofurantoin is a proven first-line treatment of urinary infections. The American College of Obstetricians and Gynecologists (2013b) has concluded that first-trimester nitrofurantoin use is appropriate if no suitable alternatives are available.

Sulfonamides

These drugs are often combined with trimethoprim and used to treat various infections during pregnancy. One example is treatment of methicillin-resistant Staphylococcus aureus (MRSA). The NBDPS found associations between first-trimester sulfonamide exposure and a threefold increased
risk for anencephaly and left ventricular outflow tract obstruction, an eightfold increased risk for choanal atresia, and a twofold increased risk for diaphragmatic hernia (Crider, 2009). The American College of Obstetricians and Gynecologists (2013b) considers sulfonamides appropriate for first-trimester use if suitable alternatives are lacking. There are also theoretical concerns that because sulfonamides displace bilirubin from protein binding sites, they may worsen hyperbilirubinemia if given near the time of preterm delivery. However, a recent population-based review of more than 800,000 births from Denmark found no association between receiving sulfamethoxazole in late pregnancy and neonatal jaundice (Klarskov, 2013).

Tetracyclines
These drugs are no longer commonly used in pregnant women. They are associated with yellowish-brown discoloration of deciduous teeth when used after 25 weeks, although the risk for subsequent dental caries does not appear increased (Billing, 2004; Kutscher, 1966).

Antineoplastic Agents
Cancer management in pregnancy includes many chemotherapeutic agents generally considered to be at least potentially toxic to the embryo, fetus, or both. For the many novel polyclonal antibody therapies designated as antineoplastics, there are scant data concerning their safety. Some risks associated with cancer treatment with antineoplastic agents are discussed elsewhere—gestational trophoblastic neoplasia in Chapter 20 and cancer chemotherapy in Chapter 63. A few more common agents for which experience in pregnancy has accrued are considered below.

Cyclophosphamide
This alkylating agent inflicts a chemical insult on developing fetal tissues and leads to cell death and heritable DNA alterations in surviving cells. Pregnancy loss is increased, and reported malformations include skeletal abnormalities, limb defects, cleft palate, and eye abnormalities (Enns, 1999; Kirshon, 1988). Surviving infants may have growth abnormalities and developmental delays. Environmental exposure among health-care workers is associated with an increased risk for spontaneous abortion (Chap. 18, p. 354).

Methotrexate
This folic-acid antagonist is a potent teratogen. It is used for cancer chemotherapy, immunosuppression in conditions such as autoimmune diseases and psoriasis, nonsurgical treatment of ectopic pregnancy, and finally, as an abortifacient. It is similar in action to aminopterin, which is no longer in clinical use, and can cause defects known collectively as the fetal methotrexate-aminopterin syndrome. This includes craniosynostosis with “clover-leaf” skull, wide nasal bridge, low-set ears, micrognathia, and limb abnormalities (Del Campo, 1999). The critical developmental period of these abnormalities is believed to be 8 to 10 weeks, at a dosage of at least 10 mg/week, although this is not universally accepted (Feldcamp, 1993). As discussed in Chapter 19 (p. 384), the standard 50 mg/m² dose given to treat ectopic pregnancy or to induce elective abortion exceeds this threshold dose. Thus, ongoing pregnancies after treatment with methotrexate—especially if it is used in conjunction with misoprostol—raise serious concerns for fetal malformations (Creinin, 1994; Nurmohamed, 2011).

Tamoxifen
This nonsteroidal selective estrogen-receptor modulator (SERM) is used as an adjuvant to treat breast cancer (Chap. 63, p. 1231). Although it has not been associated with fetal malformations, it is fetotoxic and carcinogenic in rodents, inducing malformations similar to those caused by diethylstilbestrol (DES) exposure. Consequently, tamoxifen is pregnancy category D. It is recommended that women who become pregnant while either on therapy or within 2 months of its discontinuation be apprised of potential long-term risks of a DES-like syndrome. Exposed offspring should be monitored for carcinogenic effects for up to 20 years (Briggs, 2011).

**Trastuzumab**

This is a recombinant monoclonal antibody directed to the human epidermal growth factor receptor 2 (HER2) protein. It is used to treat breast cancers that over express HER2 protein (Chap. 63, p. 1230). This drug has not been associated with fetal malformations, but cases of oligohydramnios, anhydramnios, and fetal renal failure have been described (Beale, 2009; Sekar, 2007; Watson, 2005). Use may result in fetal pulmonary hypoplasia, skeletal abnormalities, and neonatal death.

**Antiviral Agents**

The number of drugs used to treat viral infections has increased rapidly during the past 20 years. For most, experience in pregnant women is limited.

**Ribavirin**

This nucleoside analogue is a component of therapy for hepatitis C infection, discussed in Chapter 55 (p. 1091). Ribavirin causes birth defects in multiple animal species at doses significantly lower than those recommended for human use. Reported malformations include skull, palate, eye, skeleton, and gastrointestinal abnormalities. The drug has a long half-life and persists in extravascular compartments following discontinuation of therapy. It is recommended that women use two forms of contraception while on therapy and delay childbearing for 6 months following drug discontinuation (Schering Corporation, 2012).

**Efavirenz**

This is a nonnucleoside reverse transcriptase inhibitor used to treat HIV infection (Chap. 65, p. 1279). Central nervous system and ocular abnormalities have been reported in cynomolgus monkeys treated with human-comparable doses. More worrisome are multiple case reports of central nervous system abnormalities following human exposure (Bristol-Meyers Squibb, 2010).

**Endothelin-Receptor Antagonists**

Two endothelin-receptor antagonists—bosentan and ambrisentan—are used to treat pulmonary arterial hypertension (Chap. 49, p. 986). Teratogenic concerns with these drugs stem from the fact that mice deficient in endothelin receptors develop abnormalities of the head, face, and large blood vessels. However, no human data are available (Clouthier, 1998). Bosentan and ambrisentan may be obtained only through restricted programs—the Tracleer Access Program for bosentan and the Letairis Education and Access Program (LEAP) for ambrisentan. Each program has stringent requirements for women, including contraception and monthly pregnancy tests (Actelion Pharmaceuticals, 2012; Food and Drug Administration, 2012).
Sex Hormones

Some of the functions and effects of male and female hormones on the developing fetus are discussed in Chapter 7 (p. 147). It is intuitive that exposure of female fetuses to excessive male sex hormones—and vice versa—might be detrimental.

Testosterone and Anabolic Steroids

Androgen exposure in reproductive-aged women is typically anabolic steroid use to increase lean body mass and muscular strength. Exposure of a female fetus may cause varying degrees of virilization and may result in ambiguous genitalia similar to that encountered in cases of congenital adrenal hyperplasia (Fig. 7-18A, p. 149). Findings may include labioscrotal fusion with first-trimester exposure and phallic enlargement from later fetal exposure (Grumbach, 1960; Schardein, 1985).

Danazol

This ethinyl testosterone derivative has weak androgenic activity. It is used to treat endometriosis, immune thrombocytopenic purpura, migraine headaches, premenstrual syndrome, and fibrocystic breast disease. In a review of inadvertent exposure during early pregnancy, Brunskill (1992) reported that 40 percent of exposed female fetuses were virilized. There was a dose-related pattern of clitoromegaly, fused labia, and urogenital sinus malformation.

Diethylstilbestrol

From 1940 until 1971, between 2 and 10 million pregnant women were given this synthetic estrogen. Subsequently, Herbst and associates (1971) reported a series of eight women exposed to DES in utero who developed an otherwise rare neoplasm, vaginal clear-cell adenocarcinoma. The absolute cancer risk in DES-exposed fetuses was approximately 1 per 1000, with no relationship to dosage. Women with in utero DES exposure also had a twofold increase in vaginal and cervical intraepithelial neoplasia (Vessey, 1989).

Diethylstilbestrol exposure has further been associated with genital tract abnormalities in exposed fetuses of both genders. Women may have a hypoplastic, T-shaped uterine cavity; cervical collars, hoods, septa, and coxcombs; and “withered” fallopian tubes, as described and illustrated in Chapter 3 (p. 42) (Goldberg, 1999; Salle, 1996). Later in life, women exposed in utero have slightly higher rates of earlier menopause and breast cancer (Hoover, 2011). Men may develop epididymal cysts, microphallus, hypospadias, cryptorchidism, and testicular hypoplasia (Klip, 2002; Stillman, 1982).

Immunosuppressant Medications

Some of the immune functions necessary for pregnancy maintenance are discussed in Chapter 5 (p. 97). Given these important interactions, it would be logical that immunosuppressant drugs might affect pregnancy.

Corticosteroids

These medications include glucocorticoids and mineralocorticoids, which have antiinflammatory and immunosuppressive actions. They are commonly used to treat serious disorders such as asthma and autoimmune disease. Corticosteroids have been associated with clefts in animal studies. In a
metaanalysis of case-control studies by the Motherisk program, systemic corticosteroid exposure was associated with a threefold increase in clefts, an absolute risk of 3 per 1000 exposed fetuses (Park-Wyllie, 2000). A 10-year prospective cohort study by the same group, however, did not identify increased risks for major malformations. Based on these findings, corticosteroids are not considered to represent a major teratogenic risk. Unlike other corticosteroids, the active metabolite of prednisone, which is prednisolone, is inactivated by the placental enzyme 11-beta-hydroxysteroid dehydrogenase 2 and does not effectively reach the fetus.

**Mycophenolate Mofetil**

This inosine monophosphate dehydrogenase inhibitor, and a related agent, mycophenolic acid, are potent immunosuppressants used to prevent rejection in organ-transplant recipients. They are also used for treatment of autoimmune disease such as lupus nephritis (Chap. 59, p. 1172). The National Transplantation Pregnancy Registry reported that almost half of exposed pregnancies spontaneously aborted and a fifth of surviving infants had malformations—nearly half of which were ear abnormalities (Food and Drug Administration, 2008). A Risk Evaluation and Mitigation Strategy (REMS) is necessary before mycophenolate is prescribed. Providers receive a brochure detailing associated risks; acceptable protocols for contraception during therapy—because the medication may decrease oral contraceptive efficacy; importance of reporting pregnancies that are conceived while on therapy to the Pregnancy Registry; and finally, a patient-prescriber acknowledgement form.

**Radioiodine**

Radioactive iodine-131 is used in the treatment of thyroid cancer and thyrotoxicosis and for diagnostic thyroid scanning (Chap. 63, p. 1231). It is also a component of iodine-131 tositumomab therapy, which is employed to treat a type of non-Hodgkin lymphoma. Radioiodine is contraindicated during pregnancy because it readily crosses the placenta and is then concentrated in the fetal thyroid gland by 12 weeks. It causes irreversible fetal hypothyroidism and may increase the risk for childhood thyroid cancer (Chap. 58, p. 1149).

**Lead**

Prenatal lead exposure is associated with fetal-growth abnormalities and with childhood developmental delay and behavioral abnormalities. According to the CDC (2010), there is no lead exposure level that is considered safe in pregnancy. Care for at-risk pregnancies is discussed in Chapter 9 (p. 183).

**Mercury**

Environmental spills of methyl mercury in Minamata Bay, Japan, and rural Iraq demonstrated that the developing nervous system is particularly susceptible to this heavy metal. Prenatal exposure causes disturbances in neuronal cell division and migration and leads to a range of defects from developmental delay to microcephaly and severe brain damage (Choi, 1978). The principal concern for prenatal mercury exposure is the consumption of certain species of large fish (Chap. 9, p. 183). Pregnant women are advised to not eat shark, swordfish, king mackerel, or tilefish, and consumption of albacore tuna should be limited to 6 ounces per week (Food and Drug Administration, 2004).
Psychiatric Medications

Treatment of psychiatric illness in pregnancy, including a discussion of the risks and benefits of various psychiatric medications, is discussed in Chapter 61 (p. 1204). Selected birth defects and adverse effects associated with specific medications are presented here.

Lithium

This medication has been associated with Ebstein anomaly, a cardiac abnormality characterized by apical displacement of the tricuspid valve. Ebstein anomaly often results in severe tricuspid regurgitation and marked right atrial enlargement, which confer significant morbidity. Its prevalence in the absence of lithium is approximately 1 per 20,000 births. Although a report from the Lithium Baby Register initially suggested that the risk for Ebstein anomaly was as high as 3 percent, subsequent series have demonstrated that the attributable risk is only 1 to 2 per 1000 exposed pregnancies (Reprotox, 2012; Weinstein, 1977). Fetal echocardiography should be considered for pregnancies exposed to lithium in the first trimester.

Neonatal lithium toxicity from exposure near delivery has been well documented. Findings typically persist for 1 to 2 weeks and may include hypothyroidism, diabetes insipidus, cardiomegaly, bradycardia, electrocardiogram abnormalities, cyanosis, and hypotonia (American College of Obstetricians and Gynecologists, 2012b; Briggs, 2011).

Selective Serotonin- and Norepinephrine- Reuptake Inhibitors

As a class, these medications are not considered major teratogens (American College of Obstetricians and Gynecologists, 2012b; Hviid, 2013). The one exception is paroxetine, which has been associated with increased risk for cardiac anomalies, particularly atrial and ventricular septal defects. Three large databases—a Swedish national registry, a United States insurance claims database, and the Motherisk Program—all identified a similar 1.5- to twofold increased rate of cardiac malformations following first-trimester paroxetine exposure (Bar-Oz, 2007; Food and Drug Administration, 2005a). For these reasons, the American College of Obstetricians and Gynecologists (2012b) recommends that paroxetine be avoided in women planning pregnancy, and that fetal echocardiography be considered for those with first-trimester paroxetine exposure.

Neonatal effects have been associated with prenatal exposure to selective serotonin-reuptake inhibitors (SSRIs) and selective norepinephrine-reuptake inhibitors (SNRIs). Approximately 2 percent of infants exposed to SSRIs in late pregnancy have been found to manifest one or more nonspecific findings considered to represent poor neonatal adaptation (Chambers, 2006; Costei, 2002; Jordan, 2008). Collectively termed the neonatal behavioral syndrome, findings may include jitteriness, irritability, hyper- or hypotonia, feeding abnormalities, vomiting, hypoglycemia, thermoregulatory instability, and respiratory abnormalities. Fortunately, these neonatal effects are typically mild and self-limited, lasting only about 2 days. Jordan and coworkers (2008) reported that newborns of mothers whose depression was not treated with medication were not more likely to require a higher level of care or extended hospitalization than SSRI-exposed newborns. Rarely, infants exposed to SSRIs in late pregnancy may demonstrate more severe adaptation abnormalities including seizures, hyperpyrexia, excessive weight loss, or respiratory failure. This has been reported in 0.3 percent and has been compared to manifestations of SSRI toxicity or withdrawal in adults (Levin, 2004).

Another concern with late-pregnancy exposure is the possible association of SSRI medication with persistent pulmonary hypertension of the newborn. Its baseline incidence is 1 to 2 per 1000 term infants and is characterized by high pulmonary vascular resistance, right-to-left shunting, and
profound hypoxemia. Chambers and colleagues (2006) identified a sixfold increase in pulmonary hypertension among those infants exposed to SSRIs after 20 weeks. A population-based cohort study involving 1.6 million pregnancies from the five Nordic countries identified a twofold increased risk following late-pregnancy exposure, an attributable risk of approximately 2 per 1000 births (Kieler, 2012). Other investigators have not found any increased risk (Wilson, 2011).

**Antipsychotic Medications**

There are no antipsychotic medications that are considered teratogenic. Exposed neonates have manifested abnormal extrapyramidal muscle movements and withdrawal symptoms, including agitation, abnormally increased or decreased muscle tone, tremor, sleepiness, feeding difficulty, and respiratory abnormalities. These findings are nonspecific and transient, similar to the neonatal behavioral syndrome that has been described following SSRI exposure. An FDA (2011a) alert cited all medications in this class. These include older drugs such as haloperidol and chlorpromazine, as well as newer medications such as aripiprazole, olanzapine, quetiapine, and risperidone.

**Retinoids**

These vitamin A derivatives are among the most potent human teratogens. Three retinoids available in the United States are highly teratogenic when orally administered—isotretinoin, acitretin, and bexarotene. By inhibiting neural-crest cell migration during embryogenesis, they result in a pattern of cranial neural-crest defects—termed retinoic acid embryopathy—that involve the central nervous system, face, heart, and thymus (Fig. 12-4). Specific anomalies may include ventriculomegaly, maldevelopment of the facial bones or cranium, microtia or anotia, micrognathia, cleft palate, conotruncal heart defects, and thymic aplasia or hypoplasia.
**Isotretinoin**

13-\textit{cis}\textendash{}Retinoic acid is a vitamin A isomer that stimulates epithelial cell differentiation and is used for dermatological disorders, especially cystic nodular acne. First-trimester exposure is associated with a high rate of pregnancy loss, and up to a third of fetuses have malformations (Lammer, 1985). The iPLEDGE program is an FDA-mandated REMS for isotretinoin and is found at: \url{www.ipledgeprogram.com}. This web-based restricted distribution program requires participation for all patients, physicians, and pharmacies to eliminate embryo-fetal exposure. Although other countries have instituted similar programs, inadvertent exposure remains a global concern (Crijns, 2011).

**Acitretin**

This retinoid is used to treat severe psoriasis. Acitretin was introduced to replace etretinate, a lipophilic retinoid with such a long half-life (120 days) that birth defects resulted more than 2 years after therapy was discontinued. Although acitretin has a short half-life, it is metabolized to etretinate, and thus remains in the body for prolonged periods (Stiefel Laboratories, 2011). To obviate exposure, the manufacturer of acitretin has developed a pregnancy risk management program called “Do Your P.A.R.T”\textendash{}Pregnancy prevention Actively Required during and after Treatment, which is found at: \url{www.soriatane.com}. It promotes a delay of conception for at least 3 years following therapy discontinuation.
Bexarotene
This retinoid is used to treat cutaneous T-cell lymphoma. When given to rats in human-comparable doses, fetuses developed eye and ear abnormalities, cleft palate, and incomplete ossification (Eisai Inc., 2011). To receive this medication, the manufacturer requires two forms of contraception, beginning one month before therapy and continuing for one month after discontinuation, and monthly pregnancy tests during treatment (Eisai Inc., 2011). Males who have partners who could become pregnant are advised to use condoms during sexual intercourse while taking bexarotene and for one month after discontinuing therapy.

Topical Retinoids
These compounds, initially used to treat acne, have become so popular for the treatment of sun damage that they are called cosmeceuticals (Panchaud, 2011). Examples include topical tretinoin and tazarotene. Systemic absorption is low, and this argues against plausible teratogenicity. Still, the manufacturer of tazarotene cautions that application over a sufficient body surface area could be comparable with oral treatment, which causes cranial neural-crest defects in animals (Allergan, 2011). Isolated case reports have described malformations following topical tretinoin. However, a prospective study by the European Network of Teratology Information Services, which included more than 200 pregnancies with first-trimester exposure to topical retinoids, found no differences in the rate of spontaneous abortion or birth defects compared with that of nonexposed pregnancies (Panchaud, 2011).

Vitamin A
There are two natural forms of vitamin A. Beta-carotene, which is a precursor of provitamin A, is found in fruits and vegetables and has never been shown to cause birth defects (Oakley, 1995). Retinol is preformed vitamin A, which has been associated with cranial neural-crest defects when more than 10,000 IU per day were consumed in the first trimester (Rothman, 1995). It seems reasonable to avoid doses of preformed preparations that exceed the recommended 3000 IU daily allowance (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012).

Thalidomide and Lenalidomide
The drug thalidomide is likely the most notorious human teratogen. It causes malformations in 20 percent of fetuses exposed between 34 and 50 days menstrual age. The characteristic malformation is phocomelia—an absence of one or more long bones, which results in the hands or feet being attached to the trunk by a small rudimentary bone. Cardiac malformations, gastrointestinal abnormalities, and other limb reduction defects are also common following thalidomide exposure.

Thalidomide was marketed outside the United States from 1956 to 1960, before its teratogenicity was appreciated. The ensuing disaster, with thousands of affected children, was instructive of a number of important teratological principles:

1. The placenta is not a perfect barrier to the transfer of toxic substances from mother to fetus (Dally, 1998).
2. There is extreme variability in species susceptibility to drugs and chemicals. Because thalidomide produced no defects in experimental mice and rats, it had been assumed to be safe for humans.
3. There is a close relationship between exposure timing and defect type (Knapp, 1962). Upper-
limb phocomelia developed with thalidomide exposure during days 27 to 30. This coincides with appearance of the upper-limb buds at day 27. Lower-limb phocomelia was associated with exposure during days 30 to 33, gallbladder aplasia at 42 to 43 days, duodenal atresia at 40 to 47 days.

Thalidomide was first approved in the United States in 1999, and currently it is used to treat leprosy and multiple myeloma (Celgene, 2013). The FDA has mandated an REMS for thalidomide called THALOMID REMS, which is found at www.thalomidrems.com/. This web-based restricted distribution program is required before participation by patients, physicians, and pharmacies.

Lenalidomide is an analogue of thalidomide that is used to treat some types of myelodysplastic syndrome and multiple myeloma. Because of obvious teratogenicity concerns, an REMS has been developed similar to that used for thalidomide, called the Revlimid REMS and is found at www.revlimidrems.com/.

Warfarin

Like other coumarin derivatives, warfarin is a vitamin K antagonist and a potent anticoagulant. It has a low molecular weight and readily crosses the placenta, causing embryotoxic and fetotoxic effects. Exposure between the 6th and 9th weeks may result in warfarin embryopathy. This is characterized by stippling of the vertebrae and femoral epiphyses and by nasal hypoplasia with depression of the nasal bridge as shown in Figure 12-5 (Hall, 1980). Affected infants may also have choanal atresia, resulting in respiratory distress. The syndrome is a phenocopy of chondrodysplasia punctata, a group of genetic diseases thought to be caused by defects in osteocalcin. In studies conducted before the mid-1980s, warfarin embryopathy was reported in approximately 10 percent of exposed pregnancies (Briggs, 2011). A more recent study by the European Network of Teratology Information Services involving more than 600 pregnancies exposed to vitamin K antagonists found that warfarin embryopathy occurred in less than 1 percent of cases. However, the overall rate of structural abnormalities was increased nearly fourfold (Schaefer, 2006). The risk of embryopathy may be greater in women who require more than 5 mg daily (Vitale, 1999).
When used beyond the first trimester, warfarin exposure may result in hemorrhage into fetal structures, which can cause abnormal growth and deformation from scarring (Warkany, 1976). Abnormalities may include agenesis of the corpus callosum; cerebellar vermian agenesis, which is the Dandy-Walker malformation; microphthalmia; and optic atrophy (Hall, 1980). Affected infants are also at risk for blindness, deafness, and developmental delays (Briggs, 2011).

**Herbal Remedies**

Risks associated with various herbal remedies are difficult to estimate because these compounds are not regulated by the FDA. Thus, the identity, quantity, and purity of each ingredient are usually unknown. Because animal studies have not been conducted, knowledge of complications may be limited to reports of acute toxicity (Hepner, 2002; Sheehan, 1998). Given these uncertainties, it seems prudent to counsel pregnant women to avoid these substances. A list of selected herbal compounds and their potential effects is shown in Table 12-5.

| TABLE 12-5. Pharmacological Actions and Adverse Effects of Some Herbal Medicines |
Recreational Drugs

At least 10 percent of fetuses are exposed to one or more illicit drugs (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Assessment of outcomes attributable to illicit drugs may be confounded by factors such as poor maternal health, malnutrition, infectious disease, and polysubstance abuse. As discussed on page 245, alcohol is a significant teratogen, and because it is legally obtained and ubiquitous, its use also confounds that of illicit drugs. Moreover, illegal substances may contain toxic contaminants such as lead, cyanide, herbicides, and pesticides. Impurities added as diluents may independently have serious adverse perinatal effects. Some examples include fine glass beads, sawdust, strychnine, arsenic, antihistamines, and warfarin.

Amphetamines

These sympathomimetic amines are not considered to be major teratogens. Some are used to dilute other illicit drugs. Methamphetamine is prescribed to treat obesity, narcolepsy, and attention deficit disorders. In utero exposure to methamphetamine is associated with fetal-growth restriction and with behavioral abnormalities in both infancy and early childhood. Limited data are available
regarding later development (LaGasse, 2011a,b; Little, 1988).

**Cocaine**

This central nervous system stimulant is derived from the leaves of the *Erythroxylum coca* tree. Most adverse outcomes associated with cocaine result from its vasoconstrictive and hypertensive effects. It can cause serious maternal complications such as cerebrovascular hemorrhage, myocardial damage, and placental abruption. Studies of congenital abnormalities in the setting of cocaine exposure have yielded conflicting results, but associations have been reported with cleft palate, cardiovascular abnormalities, and urinary tract abnormalities (Chasnoff, 1988; Chavez, 1989; Lipshultz, 1991; van Gelder, 2009). Cocaine use is also associated with fetal-growth restriction and preterm delivery. Children exposed as fetuses are at increased risk for behavioral abnormalities and cognitive impairments (Bada, 2011; Gouin, 2011; Singer, 2002).

**Opioids–Narcotics**

As a class, opioids are not considered to be major teratogens. That said, the NBDPS has identified a slightly increased risk for spina bifida, gastroschisis, and cardiac abnormalities in the setting of periconceptional exposure to therapeutic opioid medication (Broussard, 2011).

In contrast, opioid use is strongly associated with adverse fetal and neonatal effects. Heroin-addicted pregnant women are at increased risk for preterm birth, placental abruption, fetal-growth restriction, and fetal death—in part due to the effects of repeated narcotic withdrawal on the fetus and placenta (American College of Obstetricians and Gynecologists, 2012a; Center for Substance Abuse Treatment, 2008). Neonatal narcotic withdrawal, which is called the neonatal abstinence syndrome, may manifest in up to 90 percent of exposed infants (Blinick, 1973; Finnegan, 1975; Zelson, 1973). It is characterized by central nervous system irritability that may progress to seizures if untreated, along with tachypnea, episodes of apnea, poor feeding, and failure to thrive. At-risk neonates are closely monitored using a scoring system, and those severely affected are treated with opioids (Center for Substance Abuse Treatment, 2008; Finnegan, 1975). Data from the Birth Events Records Database from Washington state suggest that the proportion of exposed infants developing neonatal abstinence syndrome has increased in the past decade (Creanga, 2012).

Methadone is a synthetic opioid that has been routinely offered to pregnant heroin users since the 1970s to obviate uncontrolled narcotic withdrawal. It has a half-life of 24 to 36 hours and blocks narcotic cravings without producing intoxication. Women treated with methadone during pregnancy have been reported to be at increased risk for preterm birth and fetal-growth restriction (Cleary, 2010). Neonatal abstinence syndrome may occur in 40 to 70 percent of methadone-exposed infants and may be more protracted than with heroin exposure (Cleary, 2011; Dashe, 2002; Seligman, 2010). There is controversy as to whether a dose-response relationship exists between the maternal methadone dosage and neonatal withdrawal. At Parkland Hospital, pregnant opioid users are offered inpatient hospitalization for controlled methadone taper, with the goal of reducing the likelihood of neonatal abstinence syndrome (Dashe, 2002; Stewart, 2013). The American College of Obstetricians and Gynecologists (2012a) discourages withdrawal from methadone during pregnancy because of high relapse rates.

**Miscellaneous Drugs**

*Marijuana* use has not been associated with an increased risk for human fetal anomalies. Its active ingredient, delta-9-tetrahydrocannabinol, is teratogenic when given in high doses to animals.
Phencyclidine (PCP) or angel dust is not associated with congenital anomalies. More than half of exposed newborns, however, experience withdrawal symptoms characterized by tremors, jitteriness, and irritability. Toluene is a common solvent used in paints and glue. Occupational exposure is reported to have significant fetal risks (Wilkins-Haug, 1997). It is abused by intentional inhalation, which produces lightheadedness, dizziness, and loss of consciousness. When abused by women in early pregnancy, it is associated with toluene embryopathy, which is phenotypically similar to fetal alcohol syndrome. Abnormalities include pre- and postnatal growth deficiency, microcephaly, and characteristic face and hand findings. These include midface hypoplasia, short palpebral fissures, wide nasal bridge, and abnormal palmar creases (Pearson, 1994). Up to 40 percent of exposed children have developmental delays (Arnold, 1994).

### Tobacco

Cigarette smoke contains a complex mixture of nicotine, cotinine, cyanide, thiocyanate, carbon monoxide, cadmium, lead, and various hydrocarbons (Stillerman, 2008). In addition to being fetotoxic, many of these substances have vasoactive effects or reduce oxygen levels. Tobacco is not considered a major teratogen, although selected birth defects have been reported to occur with increased frequency among infants of women who smoke. It is plausible that the vasoactive properties of tobacco smoke could produce congenital defects related to vascular disturbances. For example, the prevalence of Poland sequence, which is caused by an interruption in the vascular supply to one side of the fetal chest and ipsilateral arm, is increased twofold (Martinez-Frias, 1999). An increased risk for cardiac anomalies has also been reported and may be dose-related (Alverson, 2011; Malik, 2008). A study using data from the National Vital Statistics System of more than 6 million births found an association between maternal smoking and hydrocephaly, microcephaly, omphalocele, gastroschisis, cleft lip and palate, and hand abnormalities (Honein, 2001).

The best-documented adverse reproductive outcome from smoking is a dose-response reduction in fetal growth. Newborns of mothers who smoke weigh an average of 200 g less than newborns of nonsmokers (D’Souza, 1981). Smoking doubles the risk of low birthweight and increases the risk of fetal-growth restriction two- to threefold (Werler, 1997). Growth disparity can be detected sonographically between 10 and 20 weeks (Mercer, 2008). Women who stop smoking early in pregnancy generally have neonates with normal birthweights (Cliver, 1995). Cigarette smoking has also been linked to subfertility and spontaneous abortions, to an increased risk for placenta previa and placental abruption, and to preterm delivery.

Genetics

Genetics is the study of genes, heredity, and the variation of inherited characteristics. Medical genetics deals with the etiology and pathogenesis of human diseases that are at least partially genetic in origin, along with their prediction and prevention. Thus, it is closely linked to genomics, which is the study of how genes function and interact. In addition to chromosomal, mendelian, and nonmendelian genetic conditions reviewed in this chapter, medical genetics includes preimplantation and prenatal diagnosis, gene therapy, and newborn screening, which are discussed in Chapters 14, 16, and 32, respectively.

 Genetic disease is common. Between 2 and 3 percent of newborns have a recognized structural defect. In another 3 percent of individuals, a defect is diagnosed by age 5, and another 8 to 10 percent are discovered by age 18 to have one or more functional or developmental abnormalities. An astonishing two thirds of the population will experience a disease with a genetic component during their lifetime. Advances in genomics are used increasingly to provide information regarding susceptibility to genetic diseases, and there is every indication that this field will reshape prenatal diagnosis (Bodurtha, 2012).

GENOMICS IN OBSTETRICS

Completed in 2003, the Human Genome Project identified nearly 25,000 human genes and led to rapid expansion of genomic research to better understand disease biology (Bodurtha, 2012; Feero,
One example is the International HapMap (Haplotype Map) Project, which studies the effects of genetic variation (National Human Genome Research Institute, 2012). HapMap investigates the nearly 10 million single nucleotide polymorphisms that comprise 0.5 percent of our DNA. Researchers look at how groups of common polymorphisms affect factors such as propensity to particular diseases and response to treatment. Another example is dbGaP, the database of Genotypes and Phenotypes, which is maintained by the National Center for Biotechnology Information (NCBI) (2013a). This database includes studies of genotype and phenotype interactions, such as genome-wide association studies and medical diagnostic assays. It is hoped that data from dbGaP will be used to develop tests or products that address public health needs.

The NCBI also maintains several genetic and genomic databases useful in obstetrics and maternal-fetal medicine practice. These include Online Mendelian Inheritance in Man (OMIM), GeneTests, and the Genetics Home Reference. Each is freely accessible to clinicians and researchers. Of these, OMIM is a comprehensive catalog of human genes and phenotype: originally created by the National Library of Medicine in collaboration with Johns Hopkins University. Clinicians can use OMIM to gain detailed information regarding particular syndrome and their genetic basis. Or, if a syndrome is suspected but the diagnosis is unclear, it may aid formulation a differential diagnosis by searching for syndromes that include particular traits or abnormalities. As of 2013, OMIM included more than 14,000 different genes with known sequences and nearly 4000 mendelian or mitochondrial conditions—phenotypes—with a known molecular basis (Johns Hopkins University, 2013).

Another database, GeneTests, provides information on genetic conditions, the benefits and limitations of available tests for a given disorder, and how to send a specimen to a particular laboratory. As of 2013, the GeneTests website contained 575 clinical reviews and more than 3000 genetic tests, and it provided contact information for more than 600 laboratories. Additional information regarding laboratories that perform genetic tests is available from the NCBI’s Genetic Testing Registry (2013c). The NCBI (2013b) has also established a database of genetic information intended for patients, the Genetics Home Reference. This database contains information on more than 2000 genetic conditions and genes.

**CHROMOSOMAL ABNORMALITIES**

Chromosomal abnormalities figure prominently in genetic disease. They are present in approximately 50 percent of spontaneous abortions, 5 percent of stillbirths, and 0.5 percent of liveborn infants (Parker, 2010; Schwartz, 2012). In the European Surveillance of Congenital Anomalies (EUROCAT) network of population-based registries, chromosomal abnormalities were recognized in 0.4 percent of pregnancies, with Down syndrome comprising more than half of cases (Dolk, 2010).

**Standard Nomenclature**

In humans, the 22 pairs of autosomes and one pair of sex chromosomes may be affected by various abnormalities. Karyotypes are described using the International System for Human Cytogenetic Nomenclature, a standardized format agreed upon by the genetics community (Shaffer, 2009). Abnormalities fall into two broad categories—those of chromosome number, such as trisomy, and those of chromosome structure, such as a deletion or translocation. Each chromosome has a short...
arm, termed the “p” or petit arm, and a long arm known as the “q” arm, selected because it is the next letter of the alphabet. The two arms are separated by the centromere.

When reporting a karyotype, the total number of chromosomes is listed first, corresponding to the number of centromeres. This is followed by the sex chromosomes, XX or XY, and then by a description of any structural variation. Specific abnormalities are indicated by standard abbreviations, such as del (deletion) and inv (inversion). The affected region or bands of the p or q arms are then designated, so that the reader will know both the exact abnormality location and the way in which the chromosomal complement is abnormal. Some examples of standard karyotype nomenclature are shown in Table 13-1.

### Abnormalities of Chromosome Number

The most easily recognized chromosomal abnormalities are numerical. Aneuploidy is inheritance of either an extra chromosome—resulting in trisomy, or loss of a chromosome—monosomy. These differ from polyploidy, which is an abnormal number of haploid chromosome sets, such as triploidy. The estimated incidence of various numerical chromosomal abnormalities is shown in Table 13-2.
Autosomal Trisomies
Trisomy accounts for approximately half of all chromosomal abnormalities. In most cases, it results from nondisjunction, which is failure of normal chromosomal pairing and separation during meiosis. Nondisjunction may occur if the chromosomes: (1) fail to pair up, (2) pair up properly but separate prematurely, or (3) fail to separate.

The risk of any autosomal trisomy increases steeply with maternal age, particularly after age 35 (Fig. 13-1). Aging is thought to break down the chiasmata that keep the paired chromosomes aligned. Oocytes are held suspended in midprophase of meiosis I from birth until ovulation, in some cases for 50 years. Following completion of meiosis at the time of ovulation, nondisjunction will result in one gamete having two copies of the affected chromosome, leading to trisomy if fertilized. The other gamete, receiving no copy of the affected chromosome, will be monosomic if fertilized. Between 10 and 20 percent of oocytes are aneuploid secondary to meiotic errors, compared with 3 to 4 percent of sperm. Although each chromosome pair is equally likely to have a segregation error, it is rare for trisomies other than 21, 18, or 13 to result in a term pregnancy. As shown in Figure 13-2, many fetuses with autosomal trisomy will be lost before term.

**Risk %**

![Figure 13-1](image1.png)

![Figure 13-2](image2.png)
Following a pregnancy with an autosomal trisomy, the risk for any autosomal trisomy in a future pregnancy is approximately 1 percent until the woman’s age-related risk exceeds this. Accordingly, invasive prenatal diagnosis is offered in subsequent pregnancies (Chap. 14, p. 297). Parental chromosomal studies are not indicated unless Down syndrome was due to an unbalanced translocation.

**Trisomy 21—Down Syndrome.** In 1866, J. L. H. Down described a group of mentally retarded children with distinctive physical features. Nearly 100 years later, Lejeune (1959) demonstrated
that Down syndrome is caused by an autosomal trisomy. The trisomy 21 karyotype is shown in Figure 13-3. Trisomy 21 is the etiology of 95 percent of Down syndrome cases, whereas 3 to 4 percent is due to a robertsonian translocation. The remaining 1 to 2 percent is secondary to an isochromsome or mosaicism. The nondisjunction that results in trisomy 21 occurs during meiosis I in almost 75 percent of cases. The remaining events occur during meiosis II.

FIGURE 13-3 Abnormal male karyotype with trisomy 21, consistent with Down syndrome (47,XY,+21). (Photograph contributed by Dr. Frederick Elder.)

Down syndrome is the most common nonlethal trisomy. Its prevalence is approximately 1 per 500 recognized pregnancies, including abortuses, stillbirths, and liveborn infants (Dolk, 2010). There is a significant fetal loss rate, as shown in Figure 13-2. Approximately 30 percent of fetuses with Down syndrome are lost between 12 and 40 weeks, and 20 percent between 16 and 40 weeks (Snijders, 1999). As a result, Down syndrome is found in 1 per 740 live births in the United States; or 13.5 per 10,000. This represents an increase of approximately 33 percent compared with the rate in the late 1970s (Parker, 2010; Shin, 2009). The rise in prevalence is explained by the increase in maternal age distribution during this period.

Adult women with Down syndrome are fertile, and a third of their offspring will have Dow
syndrome (Scharrer, 1975). Contraceptive options are discussed in Chapter 38 (p. 695). Males with Down syndrome are almost always sterile because of markedly decreased spermato genesis.

**Clinical Findings.** It is estimated that 25 to 30 percent of second-trimester fetuses with Down syndrome will have a major malformation that can be identified sonographically (Vintzileos, 1995). Approximately 40 percent of liveborn infants with Down syndrome are found to have cardiac defects, particularly endocardial cushion defects and ventricular septal defects (Figs. 10-22 and 10-23, p. 210). Gastrointestinal abnormalities develop in 7 percent and include duodenal atresia, esophageal atresia, and Hirschsprung disease (Fig. 10-28, p. 214) (Rankin, 2012).

Characteristic features of Down syndrome are shown in Figure 13-4. Typical findings include brachycephaly; epicanthal folds and up-slanting palpebral fissures; Brushfield spots, which are grayish spots on the periphery of the iris; a flat nasal bridge; and hypotonia. Infants often have loose skin at the nape of the neck, short fingers, a single palmar crease, hypoplasia of the middle phalanx of the fifth finger, and a prominent space or “sandal-toe gap” between the first and second toes. Some of these findings are sonographic markers for Down syndrome, which are reviewed in Chapter 14 (p. 292).

**FIGURE 13-4** Trisomy 21—Down syndrome. **A.** Characteristic facial appearance. **B.** Redundant nuchal tissue. **C.** Single transverse palmar crease. (Photographs contributed by Dr. Charles P. Read and Dr. Lewis Waber.)

Health problems more common in children with Down syndrome include hearing loss in 75 percent, severe optical refractive errors in 50 percent, cataracts in 15 percent, thyroid disease in 15 percent, and an increased incidence of leukemia (American Academy of Pediatrics, 2001). The degree of mental impairment is usually mild to moderate, with an average intelligence quotient (IQ) score of 35 to 70. Social skills in affected children are often higher than predicted by their IQ scores.

Recent data suggest that approximately 95 percent of liveborn infants with Down syndrome survive the first year. The 10-year survival rate is at least 90 percent overall and is 99 percent if
major malformations are absent (Rankin, 2012; Vendola, 2010). A number of organizations offer education and support for prospective parents faced with diagnosis of a Down syndrome fetus. These include the March of Dimes, National Down Syndrome Congress (www.ndsccenter.org) and National Down Syndrome Society (www.ndss.org).

**Trisomy 18—Edwards Syndrome.** This constellation of abnormalities and their association with another autosomal trisomy was first described by Edwards (1960). In population-based series, prevalence of trisomy 18 is approximately 1 per 2000 recognized pregnancies—including abortuses, stillbirths, and live births, and approximately 1 per 6600 liveborn infants (Dolk, 2010; Parker, 2010). The difference in prevalence is explained by the high in-utero lethality of the condition, as 85 percent of trisomy 18 fetuses are lost between 10 weeks’ gestation and term (see Fig. 13-2). Perhaps not surprisingly, survival of liveborn infants is likewise bleak. More than half die within the first week, and the 1-year survival rate is only approximately 2 percent (Tennant, 2010; Vendola, 2010). The syndrome is three- to fourfold more common in females (Lin, 2006; Rosa, 2011). Unlike Down and Patau syndromes, which involve acrocentric chromosomes and thus may stem from a robertsonian translocation, it is uncommon for Edwards syndrome to result from a chromosomal rearrangement.

**Clinical Findings.** Virtually every organ system can be affected by trisomy 18. Common major anomalies include heart defects in almost 95 percent—particularly ventricular septal defects, as well as cerebellar vermian agenesis, enlarged cisterna magna, myelomeningocele, diaphragmatic hernia, omphalocele, imperforate anus, and renal anomalies such as horseshoe kidney (Lin, 2006; Rosa, 2011; Yeo, 2003). Sonographic images of several of these are shown in Chapter 10 (p. 200).

Cranial and extremity abnormalities are also particularly common and include a prominent occiput, posteriorly rotated and malformed ears, micrognathia, small mouth, clenched hands with overlapping digits, radial aplasia, hypoplastic nails, and rockerbottom or clubbed feet. Characteristic sonographic findings include a “strawberry-shaped” cranium and choroid plexus cysts (Fig. 13-5). In otherwise low-risk pregnancies, the risk for trisomy 18 is increased only when a choroid plexus cyst is associated with other abnormalities. Alone, this cyst may be considered a normal variant.

**FIGURE 13-5** Trisomy 18—Edwards Syndrome. A. This transventricular sonographic view shows fetal choroid plexus cysts and a “strawberry-shaped” (unusually angulated) skull. Although not shown here, the fetal profile typically demonstrates micrognathia, with a very small, recessed
This three-dimensional (3-D) sonographic image shows the characteristic hand position of clenched fists with overlapping digits. 3-D sonographic image displays a rockerbottom foot.

Pregnancies with trisomy 18 that reach the third trimester often develop fetal-growth restriction, and the mean birthweight is less than 2500 grams (Lin, 2006; Rosa, 2011). Mode of delivery should be discussed in advance, because abnormal fetal heart rate tracings are common during labor. In older reports, more than half of undiagnosed fetuses underwent cesarean delivery for “fetal distress” (Schneider, 1981).

**Trisomy 13—Patau Syndrome.** This constellation of fetal abnormalities and their association with yet another autosomal trisomy was described by Patau and colleagues (1960). The prevalence of trisomy 13 is approximately 1 per 12,000 live births and 1 per 5000 recognized pregnancies, which includes abortuses and stillbirths (Dolk, 2010; Parker, 2010). As with trisomy 18, trisomy 13 is highly lethal, and most affected fetuses are lost between 10 weeks and term (see Fig. 13-2).

Approximately 80 percent of pregnancies with Patau syndrome result from trisomy 13. The remainder are caused by a robertsonian translocation involving chromosomes 13 and 14, der(13;14)(q10;q10). This translocation is the most common structural chromosomal rearrangement. It is carried by approximately 1 in 1300 individuals, although the risk of an affected liveborn infant is less than 2 percent (Nussbaum, 2007).

**Clinical Findings.** Trisomy 13 is associated with abnormalities of virtually every organ system. One characteristic finding is holoprosencephaly. This is present in approximately two thirds of cases and may be accompanied by microcephaly, hypotelorism, and nasal abnormalities that range from a single nostril to a proboscis (Solomon, 2010). Cardiac defects are found in up to 90 percent of fetuses with trisomy 13 (Shipp, 2002). Other abnormalities that suggest trisomy 13 include neural-tube defects—particularly cephalocele, microphthalmia, cleft lip-palate, omphalocele, cystic renal dysplasia, polydactyly, rockerbottom feet, and areas of skin aplasia (Lin, 2007). For the fetus or infant with a cephalocele, cystic kidneys, and polydactyly, the differential diagnosis includes trisomy 13 and the autosomal-recessive Meckel-Gruber syndrome, which is lethal. Sonographic images of several of these abnormalities are shown in Chapter 10 (p. 201).

Few trisomy 13 fetuses survive until birth. Of those that do, the 1-week survival is approximately 40 percent, and 1-year survival is only about 3 percent (Tennant, 2010; Vendola, 2010). Counseling regarding prenatal diagnosis and management options is similar to that described with trisomy 18.

For the mother, trisomy 13 is the only aneuploidy linked with an increased risk for preeclampsia. Hyperplacentosis and preeclampsia develop in up to half of pregnancies with trisomy 13 carried beyond the second trimester (Tuohy, 1992). Chromosome 13 contains the gene for soluble fms-like tyrosine kinase-1, called sFlt-1, which is an antiangiogenic protein associated with preeclampsia. Investigators have documented overexpression of the sflt-1 protein by trisomic 13 placentas and in serum of women with preeclampsia (Bdolah, 2006; Silasi, 2011). The role of antiangiogenic growth factors in the etiopathogenesis of preeclampsia is discussed in Chapter 40 (p. 735).

**Other Trisomies.** In the absence of mosaicism, which is discussed below, it is rare for other autosomal trisomies to result in a live birth. There are case reports of live births with trisomy 9 and with trisomy 22 (Kannan, 2009; Tinkle, 2003). Trisomy 16 is the most common trisomy found with first-trimester losses, accounting for 16 percent, but it is not identified later in gestation.
Trisomy 1 has never been reported.

**Monosomy**

Nondisjunction creates an equal number of nullisomic and disomic gametes. As a rule, missing chromosomal material is more devastating than having extra chromosomal material, and almost all monosomic conceptuses are lost before implantation. The one exception is monosomy for the X chromosome, Turner syndrome, which is discussed subsequently. Despite the strong association between maternal age and trisomy, there is no association between maternal age and monosomy (see Fig. 13-1).

**Polyploidy**

This is an abnormal number of complete haploid chromosomal sets. Polyploidy accounts for approximately 20 percent of spontaneous abortions but is rarely encountered later in gestation.

Triploid pregnancies have three haploid sets or 69 chromosomes. To have three haploid chromosomal sets, one parent must contribute two sets, and the phenotypic presentation differs according to the parent of origin. In *diandric triploidy*, also known as type I triploidy, the extra chromosomal set is paternal, resulting from fertilization of one egg by two sperm or by a single diploid—and thus abnormal—sperm. Diandric triploidy produces a partial molar pregnancy, which is discussed in Chapter 20 (p. 396). Diandric triploidy accounts for most triploid conceptions, but the first-trimester loss rate is extremely high. As a result, two thirds of triploid pregnancies identified beyond the first trimester are caused instead by digynic triploidy (Jauniaux 1999). In a digynic triploid pregnancy, also known as type II triploidy, the extra chromosomal set is maternal, and the egg fails to undergo the first or second meiotic division before fertilization. Digynic triploid placentas do not develop molar changes. However, the fetus often displays asymmetric growth restriction (Jauniaux, 1999).

Triploidy is a lethal aneuploidy, and more than 90 percent of fetuses with either the diandric or digynic form have multiple structural anomalies. These include abnormalities of the central nervous system, heart, face, and extremities, as well as severe growth restriction (Jauniaux, 1999). Counseling, prenatal diagnosis, and delivery options are similar to those for trisomies 18 and 13. The recurrence risk for a woman whose triploid fetus survived past the first trimester is 1 to 1.5 percent, and thus prenatal diagnosis is offered in future pregnancies (Gardner, 1996).

Tetraploid pregnancies have 4 haploid sets or 92 chromosomes. Four sets of chromosomes results in either 92,XXXX or 92,XXYY. This suggests a postzygotic failure to complete an early cleavage division. The conceptus invariably succumbs, and the recurrence risk is minimal.

**Sex Chromosome Abnormalities**

**45,X—Turner Syndrome.** This is the only monosomy compatible with life. However, it is also the most common aneuploidy in abortuses and accounts for 20 percent of first-trimester losses. The prevalence of Turner syndrome is approximately 1 per 5000 live births or 1 per 2500 girls (Cragan, 2009; Dolk, 2010). The missing X chromosome is paternally derived in 80 percent of cases (Cockwell, 1991; Hassold, 1991).

Monosomy X encompasses three distinct phenotypes. Approximately 98 percent of these conceptuses are so abnormal that they abort early in the first trimester. In a second group, large cystic hygromas are identified in either the first or second trimester, frequently accompanied by hydrops (Fig. 10-16, p. 206 and Chap. 15, p. 315). In such cases, fetal demise almost invariably results. Only the third and least-common phenotype has the potential for postnatal survival.
Affected fetuses may have small cystic hygromas visible in the first or second trimester, which do not result in hydrops, and they often have other major abnormalities. One reason for the wide range of Turner syndrome phenotype is that only half of liveborn infants actually have monosomy X. Approximately one fourth have mosaicism, such as 45,X/46,XX or 45,X/46,XY. Another 15 percent have isochromosome X, that is, 46,X,i(Xq)(Milunsky, 2004; Nussbaum, 2007). Abnormalities associated with Turner syndrome include a major cardiac malformation—such as coarctation of the aorta or bicuspid aortic valve—in 30 to 50 percent; renal anomalies, particularly horseshoe kidney; and hypothyroidism. Other features include short stature, broad chest with widely spaced nipples, congenital lymphedema, webbed posterior neck (resulting from cystic hygromas), and minor bone and cartilage abnormalities. Intelligence is generally in the normal range, although affected individuals are more likely to have visual-spatial organization deficits and difficulties with nonverbal problem solving and interpretation of social cues (Jones, 2006). Growth hormone is typically administered in childhood to ameliorate short stature (Kappelgaard, 2011). More than 90 percent have ovarian dysgenesis and require estrogen repletion beginning just before adolescence. An exception is if a mosaicism involves a Y chromosome. Such cases are at risk for germ cell neoplasm—regardless of whether the child is phenotypically male or female, and eventual prophylactic bilateral gonadectomy is indicated (Cools, 2011; Schorge, 2012).

47,XXX. Approximately 1 in 1000 female infants has an additional X chromosome—47,XXX. The extra X is maternally derived in more than 90 percent of cases (Milunsky, 2004). Pubertal development and fertility are usually normal, although premature ovarian failure has been reported (Holland, 2001). Tall stature is common. The overall major malformation rate is not increased with 47,XXX. That said, atypical phenotypic features have been described in some individuals and include epicanthal folds, clinodactyly, hypotonia, genitourinary problems, and seizure disorders (Tartaglia, 2010). Attention deficit disorder and delays in language development and motor skills have also been reported (Linden, 2002). It is estimated that because of the variability in presentation and subtlety of abnormal findings, only 10 percent of affected children are ascertained clinically.

Females with two or more extra X chromosomes—48,XXXX or 49,XXXXX—are likely to have physical abnormalities apparent at birth. These abnormal X complements are associated with varying degrees of mental retardation. For both males and females, the IQ score is lower with each additional X chromosome.

47,XXY—Klinefelter Syndrome. This is the most common sex chromosome abnormality. It occurs in approximately 1 per 600 male infants. The additional X chromosome is maternally or paternally derived with equal propensity (Jacobs, 1995; Lowe, 2001). There is also a slight association with either advanced maternal age or advanced paternal age (Milunsky, 2004). Infants with XXY appear phenotypically normal and usually do not have an increased incidence of anomalies. As children, boys are typically tall and have normal prepubertal development. However, they have gonadal dysgenesis, do not undergo normal virilization, and require testosterone supplementation beginning in adolescence. They may develop gynecomastia. In general, IQ scores are within the normal range but slightly below those of siblings, and delays in speech, reading, and motor skills are not uncommon (Girardin, 2011).

47,XYY. This aneuploidy occurs in approximately 1 in 1000 male infants. There is no association with paternal age, anomaly rates are not increased, and there are no unusual phenotypic features. These boys tend to be tall, they have normal puberty, and fertility is unimpaired. They are at
increased risk for oral and written language impairments, but intelligence is generally normal (Ross, 2009). A commonly held misconception was that XYY karyotype was associated with criminal or violent behavior. However, these early reports have been refuted.

Males with more than two Y chromosomes—48,XYYY—or with both additional X and Y chromosomes—48,XXYY or 49,XXXYY—have obvious physical abnormalities and significant mental retardation.

Abnormalities of Chromosome Structure

Structural chromosomal abnormalities include deletions, duplications, translocations, isochromosomes, inversions, ring chromosomes, and mosaicism (see Table 13-1). Their overall birth prevalence is approximately 0.3 percent (Nussbaum, 2007). Identification of a structural chromosomal abnormality raises two primary questions. First, what phenotypic abnormalities or later developmental abnormalities are associated with this finding? Second, is evaluation of parental karyotype indicated—specifically, are the parents at increased risk to carry this abnormality? If so, what is their risk to have future affected offspring?

Deletions and Duplications

A chromosomal deletion indicates that a portion of a chromosome is missing, and a duplication means that a portion has been included twice. Deletions involving DNA segments large enough to be seen with standard cytogenetic karyotyping are identified in approximately 1 per 7000 births (Nussbaum, 2007). Common deletions may be referred to by eponyms—for example, del 5p is called cri du chat syndrome.

Most deletions and duplications occur during meiosis and result from malalignment or mismatching during the pairing of homologous chromosomes. When this happens, the misaligned segment may be deleted (Fig. 13-6). Or, if the mismatch remains when the two chromosomes recombine, it may result in a deletion in one chromosome and a duplication in the other. When a deletion or duplication is identified in a fetus or infant, the parents should be offered karyotyping to determine if either carries a balanced translocation—as this would significantly increase the recurrence risk.
A mismatch during pairing of homologous chromosomes may lead to a deletion in one chromosome and a duplication in the other. del = deletion; dup = duplication.

**Microdeletion Syndromes.** A chromosomal deletion smaller than 3 million base pairs may not be detectable with standard karyotyping. Termed microdeletions, these may require molecular cytogenetic techniques for identification. Despite the relatively small size, a microdeletion may involve a stretch of DNA that contains multiple genes—causing a contiguous gene syndrome, which can include serious but unrelated phenotypic abnormalities (Schmickel, 1986). When a specific microdeletion syndrome is suspected, it is usually confirmed using fluorescence in situ hybridization (p. 276). Examples of common microdeletion syndromes are listed in Table 13-3.

The region of DNA that is deleted in a microdeletion syndrome (or duplicated in a microduplication) is termed a genomic copy number variant when applied to chromosomal microarray analysis discussed on page 277. Use of array-based technology has identified copy number variants that result in previously uncharacterized microdeletion syndromes—including single gene and intragenic deletions (Mikhail, 2011; Schwartz, 2012). It is likely that continued expansion of this technology will dramatically advance our knowledge of the genetic basis of disease.

22q11 Microdeletion Syndrome. This syndrome is also known as DiGeorge syndrome, Shprintzen syndrome, and velocardiofacial syndrome. It is the most common microdeletion, with prevalence of 1 per 2000 to 7000 births (Shprintzen, 2008). Although it is inherited in an autosomal dominant fashion, most cases arise from de novo mutations. The full deletion includes 3 million base pairs, encompasses 40 genes, and may include 180 different features—thus posing some counseling challenges (Shprintzen, 2008). It was once thought that different constellations of features characterized the DiGeorge and Shprintzen phenotypes, but it is now accepted that they represent the same microdeletion (McDonald-McGinn, 2011).

Associated abnormalities include conotruncal cardiac anomalies in more than 75 percent of affected individuals, such as tetralogy of Fallot, pulmonary atresia, truncus arteriosus, interrupted aortic arch, and ventricular septal defects. Immune deficiency, such as T-cell lymphopenia, also
develops in approximately 75 percent. More than 70 percent have velopharyngeal insufficiency or cleft palate. Other manifestations include learning disabilities and mental retardation, hypocalcemia, renal anomalies, esophageal dysmotility, hearing loss, behavioral disorders, and psychiatric illness. Short palpebral fissures, bulbous nose tip, micrognathia, short philtrum, and small or posteriorly rotated ears are characteristic facial features (McDonald-McGinn, 2011).

**Microduplication Syndromes.** These syndromes are caused by duplication of DNA regions smaller than 3 million base pairs. In some cases, a microduplication may involve the exact DNA region that causes a recognized microdeletion syndrome. Examples of these include the velocardiofacial, Smith-Magenis, and Williams-Beuren syndromes (Hassed, 2004; Potocki, 2000; Somerville, 2005).

**Chromosomal Translocations**

These are DNA rearrangements in which a segment of DNA breaks away from one chromosome and attaches to another. The rearranged chromosomes are called derivative (der) chromosomes. There are two types—reciprocal and robertsonian translocations.

**Reciprocal Translocations.** A double-segment or reciprocal translocation develops when there are breaks in two different chromosomes and the broken fragments are exchanged, so that each affected chromosome contains a fragment of the other. If no chromosomal material is gained or lost in this process, the translocation is considered balanced. The prevalence of reciprocal translocations is approximately 1 per 600 births (Nussbaum, 2007). Although transposition of chromosomal segments can cause abnormalities—due to repositioning of specific genes—the balanced carrier is usually phenotypically normal. The risk of a major structural or developmental abnormality in an apparent balanced translocation carrier is approximately 6 percent. Interestingly, using microarray-based studies, as many as 20 percent of individuals who would otherwise appear to have a balanced translocation may have missing or redundant DNA segments that are below the resolution of a standard karyotype (Manning, 2010).

Balanced translocation carriers are at risk to produce unbalanced gametes that result in abnormal offspring. As shown in Figure 13-7, if an oocyte or sperm contains a translocated chromosome, fertilization results in an unbalanced translocation—monosomy for part of one affected chromosome and trisomy for part of the other. The observed risk of a specific translocation can often be estimated by a genetic counselor. In general, translocation carriers identified after the birth of an abnormal child have a 5- to 30-percent risk of having liveborn offspring with unbalanced chromosomes. Carriers identified for other reasons, for example, during an infertility evaluation, have only a 5-percent risk. This is probably because the gametes are so abnormal that conceptions are nonviable.
A carrier of a balanced translocation may produce offspring who are also carriers of the balanced rearrangement (B), offspring with unbalanced translocations (C, D), or offspring with normal chromosomal complements (A).

Robertsonian Translocations. These involve only acrocentric chromosomes, which are chromosomes 13, 14, 15, 21, and 22. In an acrocentric chromosome, the p arm is extremely short. In a robertsonian translocation, the q arms of two acrocentric chromosomes fuse at one centromere to form a derivative chromosome. Also, one centromere and the p arms of each chromosome are lost. The p arms contain the satellite regions, which contain only genes coding for ribosomal RNA. As these are present in multiple copies on other acrocentric chromosomes, the translocation carrier is usually phenotypically normal. Because the number of centromeres determines the chromosome count, a robertsonian translocation carrier has only 45 chromosomes.

Robertsonian translocations are found in approximately 1 per 1000 newborns. Balanced carriers have reproductive difficulties for a number of reasons. If the fused chromosomes are homologous, from the same chromosome pair, the carrier can produce only unbalanced gametes. Each egg or sperm contains either both copies of the translocated chromosome, which would result...
in trisomy if fertilized, or no copy, which would result in monosomy. If the fused chromosomes are nonhomologous, four of the six possible gametes would be abnormal.

The most common robertsonian translocation is der(13;14)(q10;q10), which may result in Patau syndrome, discussed on page 263. The observed incidence of abnormal offspring is approximately 15 percent if a robertsonian translocation is carried by the mother and 2 percent if carried by the father. Robertsonian translocations are not a major cause of miscarriage and are found in fewer than 5 percent of couples with recurrent pregnancy loss. When a fetus or child is found to have a translocation trisomy, both parents should be offered karyotype analysis. If neither parent is a carrier, the recurrence risk is extremely low.

Isochromosomes
These abnormal chromosomes are composed of either two q arms or two p arms of one chromosome fused together. Isochromosomes are thought to arise when the centromere breaks transversely instead of longitudinally during meiosis II or mitosis. They can also result from a meiotic error in a chromosome with a robertsonian translocation. An isochromosome containing the q arms of an acrocentric chromosome behaves like a homologous robertsonian translocation, and such a carrier can produce only abnormal unbalanced gametes. When an isochromosome involves nonacrocentric chromosomes, with p arms containing functional genetic material, the fusion and abnormal centromere break results in two isochromosomes. One is composed of both p arms, and one is composed of both q arms. It is likely that one of these isochromosomes would be lost during cell division, resulting in the deletion of all the genes located on the lost arm. Thus, a carrier is usually phenotypically abnormal and produces abnormal gametes. The most common isochromosome involves the long arm of the X chromosome, i(Xq), which is the etiology of 15 percent of Turner syndrome cases.

Chromosomal Inversions
When there are two breaks in the same chromosome, and the intervening genetic material is inverted before the breaks are repaired, the result is a chromosomal inversion. Although no genetic material is lost or duplicated, the rearrangement may alter gene function. There are two types—pericentric and paracentric.

Pericentric Inversion. If there are breaks in both the p and q arms of a chromosome, such that the inverted material includes the centromere, the inversion is pericentric (Fig. 13-8). This causes problems in chromosomal alignment during meiosis and confers significant risk for the carrier to produce abnormal gametes and abnormal offspring. In general, the observed risk of abnormal offspring in a pericentric inversion carrier is 5 to 10 percent if ascertainment was made after the birth of an abnormal child. However, the risk is only 1 to 3 percent if prompted by another indication. An important exception is a pericentric inversion on chromosome 9—inv(9)(p11q12), which is a normal variant present in approximately 1 percent of individuals.
FIGURE 13-8 Mechanism of meiosis in the setting of either pericentric inversion (one involving the centromere) or paracentric inversion (not involving the centromere). Individuals with pericentric inversions are at increased risk to produce offspring with a duplication/deletion. Those with paracentric inversions are at increased risk for early pregnancy loss.

Paracentric Inversion. If there are two breaks within one arm of a chromosome, and the inverted material does not include the centromere, the inversion is paracentric (see Fig. 13-8). The carrier makes either normal balanced gametes or gametes that are so abnormal as to preclude fertilization. Thus, although infertility may be a problem, the risk of having an abnormal offspring is extremely low.

Ring Chromosomes
If deletions occur at both ends of the same chromosome, the ends may come together to form a ring chromosome. The regions at the end of each chromosome are called telomeres and contain specialized nucleoprotein complexes that stabilize chromosomes. If only telomeres are lost, all necessary genetic material is retained, so the carrier is essentially balanced. With deletions extending more proximally than the telomeres, the carrier is likely to be phenotypically abnormal. An example of this is a ring X chromosome, which may result in Turner syndrome.
Ring chromosome carriers have reproductive difficulties. The ring prevents normal chromosome alignment during meiosis and thus produces abnormal gametes. It also disrupts cell division, which may cause abnormal tissue growth and lead to short stature, borderline to moderate mental deficiency, and minor dysmorphisms. A ring chromosome may form de novo or may be inherited from a carrier parent. Parent-to-child transmission is always maternal, possibly because of compromised spermatogenesis.

**Chromosomal Mosaicism**

A mosaic individual has two or more cytogenetically distinct cell lines that are derived from a single zygote. Phenotypic expression of mosaicism depends on several factors, including whether the cytogenetically abnormal cells involve the placenta, the fetus, part of the fetus, or some combination. For example, mosaicism found in cells from amnionic fluid culture does not always reflect the fetal chromosome complement. The different levels of mosaicism and their clinical significance are presented in Table 13-4. When the abnormal cells are present in only a single flask of amnionic fluid, the finding is likely pseudomosaicism, caused by cell-culture artifact (Bui, 1984; Hsu, 1984). When abnormal cells involve multiple cultures, however, true mosaicism is more likely, and further testing of fetal blood or skin fibroblasts may be warranted. A second cell line is verified in 60 to 70 percent of these fetuses (Hsu, 1984; Worton, 1984).

**Confined Placental Mosaicism.** According to studies of chorionic villus sampling (CVS), 2 percent of placentas are mosaic, even though the associated fetus is usually normal (Henderson, 1996). The mechanism underlying confined placental mosaicism may be either mitotic nondisjunction or partial correction of a meiotic error, and the mechanism appears to be chromosome-specific (Robinson, 1997). Fifteen to 20 percent of cases are associated with an adverse pregnancy outcome, such as miscarriage, fetal-growth restriction, or stillbirth (Reddy, 2009).

Fetal-growth restriction from placental mosaicism may arise in one of two ways. If the placenta has a population of aneuploid cells, impaired placental function may affect the growth of a cytogenetically normal fetus (Kalousek, 1983). Alternatively, if the fetus receives two otherwise normal copies of one chromosome, but both copies are from the same parent—uniparental disomy, then abnormal growth may result (p. 273).
In some cases, survival of cytogenetically abnormal fetuses may be due to placental mosaicism. Examples are trisomy 13 and 18 fetuses, who survive to term because of early “trisomic correction” in some cells that become trophoblasts (Kalousek, 1989).

Gonadal Mosaicism. Mosaicism confined to the gonads likely arises from a mitotic error in cells destined to become the gonad and results in a population of abnormal germ cells. Because spermatogonia and oogonia divide throughout fetal life, and spermatogonia continue to divide throughout adulthood, gonadal mosaicism may also follow a meiotic error in previously normal germ cells. Gonadal mosaicism may explain de novo autosomal dominant mutations in the offspring of normal parents. It may cause autosomal dominant diseases such as achondroplasia and osteogenesis imperfecta, as well as X-linked diseases such as Duchenne muscular dystrophy. Gonadal mosaicism may also explain the recurrence of such diseases in more than one child in a previously unaffected family. The potential for gonadal mosaicism explains the 6-percent recurrence risk after the birth of a child with a disease caused by a “new” mutation.

**MODES OF INHERITANCE**

### Monogenic (Mendelian) Inheritance

A monogenic disorder is caused by a mutation or alteration in a single locus or gene in one or both members of a gene pair. Monogenic disorders are also called mendelian to signify that their transmission follows the laws of inheritance proposed by Gregor Mendel. Types of mendelian inheritance include autosomal dominant, autosomal recessive, X-linked, and Y-linked. Other monogenic patterns of inheritance are mitochondrial inheritance, uniparental disomy, imprinting, and trinucleotide repeat expansion, which is also termed anticipation. By age 25, approximately 0.4 percent of the population exhibits an abnormality attributed to a monogenic disorder, and 2 percent will have at least one such disorder during their lifetime. Some common single-gene disorders are listed in [Table 13-5](#).

**Relationship between Phenotype and Genotype**

When considering inheritance, it is the phenotype that is dominant or recessive, not the genotype. With a dominant disease, the normal gene may direct the production of normal protein, but the phenotype is abnormal because it is determined by protein produced by the abnormal gene. With a recessive disease, a heterozygous carrier may produce detectable levels of an abnormal gene product but have no features of the condition because the phenotype is directed by the product of the normal co-gene. For example, erythrocytes from carriers of sickle-cell anemia contain approximately 30 percent hemoglobin S, but because the other 70 percent is hemoglobin A, these cells do not sickle in vitro.

**Heterogeneity.** Genetic heterogeneity explains how different genetic mechanisms can result in the same phenotype. Locus heterogeneity indicates that a specific disease phenotype can be caused by mutations in different genetic loci. It also explains why some diseases appear to follow more than
one type of inheritance. An example is retinitis pigmentosa, which may develop following mutations in at least 35 different genes or loci and may result in autosomal dominant, autosomal recessive, or X-linked forms.

Allelic heterogeneity describes how different mutations of the same gene may affect presentation of a particular disease. For example, although only one gene has been associated with cystic fibrosis—the cystic fibrosis conductance transmembrane regulator gene (CFTR)—more than 1000 mutations in this gene have been described and result in varying disease severity. This is discussed in Chapter 14 (p. 295).

Phenotypic heterogeneity explains how different disease states can arise from different mutations in the same gene. For example, mutations in the fibroblast growth factor receptor 3 (FGFR3) gene may result in several different skeletal disorders, including achondroplasia and thanatophoric dysplasia, both of which are discussed in Chapter 10 (p. 217).

**Autosomal Dominant Inheritance**

If only one member of a gene pair determines the phenotype, that gene is considered to be dominant. Carriers have a 50-percent chance of passing on the affected gene with each conception. A gene with a dominant mutation generally specifies the phenotype in preference to the normal gene. That said, not all individuals will necessarily manifest an autosomal dominant condition the same way. Factors that affect the phenotype of an autosomal dominant condition include penetrance, expressivity, and occasionally, presence of codominant genes.

**Penetrance.** This term describes whether or not a dominant gene is expressed at all. A gene with recognizable phenotypic expression in all individuals has 100-percent penetrance. If some carriers express the gene but some do not, then penetrance is incomplete. This is quantitatively expressed by the ratio of those individuals with any phenotypic characteristics of the gene to the total number of gene carriers. For example, a gene that is expressed in some way in 80 percent of individuals who have that gene is 80-percent penetrant. Incomplete penetrance explains why some autosomal dominant diseases appear to “skip” generations.

**Expressivity.** Individuals with the same autosomal dominant trait—even within the same family—may manifest the condition differently. Genes with such variable expressivity can produce disease manifestations from mild to very severe. Examples include neurofibromatosis, tuberous sclerosis, and adult polycystic kidney disease.

**Codominant Genes.** If two different alleles in a gene pair are both expressed in the phenotype, they are considered to be codominant. Blood type, for example, is determined by expression of dominant A and B red-cell antigens that can be expressed simultaneously. Another example is the group of genes responsible for hemoglobin production. An individual with one gene directing production of hemoglobin S and the other directing production of hemoglobin C will produce both S and C hemoglobin.

**Advanced Paternal Age.** Paternal age older than 40 is associated with increased risk for spontaneous genetic mutations, particularly single base substitutions. This may result in offspring with new autosomal dominant disorders or X-linked carrier states. The risk is greater for some conditions than for others. In particular, advanced paternal age has been associated with mutations in the fibroblast growth factor receptor 2 (FGFR2) gene, which may cause craniosynostosis syndromes such as Apert, Crouzon, and Pfeiffer syndromes; mutations in the FGFR3 gene, which may result in achondroplasia and thanatophoric dysplasia; and mutations in the RET proto-
oncogene, which may cause multiple endocrine neoplasia syndromes (Jung, 2003; Toriello, 2008). Because these disorders are uncommon, the actual risk for any individual condition is low.

Advanced paternal age has also been associated with a slightly increased risk for Down syndrome and for isolated structural abnormalities (Grewal, 2011; Toriello, 2008; Yang, 2007). It is not generally considered to pose an increased risk for other aneuploidies, probably because the aneuploid sperm cannot fertilize an egg.

**Autosomal Recessive Inheritance**

A recessive trait is expressed only when both copies of the gene function in the same way. Thus, autosomal recessive diseases develop only when both gene copies are abnormal. Heterozygous carriers are usually undetectable clinically but may have biochemical test abnormalities. Many enzyme deficiency diseases display autosomal recessive inheritance, and enzyme activity in the carrier is approximately half of normal. Although this reduction usually does not cause clinical disease, it provides a phenotypic alteration that can be used for carrier screening. Other recessive conditions can be identified only by molecular genetic testing.

Unless carriers are screened for a specific disease, such as cystic fibrosis, they usually are recognized only after the birth of an affected child or the diagnosis of an affected family member (Chap. 14, p. 295). If a couple has a child with an autosomal recessive disease, the recurrence risk is 25 percent for each subsequent pregnancy. Thus, 1/4 of offspring will be homozygous normal, 2/4 will be heterozygous carriers, and 1/4 will be homozygous abnormal. In other words, three of four children will be phenotypically normal, and 2/3 of phenotypically normal siblings are actually carriers.

A heterozygous carrier of a recessive condition is only at risk to have affected children if his or her partner is heterozygous or homozygous for the disease. Genes for rare autosomal recessive conditions have low prevalence in the general population. Thus, the likelihood that a partner will be a gene carrier is low—unless there is consanguinity or the partner is a member of an at-risk group (American College of Obstetricians and Gynecologists, 2009b). This is discussed further in Chapter 14 (p. 294).

**Inborn Errors of Metabolism.** Most of these autosomal recessive diseases result from absence of a crucial enzyme, leading to incomplete metabolism of proteins, lipids, or carbohydrates. The metabolic intermediates that build up are toxic to a variety of tissues and may result in mental retardation or other abnormalities.

**Phenylketonuria.** This classic example of an autosomal recessive disease is caused by mutations in the phenylalanine hydroxylase (PAH) gene. PAH is needed to metabolize phenylalanine to tyrosine, and homozygotes have diminished or absent enzyme activity. This leads to abnormally high levels of phenylalanine, resulting in progressive intellectual impairment, autism, seizures, motor deficits, and neuropsychological abnormalities (Blau, 2010). Also, because phenylalanine competitively inhibits tyrosine hydroxylase—which is essential for melanin production, affected individuals have hair, eye, and skin hypopigmentation.

Approximately 3000 reproductive-aged women in the United States have phenylketonuria (PKU). The carrier frequency is approximately 1 in 60, and the disease affects 1 in 10,000 to 15,000 white newborns (American College of Obstetricians and Gynecologists, 2009a). PKU is one of the few metabolic disorders for which there is treatment. Early diagnosis and limitation of dietary phenylalanine beginning in infancy are essential to prevent neurological damage. Accordingly, all states and many countries now mandate newborn screening for PKU, and
approximately 100 cases per million births are identified worldwide. The special diet should be continued indefinitely, as those who abandon the phenylalanine-restricted diet have a significantly lower IQ and neuropsychological impairments (Blau, 2010).

Affected women who do not adhere to a phenylalanine-free diet are at risk to have otherwise normal (heterozygous) offspring who sustain in utero damage as a result of being exposed to toxic phenylalanine concentrations. Phenylalanine is actively transported to the fetus, and hyperphenylalaninemia increases the risk for miscarriage and for PKU embryopathy. This is characterized by mental retardation, microcephaly, seizures, growth impairment, and cardiac anomalies. Among women on unrestricted diets, the risk to have a child with mental retardation may exceed 90 percent, and as many as 1 in 8 children have cardiac defects (Lenke, 1980). The Maternal Phenylketonuria Collaborative Study, which included 572 pregnancies followed more than 18 years, reported that maintenance of serum phenylalanine levels between 160 and 360 μmol/L (2 to 6 mg/dL) significantly reduced the fetal abnormality risk (Koch, 2003; Platt, 2000). Women who achieved optimal phenylalanine levels before 10 weeks’ gestation had children with mean IQ scores in the normal range when assessed at age 6 to 7 years (Koch, 2003). Preconceptional counseling is recommended with a goal of maintaining an optimal phenylalanine concentration from 3 months before conception and continuing this throughout pregnancy (American College of Obstetricians and Gynecologists, 2009a).

Consanguinity. Two individuals are considered consanguineous if they have at least one recent ancestor in common. First-degree relatives share half of their genes, second-degree relatives share a fourth, and third-degree relatives—cousins—share one eighth. Because of the potential for shared deleterious genes, consanguinity confers an increased risk to have offspring with otherwise rare autosomal recessive diseases or multifactorial disorders. First cousins have a twofold increased risk—4 to 6 percent overall, in the absence of a family history of genetic disease.

Incest is defined as a sexual relationship between first-degree relatives such as parent-child or brother-sister and is universally illegal. Progeny of such unions carry the highest risk of abnormal outcomes, and up to 40 percent of offspring are abnormal as a result of recessive and multifactorial disorders (Freire-Maia, 1984; Nadiri, 1979).

X-Linked and Y–Linked Inheritance

Most X-linked diseases are recessive. Common examples include color blindness, hemophilia A and B, and Duchenne and Becker muscular dystrophy. When a woman carries a gene causing an X-linked recessive condition, each of her sons has a 50-percent risk of being affected, and each daughter has a 50-percent chance of being a carrier.

Males with an X-linked recessive gene are usually affected because they lack a second X chromosome to express the normal dominant gene. A male with an X-linked disease cannot have affected sons because they cannot receive his X chromosome. Women with an X-linked recessive gene are generally unaffected by the disease it causes. In some cases, however, the random inactivation of one X chromosome in each cell—termed lyonization—is skewed, and female carriers may have features of the condition. For example, approximately 10 percent of female carriers of hemophilia A display factor VIII levels less than 30 percent of normal, and a similar proportion of female hemophilia B carriers have factor IX levels less than 30 percent. With either type of hemophilia, the female carrier is at increased risk for abnormal bleeding at the time of delivery (Plug, 2006). Similarly, because female carriers of Duchenne or Becker muscular dystrophy are at increased risk for cardiomyopathy, periodic evaluation for cardiac dysfunction and neuromuscular disorders is recommended (American Academy of Pediatrics, 2005).
X-linked dominant disorders mainly affect females, because they tend to be lethal in males. Two examples are vitamin D-resistant rickets and incontinentia pigmenti. One exception is fragile X syndrome, which is discussed subsequently.

The prevalence of Y-linked chromosomal disorders is low. This chromosome carries genes important for sex determination and a variety of cellular functions related to spermatogenesis and bone development. Deletion of genes on the long arm of Y results in severe spermatogenic defects, whereas genes at the tip of the short arm are critical for chromosomal pairing during meiosis and for fertility.

Mitochondrial Inheritance

Human cells contain hundreds of mitochondria, each with its own genome and associated replication system. Oocytes contain approximately 100,000, but sperm contain only about 100, and these are destroyed after fertilization. Each mitochondrion has multiple copies of a 16.5-kb circular DNA molecule that contains 37 genes. Mitochondrial DNA encodes peptides required for oxidative phosphorylation, as well as ribosomal and transfer RNAs.

Mitochondria are inherited exclusively from the mother. Thus, although males and females both can be affected by a mitochondrial disorder, transmission is only through the mother. When a cell replicates, mitochondrial DNA sorts randomly into each of the daughter cells, a process termed replicative segregation. A consequence of replicative segregation is that any mitochondrial mutation will be propagated randomly into the daughter cells. Because there are multiple copies of mitochondrial DNA in each cell, the mitochondrion may contain only normal or only abnormal DNA—homoplasmy, or it may contain both normal and abnormally mutated DNA—heteroplasmy. If a heteroplasmic oocyte is fertilized, the relative proportion of abnormal DNA may affect whether the individual manifests a given mitochondrial disease. It is not possible to predict the potential degree of heteroplasmy among offspring, and this poses a challenge for genetic counseling.

As of 2013, 28 mitochondrial diseases or conditions with known molecular basis were described in OMIM (Johns Hopkins University, 2013). Examples include myoclonic epilepsy with ragged red fibers (MERRF), Leber optic atrophy, Kearns-Sayre syndrome, Leigh syndrome, several forms of mitochondrial myopathy and cardiomyopathy, and susceptibility to both aminoglycoside-induced deafness and chloramphenicol toxicity. Even aging is considered a mitochondrial disease!

DNA Triplet Repeat Expansion—Anticipation

Mendel’s first law is that genes are passed unchanged from parent to progeny, and barring new mutations, this is true for many genes or traits. However, certain genes are unstable, and their size, and thus function, may be altered during parent-to-child transmission. This is manifested clinically by anticipation—a phenomenon in which disease symptoms seem to be more severe and to appear at an earlier age in each successive generation. Examples of some DNA triplet (trinucleotide) repeat diseases are shown in Table 13-6.

</tbody>
</table>
Fragile X Syndrome. This is the most common inherited form of mental retardation and affects approximately 1 in 3600 males and 1 in 4000 to 6000 females (American College of Obstetricians and Gynecologists, 2010). Fragile X syndrome is caused by expansion of a repeated trinucleotide DNA segment—cytosine-guanine-guanine (CGG)—at chromosome Xq27. When the CGG repeat number reaches a critical size—the full mutation—the fragile X mental retardation 1 (FMR1) gene becomes methylated. Methylation inactivates the gene, which halts expression of FMR1 protein.

Although transmission of the syndrome is X-linked, both the sex of the affected individual and the number of CGG repeats determine whether offspring are affected and to what degree. Intellectual disability is generally more severe in males, in whom average IQ scores are 35 to 45 (Nelson, 1995). Affected individuals may have speech and language problems and attention deficit-hyperactivity disorder. Fragile X syndrome is also the most common known cause of autism. Associated phenotypic abnormalities become more prominent with age and include a narrow face with large jaw, prominent ears, connective tissue abnormalities, and macroorchidism in postpubertal males. Clinically, four groups have been described (American College of Obstetricians and Gynecologists, 2010):

- Full mutation—more than 200 repeats
- Premutation—55 to 200 repeats
- Intermediate—45 to 54 repeats
- Unaffected—fewer than 45 repeats

When a full mutation is present, males typically have significant cognitive and behavioral abnormalities and phenotypic features. In females, however, random X-inactivation results in variable expression, and the disability may be much less severe.

For individuals with a premutation, evaluation and counseling are more complex. A female with the fragile X premutation is at risk to have offspring with the full mutation. The likelihood of expansion to a critical full mutation depends on the current number of maternal repeats. The risk of a full mutation in an offspring is 5 percent or less if the CGG repeat number is below 70 but exceeds 95 percent with 100 to 200 CGG repeats (Nolin, 2003). Expansion is extremely unlikely in a male premutation carrier, but all of his daughters will carry the premutation. Among women with no risk factors, approximately 1 in 250 carries a fragile X premutation, and the risk is about 1 in 90 in those with a family history of mental retardation (Cronister, 2008). Premutation carriers may themselves experience significant health consequences. Males with the premutation are at increased risk for the fragile X tremor ataxia syndrome (FXTAS). Females are less likely to have FXTAS, although they have a 20-percent risk for fragile X-associated primary ovarian insufficiency.

The American College of Obstetricians and Gynecologists (2010) recommends testing for women with a family history of fragile X syndrome; individuals with unexplained mental retardation, developmental delay, or autism; and women with premature ovarian insufficiency. Prenatal diagnosis can be accomplished by amniocentesis or CVS (Chap. 14, p. 297). Specimens
obtained by either can be used to accurately determine the CGG repeat number, although CVS may not accurately determine \textit{FMR1} gene methylation status. Thus, DNA-based molecular testing with Southern blot and polymerase chain reaction are preferred.

**Uniparental Disomy**

This occurs when both members of a chromosome pair are inherited from the same parent. Often, uniparental disomy does not have clinical consequences. However, if chromosomes 6, 7, 11, 14, or 15 are involved, offspring are at increased risk for an abnormality because of parent-of-origin differences in gene expression (Shaffer, 2001). Although several genetic mechanisms may cause uniparental disomy, the most common is trisomic rescue, shown in Figure 13-9. After a nondisjunction event produces a trisomic conceptus, one of the three homologues may be lost. This will result in uniparental disomy for that chromosome in approximately one third of cases.

**FIGURE 13-9** Mechanism of uniparental disomy arising from trisomic “rescue.” A. In normal meiosis, one member of each pair of homologous chromosomes is inherited from each parent. B. If nondisjunction results in a trisomic conceptus, one homologue is sometimes lost. In a third of cases, loss of one homologue leads to uniparental disomy.

Isodisomy is the unique situation in which an individual receives two identical copies of one
chromosome in a pair from one parent. This mechanism explains some cases of cystic fibrosis, in which only one parent is a carrier but the fetus inherits two copies of the same abnormal chromosome from that parent (Spence, 1988; Spotila, 1992). It also has been implicated in abnormal growth related to placental mosaicism.

**Imprinting**

A gene may be inherited in a transcriptionally silent state—inaherited but not expressed—depending on whether it is inherited from the mother or father. The phenotype of the individual varies according to the parent of origin. Imprinting affects gene expression by epigenetic control, that is, gene activity regulation by modification of genetic structure other than alteration of the underlying nucleotide sequence. For example, methyl group addition may alter gene expression and thereby affect the phenotype without changing the genotype. Importantly, the effect may be reversed in a subsequent generation, because a female who inherits an imprinted gene from her father will pass it on in her oocytes with a maternal—rather than paternal—imprint, and vice versa.

Selected diseases that can involve imprinting are shown in Table 13-7. A useful example includes two very different diseases that may be caused by microdeletion, uniparental disomy, or imprinting for the 15q11-q13 DNA region. First, Prader–Willi syndrome is characterized by obesity and hyperphagia; short stature; small hands, feet, and external genitalia; and mild mental retardation. In more than 70 percent of cases, Prader-Willi syndrome is caused by microdeletion or disruption for the paternal 15q11.2-q13. The remaining cases are due to maternal uniparental disomy or due to maternal gene imprinting with the paternal gene inactivated.

</tbody>
</table>

Data from Online Mendelian Inheritance in Man (Johns Hopkins University, 2013).

In contrast, Angelman syndrome includes severe mental retardation; normal stature and weight; absent speech; seizure disorder; ataxia and jerky arm movements; and paroxysms of inappropriate laughter. In approximately 70 percent of cases, Angelman syndrome is caused by microdeletion for the maternal 15q11.2-q13. In 2 percent, the syndrome is caused by paternal uniparental disomy, and another 2 to 3 percent are due to paternal gene imprinting with the maternal genes inactivated.

There are other examples of imprinting important to obstetrics. Complete hydatidiform mole, with a paternally derived diploid chromosomal complement, is characterized by abundant
placental growth with no fetal structures (Chap. 20, p. 396). Conversely, an ovarian teratoma, with a maternally derived diploid chromosomal complement, is characterized by the growth of various fetal but no placental tissues (Porter, 1993). It thus appears that paternal genes are vital for placental development, maternal genes essential for fetal development, and that both are necessary for normal fetal development.

**Multifactorial Inheritance**

Traits or diseases are considered to have multifactorial inheritance if they are determined by the combination of multiple genes and environmental factors. Polygenic traits are determined by the combined effects of more than one gene. Most congenital and acquired conditions, as well as common traits, display multifactorial inheritance. Examples include malformations such as clefts and neural-tube defects, diseases such as diabetes and heart disease, and features or traits such as head size or height. Abnormalities that display multifactorial inheritance tend to recur in families, but not according to a mendelian pattern. If a couple has had a child with a multifactorial birth defect, their empiric risk to have another affected child is 3 to 5 percent. This risk declines exponentially with successively more distant relationships. Some characteristics of multifactorial conditions are shown in Table 13-8.

Adapted from Nussbaum, 2007.

Multifactorial traits that have a normal distribution in the population are termed continuously variable. A measurement that is more than two standard deviations above or below the population mean is considered abnormal. Continuously variable traits tend to be less extreme in the offspring of affected individuals, because of the statistical principle of regression to the mean.

**Threshold Traits.** Some multifactorial traits do not appear until a threshold is exceeded. Genetic and environmental factors that create propensity or liability for the trait are themselves normally distributed, and only individuals at the extreme of the distribution exceed the threshold and exhibit the trait or defect. Phenotypic abnormality is thus an all-or-none phenomenon. Examples include cleft lip-palate and pyloric stenosis.
Certain threshold traits have a clear male or female predominance. If an individual of the less common gender has the characteristic or defect, the recurrence risk is greater in his or her offspring (Fig. 13-10). An example is pyloric stenosis, which is approximately four times more common in males (Krogh, 2012). A female with pyloric stenosis has likely inherited more predisposing genetic factors than are necessary to produce the defect in a male, and the recurrence risk for her children or siblings is thus higher than the expected 3 to 5 percent. Her male siblings or male offspring would have the highest liability because they not only will inherit more than the usual number of predisposing genes but also are the more susceptible gender.

**FIGURE 13-10** Schematic example of a threshold trait, such as pyloric stenosis, which has a predilection for males. Each gender is normally distributed, but at the same threshold, more males than females will develop the condition.

The recurrence risk for threshold traits is also greater if the defect is severe. An example is that the recurrence risk after the birth of a child with bilateral cleft lip and palate is approximately 8 percent, but it is only about 4 percent following a child with unilateral cleft lip alone.

**Cardiac Defects.** Structural cardiac anomalies are the most common birth defects, with a birth prevalence of 8 per 1000. More than 100 genes believed to be involved in cardiovascular morphogenesis have been identified, including those directing production of various proteins, protein receptors, and transcription factors (Olson, 2006; Weismann, 2007).

The risk to have a child with a cardiac anomaly is approximately 5 to 6 percent if the mother has the defect and 2 to 3 percent if the father has the defect (Burn, 1998). Selected left-sided lesions, including hypoplastic left heart syndrome, coarctation of the aorta, and bicuspid aortic valve, may have recurrence risks four- to sixfold higher (Lin, 1988; Lupton, 2002; Nora, 1988). Observed recurrence risks for specific cardiac malformations are listed in Table 49-4 (p. 977).

**Neural-Tube Defects.** This is the second most common class of birth defects after cardiac anomalies. Their sonographic features and prenatal diagnosis are described in Chapters 10 (p. 201) and 14 (p. 283), respectively, and their prevention with folic acid is discussed in Chapter 9 (p. 181).

Neural-tube defects (NTDs) are classic examples of multifactorial inheritance. Their development may be influenced by hyperthermia, hyperglycemia, teratogen exposure, ethnicity, family history, fetal gender, and various genes. Selected risk factors are more strongly associated
with specific NTD location. Hyperthermia has been associated with anencephaly risk; pregestational diabetes with cranial and cervical-thoracic defects; and valproic acid exposure with lumbosacral defects (Becerra, 1990; Hunter, 1984; Lindhout, 1992).

Almost 50 years ago, Hibbard and Smithells (1965) postulated that abnormal folate metabolism was responsible for many NTDs. For a woman with a prior affected child, the recurrence risk of 2 to 5 percent is decreased by at least 70 percent—and potentially by as much as 85 to 90 percent—with periconceptional folic acid supplementation at a dosage of 4 mg/day (Grosse, 2007; MRC Vitamin Study Research Group, 1991). However, most NTD cases do not occur in the setting of maternal folic acid deficiency, and it has become clear that the gene-nutrient interactions underlying folate-responsive NTDs are complex. The NTD risk may be affected by genetic variation in folate transport or accumulation, impaired folate utilization via secondary nutrient deficiencies such as vitamin B\textsubscript{12} or choline deficiency, and genetic variation in activity of folate-dependent metabolic enzymes (Beaudin, 2009).

**GENETIC TESTS**

The two most common prenatal genetic tests, cytogenetic analysis and fluorescence in situ hybridization (FISH), are used primarily for aneuploidy detection. For the diagnosis of a specific disease in which the genetic basis is known, DNA-based tests are often employed, typically using polymerase chain reaction (PCR) for rapid amplification of DNA sequences. A new technology that has become clinically available is chromosomal microarray analysis (CMA), which allows the entire genome to be screened for differences in small DNA sequences that characterize genetic disease. Traditionally, each of the above tests has been performed on amniotic fluid or chorionic villi. Recently, however, attention has focused on use of cell-free fetal DNA found in the maternal circulation. A technique known as massively parallel sequencing has enabled researchers to identify trisomy 21 and other aneuploidies using cell-free fetal DNA from maternal blood, and there is potential for cell-free fetal DNA to be used to diagnose a wide range of genetic conditions in the future.

**Cytogenetic Analysis**

Any tissue containing dividing cells or cells that can be stimulated to divide is suitable for cytogenetic analysis. The dividing cells are arrested in metaphase, and their chromosomes are stained to reveal light and dark bands. The most commonly used technique is Giemsa staining, which yields the G-bands shown in Figure 13-3. Each chromosome has a unique banding pattern that permits its identification as well as detection of deleted, duplicated, or rearranged segments. The accuracy of cytogenetic analysis increases with the number of bands produced. High-resolution metaphase banding routinely yields 450 to 550 visible bands per haploid chromosome set. Banding of prophase chromosomes generally yields 850 bands.

Because only dividing cells can be evaluated, the rapidity with which results are obtained correlates with the rapidity of cell growth in culture. Fetal blood cells often produce results in 36 to 48 hours. Amnionic fluid, which contains epithelial cells, gastrointestinal mucosal cells, and amniocytes, usually yields results in 7 to 10 days. If fetal skin fibroblasts are evaluated postmortem, stimulation of cell growth can be more difficult, and cytogenetic analysis may take 2 to 3 weeks.
Fluorescence In Situ Hybridization

This tool provides a rapid method for determining numerical changes of selected chromosomes and confirming the presence or absence of a specific gene or DNA sequence. FISH is particularly useful for the rapid identification of a specific aneuploidy and for verification of suspected microdeletion or duplication syndromes. Speed is important in some instances because these findings may alter pregnancy management.

To perform FISH, cells are fixed onto a glass slide, and fluorescent-labeled chromosome or gene probes are hybridized to the fixed chromosomes, as shown in Figures 13-11 and 13-12. Each probe is a DNA sequence that is complementary to a unique region of the chromosome or gene being investigated. If the DNA sequence of interest is present, hybridization is detected as a bright signal, visible by microscopy. The number of signals indicates the number of chromosomes or genes of that type in the cell being analyzed. Findings are probe-specific. Thus, FISH does not provide information on the entire chromosomal complement but merely the chromosomal or gene region of interest.

FIGURE 13-11 Steps in fluorescence in situ hybridization (FISH).
The most common prenatal application of FISH involves testing interphase chromosomes with DNA sequences specific to chromosomes 21, 18, 13, X, and Y. Shown in Figure 13-12 is an example of interphase FISH using α-satellite probes for chromosomes 18, X, and Y to confirm trisomy 18. In a review of more than 45,000 cases, the concordance between FISH analysis and standard cytogenetic karyotyping was 99.8 percent (Tepperberg, 2001). The American College of Medical Genetics (2000) recommends that clinical decision making based on FISH also incorporate consistent clinical information or confirmatory chromosomal analysis.

**Southern Blotting**

This technique, named after Edward Southern, allows identification of one or several DNA fragments of interest from among the million or so typically obtained by enzyme digestion of the entire genome. As illustrated in Figure 13-13, a restriction endonuclease enzyme digests the DNA, resulting in fragments that are then separated using agarose gel electrophoresis. This is followed by transfer to a nitrocellulose membrane that binds DNA. Probes homologous for the DNA segment of interest are then hybridized to the DNA bound to the membrane, using a marker that permits their identification. Basic principles of the Southern blot technique also can be applied to RNA—known as Northern blotting—and to proteins—Western blotting.
FIGURE 13-13 Southern blotting analysis. Genomic DNA is isolated from leukocytes or amniocytes and digested with a restriction enzyme. This procedure yields a series of reproducible fragments that are separated by agarose gel electrophoresis. The separated DNA fragments are then transferred (“blotted”) to a nitrocellulose membrane that binds DNA. The membrane is treated with a solution containing a radioactive single-stranded nucleic acid probe, which forms a double-stranded nucleic acid complex at membrane sites when homologous DNA is present. These regions are then detected by autoradiography.

Polymerase Chain Reaction

This tool enables the rapid synthesis of large amounts of a specific DNA sequence or gene. To do this, either the entire gene sequence must be known or the DNA sequences at the beginning and end of the gene must be known. PCR involves three steps that are repeated many times. First, double-stranded DNA is denatured by heating. Then, oligonucleotide primers corresponding to a target sequence on each separated DNA strand are added and become annealed to either end of the target sequence. Finally, a mixture of nucleotides and heat-stable DNA polymerase is added to elongate the primer sequence, and new complementary strands of DNA are synthesized. The procedure is repeated multiple times to permit exponential amplification of the DNA segment.

Real-time PCR is used to amplify a specific gene while simultaneously quantifying the target gene. This allows accurate quantification of gene expression. Massively parallel genomic sequencing or “shotgun sequencing” uses random small DNA fragments, which are amplified using millions of sequence tags. These small amplified sequences are computer-aligned, allowing the entire genome sequence to be ascertained. The number of unique sequences can then be counted and expressed as a percentage. This permits relative quantification of specific genes or, in the case of aneuploidy determination, chromosomes.
Linkage Analysis

If a specific disease-causing gene has not been identified, then linkage analysis may be used to estimate the likelihood that an individual or fetus has inherited the abnormal trait. This technique is used to estimate the location of different genes and their approximate distance from each other.

Specific scattered markers are selected for study based on the suspected location of the gene responsible for the condition. DNA from each family member is analyzed to determine whether any of the selected markers have been transmitted along with the disease gene. If individuals with the disease have the marker but individuals without the disease do not, the gene causing the disease is said to be linked to that marker. This suggests that they lie close to each other on the same chromosome. Limitations of this technique are that it is imprecise, that it depends on family size and availability of family members for testing, and that it relies on the presence of informative markers near the gene.

Chromosomal Microarray Analysis

This testing uses the principles of PCR and nucleic acid hybridization to screen DNA for many different genes or mutations simultaneously. Doing so can identify deletions and duplications as small as 1 kilobase—termed genomic copy number variants—whereas the resolution of standard karyotyping is approximately 3 megabases. Two types of arrays are used clinically: (1) comparative genomic hybridization (CGH) arrays, which detect microdeletions and microduplications in DNA and (2) single-nucleotide polymorphism (SNP) arrays, in which the variation may involve just one nucleotide. As shown in Figure 13-14, the CGH microarray platform contains DNA fragments of known sequence. DNA from the individual (or fetus) to be tested is labeled with a fluorescent dye and then exposed to the DNA fragments fixed on the chip. Normal control DNA is labeled with a different fluorescent probe. Finally, the intensity of fluorescent probe signals is determined with a laser scanner. Use of SNP arrays is similar, except that the DNA is compared with known sequence variants, allowing determination of whether the fetus is heterozygous or homozygous for a mutation.
FIGURE 13-14 Chromosomal microarray analysis. A. Actual microarray chip size. B. Each chip contains thousands of cells (squares). C & D. Each cell contains thousands of identical oligonucleotides on its surface, and each cell is unique in its nucleotide content. E. During genetic analysis, a mixture containing tagged fetal DNA is presented to the chip. Complementary DNA sequences bind. F. If a laser is shined on the chip, DNA sequences that have bound will glow. This identifies a matching sequence. (From Doody, 2012, with permission.)

Arrays may be genome-wide or may be targeted to known genetic syndromes. Genome-wide arrays are used in research settings, for example, to identify novel microdeletion syndromes in individuals with intellectual disability (Slavotinek, 2008). In the prenatal setting, only targeted arrays are used. A major drawback of either type is the detection of copy number variants of uncertain clinical significance (Manning, 2010). When an abnormal pregnancy is found to have a variant that has not previously been associated with an abnormality, it may not be possible to determine whether the variant is benign or pathological.
Clinical Applications

CMA is used clinically for prenatal diagnosis and for stillbirth evaluation. The technique is expected to identify autosomal trisomies, sex chromosomal abnormalities, and other unbalanced chromosomal rearrangements visible with standard karyotype analysis. However, balanced chromosomal rearrangements such as translocations and inversions may not be identified. In addition, CGH arrays will not detect triploidy, mosaicism below 20 percent, or some marker chromosomes (Bui, 2011). A potential benefit of SNP arrays is the detection of triploidy. SNP arrays may also demonstrate loss of heterozygosity in a specimen, important for detection of uniparental disomy and consanguinity.

In pediatrics, CMA is considered a first-tier diagnostic test for children with mental retardation, congenital abnormalities, or dysmorphic features but with a normal karyotype. In such cases, CMA identifies an abnormality in up to 15 percent (Manning, 2010; Miller, 2010).

For stillbirth evaluation, CMA is more likely to provide a genetic diagnosis than standard karyotyping, in part because it does not require dividing cells. The Stillbirth Collaborative Research Network found that when karyotyping was uninformative, approximately 6 percent of cases had either aneuploidy or a pathogenic copy number variant identified with CMA (Reddy, 2012). Overall, CMA yielded results nearly 25 percent more often than standard karyotyping alone.

Targeted arrays are performed in the prenatal setting using chorionic villi or amnionic fluid. In a multicenter trial of more than 4000 pregnancies, Wapner and coworkers (2012) found that CMA identified all cases of common aneuploidies and unbalanced chromosomal rearrangements seen with standard karyotyping. When standard karyotyping results were normal, a microdeletion or microduplication of known or likely clinical significance was found in 6 percent if the indication was a fetal structural abnormality and in nearly 2 percent if performed for advanced maternal age or abnormal serum aneuploidy screening. Similar results have been reported by others (Hillman, 2011). Of concern is that variants of uncertain clinical significance are also identified in approximately 2 percent, which poses a challenge for counseling (Dugoff, 2012; Wapner, 2012). When copy number variants of uncertain clinical significance are encountered, parental testing is indicated.

Recently, the American College of Obstetricians and Gynecologists (2013) endorsed offering CMA testing when prenatal sonography identifies major fetal abnormalities. If the abnormalities suggest trisomy 21, 18, or 13, then karyotype analysis or FISH may be the initial test, and CMA can also be considered. Comprehensive genetic counseling is required before and after CMA testing. Also, depending on the platform used, it may need to include not only the potential to detect findings of uncertain clinical significance, but also adult-onset disease, consanguinity, and even non-paternity (American College of Obstetricians and Gynecologists, 2013).

Fetal DNA in the Maternal Circulation

Fetal cells are present in maternal blood at a very low concentration, only 2 to 6 cells per milliliter (Bianchi, 2006). And, some intact fetal cells may persist in the maternal circulation for decades following delivery. Persistent fetal cells may result in microchimerism, which has been implicated in maternal autoimmune diseases such as scleroderma, systemic lupus erythematosus, and Hashimoto thyroiditis. For prenatal diagnosis, the use of intact fetal cells is limited by their low concentration, persistence into successive pregnancies, and difficulties in distinguishing fetal from maternal cells. Cell-free fetal DNA overcomes these limitations.
Cell-Free Fetal DNA

This is released from apoptotic placental trophoblast—rather than actual fetal cells—and can be reliably detected in maternal blood after 7 weeks’ gestation (Bodurtha, 2012). It comprises 3 to 6 percent of the circulating cell-free DNA in maternal plasma, with proportions increasing as gestation advances (Lo, 1998). Unlike intact fetal cells, cell-free fetal DNA is cleared within minutes from maternal blood (Lo, 1999). In the research setting, cell-free fetal DNA has been used to detect numerous single-gene disorders through paternally inherited alleles. These include myotonic dystrophy, achondroplasia, Huntington disease, congenital adrenal hyperplasia, cystic fibrosis, and β-thalassemia (Wright, 2009). Clinical applications of cell-free fetal DNA include determination of Rh (CDE) genotype, determination of fetal gender, and detection of autosomal trisomies (Fig. 13-15).

FIGURE 13-15 Cell-free fetal DNA is actually derived from apoptotic trophoblast. The DNA is isolated from maternal plasma, and real-time quantitative PCR may be used to target specific regions or sequences. This may be used for Rh D genotyping, identification of paternally inherited single-gene disorders, or fetal sex determination. Using a technique called massively parallel genomic sequencing, screening for trisomies 21, 18, and 13 may be performed.

Rh D Genotype Evaluation. Fetal Rh D genotype assessment from maternal blood offers several potential benefits. Administration of anti-D immune globulin to an Rh D-negative pregnant woman carrying an Rh D-negative fetus can be eliminated. In the setting of Rh D alloimmunization, early identification of an Rh D-negative fetus can avoid unnecessary amniocentesis and/or serial fetal middle cerebral artery Doppler assessment. Rh D genotype evaluation using cell-free fetal DNA is done using real-time PCR to target multiple exons of the RH D gene. In a metaanalysis of more than 3000 pregnancies by Geifman-Holtzman and associates (2006), the average diagnostic accuracy approximated 95 percent, and only 3 percent of samples had inconclusive results. Subsequent studies have described accuracies of 99 to 100 percent (Minon, 2008; Tynan, 2011). Rh D genotyping using cell-free fetal DNA is used routinely in Europe. However, as of 2013, it has not
been widely adopted in the United States. A theoretical concern is that women with false-negative test results would not receive anti-D immune globulin, leading to a potential increase in Rh D alloimmunization (Szczepura, 2011).

**Fetal Sex Determination.** From the standpoint of genetic disease, fetal sex determination may be clinically useful if the fetus is at risk for an X-linked disorder. It may also be beneficial if the fetus is at risk for congenital adrenal hyperplasia because maternal corticosteroid therapy may be avoided if the fetus is male. In a metaanalysis of more than 6000 pregnancies by Devaney and colleagues (2011), the sensitivity of cell-free fetal DNA testing for fetal sex determination approximated 95 percent between 7 and 12 weeks’ gestation, improving to 99 percent after 20 weeks. The test specificity was 99 percent at both time periods, suggesting that cell-free fetal DNA is a reasonable alternative to invasive testing in selected cases.

**Aneuploidy Screening.** Fetal Down syndrome and other autosomal trisomies can be detected from maternal plasma using massively parallel sequencing or by targeted (selective) sequencing of chromosome-specific regions (Chiu, 2008; Fan, 2008; Sparks, 2012). By simultaneously sequencing millions of DNA fragments, investigators can identify whether the proportion or ratio of fragments from one chromosome is higher than expected. Because sequences of fetal DNA are specific to individual chromosomes, samples from those with Down syndrome have a larger proportion of DNA sequences from chromosome 21. This technology has been termed noninvasive prenatal testing (NIPT).

Recent trials of NIPT in high-risk pregnancies have yielded detection rates for trisomies 21, 18, and 13 of approximately 98 percent, at a false-positive rate of 0.5 percent or less (American College of Obstetricians and Gynecologists, 2012; Bianchi, 2012; Palomaki, 2011, 2012). NIPT has recently become clinically available as a screening test, but it is not currently considered a replacement diagnostic test. Pretest counseling is recommended, with formal genetic counseling if an abnormal result is identified. Recommendations for its use are discussed in Chapter 14 (p. 292).

**Limitations.** There are several important limitations to using cell-free fetal DNA testing in its present form (Benn, 2012; Geifman-Holtzman, 2006). Because placental cells are being evaluated, confined placental mosaicism may yield abnormal results that do not reflect fetal karyotype. Similarly, results may not be as accurate in a multifetal gestation or with a vanishing twin (Chap. 45, p. 892). There may be false-negative results if fetal DNA levels are insufficient in the sample. This theoretically results in failure to detect an Rh-negative fetus. In the case of aneuploidy, there may be inability to differentiate trisomy from unbalanced translocation (Benn, 2012; Geifman-Holtzman, 2006). Finally, because the technology identifies differences in the relative proportion of chromosomal fragments, triploidy may not be identified.

Lindhout D, Omtzigt JGC, Cornel MC: Spectrum of neural tube defects in 34 infants prenatally exposed to antiepileptic drugs. Neurology 42(suppl 5):111, 1992

2011

Major congenital abnormalities are identified during pregnancy or shortly after birth in 2 to 3 percent of pregnancies. They account for 20 percent of infant deaths in the United States, surpassing preterm birth as the most common cause (Kochanek, 2011). Prenatal diagnosis is the science of identifying malformations, disruptions, chromosomal abnormalities, and other genetic syndromes in the fetus. It encompasses routine screening tests for aneuploidy and neural-tube defects, invasive diagnostic tests such as chorionic villus sampling and amniocentesis, additional screening and diagnostic tests offered to those at risk for specific genetic disorders, and the diagnosis of structural malformations with specialized sonography and other fetal imaging techniques discussed in Chapter 10. The goal of prenatal diagnosis is to provide accurate information regarding short- and long-term prognosis, recurrence risk, and potential therapy and to thereby improve counseling and optimize outcomes.

Structural fetal abnormalities may develop in at least three ways. The most common mechanism is malformation—an intrinsic abnormality “programmed” in development, regardless of whether a precise genetic etiology is known. Examples include spina bifida and omphalocele. A second mechanism is deformation, by which a fetus develops abnormally because of extrinsic mechanical forces imposed by the uterine environment. An example is limb contractures that develop with oligohydramnios from bilateral renal agenesis. A third type is disruption, which is a more severe change in form or function that occurs when genetically normal tissue is modified as the result of a specific insult. An example is damage from an amniotic band, which can cause a limb-reduction defect.

Multiple structural or developmental abnormalities may also present together as a syndrome, sequence, or association. A syndrome is a cluster of several anomalies or defects that have the
same cause—for example, trisomy 18. A sequence describes anomalies that all developed sequentially from one initial insult. An example is the Pierre-Robin sequence in which micrognathia causes posterior displacement of the tongue—glossoptosis—which leads to a posterior rounded cleft in the palate. An association is a group of specific abnormalities that occur together frequently but do not seem to be linked etiologically. Diagnosis of the VACTERL association, for example, includes three or more of the following: vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities. Because of overlap of anomaly patterns, it is readily apparent that classification of fetal malformations is challenging, and reclassification is required periodically.

NEURAL-TUBE DEFECTS

These defects include anencephaly, spina bifida, cephalocele, and other rare spinal fusion (schisis) abnormalities. Features of these anomalies are detailed in Chapter 10 (p. 201), and fetal surgery for spina bifida is discussed in Chapter 16 (p. 325). Neural-tube defects (NTDs) are the second most common class of birth defect after cardiac anomalies, and their reported frequency is approximately 0.9 per 1000 births (Cragan, 2009; Dolk, 2010). More than 40 years ago, Brock and associates (1972, 1973) observed that pregnancies complicated by NTDs had higher levels of alpha-fetoprotein (AFP) in both maternal serum and amniotic fluid. This formed the basis for the first maternal serum screening test for a fetal defect.

Risk Factors

Selected risk factors for NTDs are listed in Table 14-1, and genetic factors represent the largest category. Isolated NTDs display multifactorial inheritance. The recurrence risk is approximately 3 to 5 percent if a couple has previously had a child with either anencephaly or spina bifida, 5 percent if either parent was born with an NTD, and as high as 10 percent if a couple has two affected children. Importantly, almost 95 percent of NTDs develop in the absence of a family history. Polymorphisms in the methylene tetrahydrofolate reductase gene, which leads to impaired homocysteine and folate metabolism, have been associated with increased risk for anencephaly and spina bifida, as well as for cardiac malformations (Aneji, 2012; Harisha, 2010; Munoz, 2007; Yin, 2012). NTDs are a component of more than 80 genetic syndromes, many including other anomalies that may be amenable to prenatal diagnosis (Milunsky, 2004).

Diabetes—hyperglycemia  
Hyperthermia—hot tub or sauna, fever (controversial)  
Medications—valproic acid, carbamazepine, coumadin, thalidomide, efavirenz  

Geographical—Ethnicity, Diet, and Other Factors  
United Kingdom, India, China, Egypt, Mexico, Southern Appalachian United States  

MTHFR = methylene tetrahydrofolate reductase.

Other risk factors for NTDs include hyperthermia, medications that disturb folic acid metabolism, and hyperglycemia from insulin-dependent diabetes. Although the exact mechanism by which diabetes causes these anomalies is unknown, rodent studies have found that oxidative stress from embryonic hyperglycemia is associated with apoptosis in the developing neural tube (Li, 2012; Sugimura, 2009; Yang, 2008). The risk for these defects is also increased in certain racial or ethnic groups as well as in populations from selected geographical regions. For example, recent data from population-based registries indicate an NTD prevalence of 1.0 to 1.3 per 1000 births in the United Kingdom, which compares with 0.9 per 1000 in the United States (Cragan, 2009; Dolk, 2010). In the United States, the risk may be twice as high among Mexican-born women (Velie, 2006).

Prevention
Most women at increased risk for NTDs benefit from 4 mg folic acid taken daily before conception and through the first trimester. This is particularly important if a woman has one or more prior affected children or if either the pregnant woman or her partner has such a defect. Folic acid supplementation may not decrease the risk for NTDs in those with valproic acid exposure, pregestational diabetes, first-trimester fever or hot tub exposure, or defects associated with a genetic syndrome (American College of Obstetricians and Gynecologists, 2013b).

The policy of routine fortification of cereal grains with folic acid, which has been in place in the United States since 1998, provides approximately 200 additional micrograms of folic acid daily and may reduce the first occurrence of NTDs in low-risk women by approximately 20 percent (Honein, 2001). It is recommended that all women at low risk take 400 μg of folic acid orally every day before conception and through the first trimester, to reduce the NTD risk by as much as 80 percent (Chap. 8, p. 159).

Maternal Serum Alpha-Fetoprotein Screening (MSAFP)

Alpha-fetoprotein (AFP) is a glycoprotein synthesized by the fetal yolk sac and later by the fetal gastrointestinal tract and liver. It is the major serum protein in the embryo and fetus and is thus analogous to albumin. As shown in Figure 14-1, its concentration increases steadily in both fetal serum and amniotic fluid until 13 weeks’ gestation, after which, levels rapidly decline. Conversely, AFP is found in steadily increasing quantities in maternal serum after 12 weeks. The normal concentration gradient between fetal plasma and maternal serum is on the order of 50,000:1. Defects in fetal integument, such as neural-tube and ventral wall defects, permit AFP to leak into the amniotic fluid, resulting in dramatically increased maternal serum AFP levels.
It was shown more than 30 years ago that maternal serum AFP concentrations at 16 to 18 weeks exceeded 2.5 multiples of the median (MoM) in a large proportion of women carrying fetuses with anencephaly or spina bifida (Wald, 1977). Since the mid-1980s, MSAFP concentration has been routinely measured as a screening test for NTDs.

Maternal serum AFP screening is generally performed from 15 through 20 weeks, within a protocol that includes quality control, counseling, and follow-up. AFP is measured in nanograms per milliliter and reported as multiples of the median (MoM) of the unaffected population. Using MoM normalizes the distribution of AFP levels and permits comparison of results from different laboratories and populations. Using a maternal serum AFP level of 2.0 or 2.5 MoM as the upper limit of normal, most laboratories report a detection rate—test sensitivity—of at least 90 percent for anencephaly and 80 percent for spina bifida at a screen-positive rate of 3 to 5 percent (Milunsky, 2004). The positive predictive value—the proportion with AFP elevation that have an affected fetus—is only 2 to 6 percent. This is explained by the overlap in AFP distributions in affected and unaffected pregnancies, as shown in Figure 14-2.
Several factors influence maternal serum AFP levels and are considered when calculating the AFP MoM:

1. Maternal weight—The AFP concentration is adjusted for the maternal volume of distribution.
2. Gestational age—The maternal serum concentration increases by approximately 15 percent per week during the second trimester (Knight, 1992). In general, the MoM should be recalculated if the biparietal diameter differs from the stated gestational age by more than 1 week.
3. Race/ethnicity—African American women have at least 10-percent higher serum AFP concentrations but are at lower risk for fetal NTDs.
4. Diabetes—Serum levels may be 10 to 20 percent lower in women with insulin-treated diabetes, despite a three- to fourfold increased risk for NTDs (Greene, 1988; Huttly, 2004). There is controversy whether such adjustment remains necessary or if results should apply to all types of diabetes (Evans, 2002; Sancken, 2001; Thornburg, 2008).
5. Multifetal gestation—Higher screening threshold values are used in twin pregnancies (Cuckle, 1990). At Parkland Hospital, an AFP level is considered elevated in a twin pregnancy if greater than 3.5 MoM, but other laboratories use 4.0 or even 5.0 MoM.

According to the American College of Obstetricians and Gynecologists (2013b), all pregnant women should be offered screening for NTDs. Women who present for care early in pregnancy often have the option of several different screening tests for aneuploidy, as discussed subsequently. Those who elect second-trimester multiple marker serum screening will have a maternal serum AFP level measured as a component. Those who elect first-trimester screening or chorionic villus sampling may receive neural-tube defect screening either with serum AFP at 15 to 20 weeks or with sonography (American College of Obstetricians and Gynecologists, 2013c).

**MSAFP Elevation**

One algorithm for evaluating elevated maternal serum AFP levels is shown in Figure 14-3. The evaluation begins with a standard sonogram, if not already performed earlier in gestation, as this can reliably exclude three common causes of AFP level elevation: underestimation of gestational age, multifetal gestation, and fetal demise. Virtually all cases of anencephaly and many cases of spina bifida may be detected or suspected during a standard second-trimester sonographic examination (Dashe, 2006). Once the gestational age is verified and the screening test is confirmed to be abnormal, a patient is offered diagnostic evaluation.
Maternal serum AFP determined as part of multiple marker screening at 15–20 weeks

AFP value (MoM) adjusted for maternal age, weight, ethnicity, gestational age, and insulin-dependent diabetes

- **AFP value < 2.00 MoM**
  - Normal screening result

- **AFP value ≥ 2.00 MoM**
  - If not already done, standard sonographic evaluation is performed to verify gestational age and to exclude twins or fetal demise, with recalculation of AFP MoM as needed
    - **AFP value < 2.50 MoM**
      - Normal screening result
    - **AFP value ≥ 2.50 MoM**
      - Abnormal result. Patient counseled, offered specialized sonography, consideration for amniocentesis

---

*a* If first trimester aneuploidy screening or CVS is elected, MSAFP is drawn as a single marker. If amniocentesis is elected for fetal karyotype, amnionic fluid AFP may be substituted for serum AFP screening.

*b* For twin gestations, the AFP threshold is higher, e.g. ≥ 3.50 MoM.
Numerous fetal and placental abnormalities have been associated with AFP elevation (Table 14-2). The likelihood of one of these abnormalities or of an adverse pregnancy outcome in the absence of a recognized abnormality increases in proportion to the AFP level. More than 40 percent of pregnancies may be abnormal if the AFP level is greater than 7 MoM (Reichler, 1994).

### Table 14-2. Conditions Associated with Abnormal Maternal Serum Alpha-Fetoprotein Concentrations

#### Elevated Levels
- Underestimated gestational age
- Multifetal gestation<sup>a</sup>
- Fetal death
- Neural-tube defect
- Gastrochisis
- Omphalocele
- Cystic hygroma
- Esophageal or intestinal obstruction
- Liver necrosis
- Renal anomalies—polycystic kidneys, renal agenesis, congenital nephrosis, urinary tract obstruction
  - Cloacal extrophy
  - Osteogenesis imperfecta
  - Sacrococcygeal teratoma
  - Congenital skin abnormality
  - Pilonidal cyst
  - Chorioangioma of placenta
  - Placenta intervillous thrombosis
  - Placental abruption
  - Oligohydramnios
  - Preeclampsia
  - Fetal-growth restriction
  - Maternal hepatoma or teratoma

#### Low Levels
- Obesity<sup>a</sup>
- Diabetes mellitus<sup>a</sup>
- Trisomies 21 or 18
- Gestational trophoblastic disease
- Fetal death
- Overestimated gestational age
Alpha-fetoprotein is adjusted for these factors when multiples of the median are calculated.

For the foregoing reasons, women with a confirmed serum AFP level elevation should be referred for additional counseling and offered a diagnostic test, either specialized sonography or amniocentesis. Some women have risk factors that warrant referral for a diagnostic test even in the setting of a normal AFP level. These include personal history of or first-degree relative with an NTD, insulin-treated diabetes, and first-trimester exposure to a medication associated with increased risk.

Targeted Sonography
More than 25 years ago, Nicolaides and colleagues (1986) described frontal bone scalloping—the lemon sign, and anterior curvature of the cerebellum with effacement of the cisterna magna—the banana sign—in second-trimester fetuses with open spina bifida (Fig. 14-4). These investigators also frequently noted a small biparietal diameter and ventriculomegaly in such cases. Watson and coworkers (1991) reported that 99 percent of fetuses with open spina bifida had one or more of these findings. In addition to these cranial findings, transverse and sagittal images of the spine are increasingly used to characterize the size and location of spinal defects (Chap. 10, p. 202). Using these findings, experienced investigators have described nearly 100-percent detection of open NTDs (Norem, 2005; Sepulveda, 1995). Overall NTD risk may be reduced by at least 95 percent when no spine or cranial abnormality is observed (Morrow, 1991; Van den Hof, 1990).

**FIGURE 14-4 A.** Image of the fetal head at the level of the lateral ventricles in the setting of spina bifida, demonstrating inward bowing or scalloping of the frontal bones (arrows)—the lemon sign. The image also depicts ventriculomegaly. **B.** Image of the fetal head at the level of the posterior fossa, demonstrating anterior curvature of the cerebellum (white arrows) with effacement of the cisterna magna—the banana sign.
Most centers use targeted sonography as the primary method of evaluating maternal serum AFP level elevation. The American College of Obstetricians and Gynecologists (2013b) recommends that women be counseled regarding the risks and benefits of targeted sonography and amniocentesis, the risk associated with the degree of AFP level elevation or other risk factors, and the quality and findings of the sonographic examination before making a decision.

**Amniocentesis**

Although amniocentesis for amnionic fluid AFP measurement was once considered the standard for open NTD diagnosis, it has been replaced in most centers by targeted sonography. If the amnionic fluid AFP level was elevated, an assay for acetylcholinesterase was performed, and if positive, was considered diagnostic of an NTD. Acetylcholinesterase leaks directly from exposed neural tissue into the amnionic fluid. The overall sensitivity of amniocentesis is approximately 98 percent for open NTDs, with a false-positive rate of 0.4 percent (Milunsky, 2004). Other fetal abnormalities associated with elevated amnionic fluid AFP levels and positive assay for acetylcholinesterase include ventral wall defects, esophageal atresia, fetal teratoma, cloacal extrophy, and skin abnormalities such as epidermolysis bullosa.

**Unexplained Maternal Serum AFP Level Elevation**

If no fetal or placental abnormality is detected after a specialized sonographic evaluation, with or without amniocentesis, then an MSAFP elevation is considered unexplained. These pregnancies are at increased risk for various subsequent adverse pregnancy outcomes. These include fetal abnormalities or genetic syndromes not detectable sonographically, fetal-growth restriction, oligohydramnios, placental abruption, preterm membrane rupture, preterm birth, and fetal death. Many of these complications are assumed to result from placental damage or dysfunction. Importantly, AFP level elevation is not considered to be clinically useful as a screening tool for adverse pregnancy outcomes, due to its low sensitivity and positive predictive value. No specific program of maternal or fetal surveillance has been found to favorably affect pregnancy outcomes (Dugoff, 2010). At Parkland Hospital, prenatal care for these women is not altered unless a specific complication arises. Despite the extensive list of possible adverse outcomes, it is reassuring that most women with unexplained AFP level elevation have normal outcomes. Abnormally high or low values of other serum analytes used in aneuploidy screening protocols are reviewed on page 290.

**Management of the Fetus with Spina Bifida**

The optimal mode of delivery for a fetus with open spina bifida remains controversial. Some have recommended cesarean delivery before the onset of labor, positing that it may reduce the risk of mechanical trauma and spinal infection. Although some have found improved motor function in children delivered operatively, others have not identified benefit in short- or long-term outcomes (Lewis, 2004; Luthy, 1991; Merrill, 1998). The American College of Obstetricians and Gynecologists (2013b) recommends that the route of delivery for the fetus with spina bifida should be individualized.

Open fetal surgery to repair NTDs has been the subject of several clinical studies. A landmark trial designed to compare open fetal surgery for spina bifida with standard postnatal care was described by Adzick and colleagues (2011). These authors of the Management of Myelomeningocele or MOMS trial found that in selected cases, fetal surgery resulted in improved
motor outcomes and reduced need for ventriculoperitoneal shunt placement at age 2 to 3 years. They also reported, however, that the surgery itself was associated with significant maternal and fetal risks. This is discussed further in Chapter 16 (p. 325).

DOWN SYNDROME AND OTHER ANEUPLOIDIES

At least 8 percent of conceptuses are aneuploid, accounting for 50 percent of first-trimester abortions and 5 to 7 percent of all stillbirths and neonatal deaths. As discussed in Chapter 13 (p. 260), the risk of fetal trisomy increases with maternal age, particularly after age 35. Specific maternal age-related aneuploidy risks for singleton and twin pregnancies are shown in Tables 14-3 and 14-4. Other significant risk factors include a prior pregnancy with autosomal trisomy or triploidy or a woman or her partner with a numerical chromosomal abnormality or structural chromosomal rearrangement, such as a balanced translocation.

TABLE 14-4. Maternal Age-Related Risk for Down Syndrome and Any Aneuploidy at Midtrimester and at Term in Dizygotic Twin Pregnancies

a
Types of Screening Tests

Until the mid-1980s, prenatal diagnostic testing for fetal aneuploidy was offered for “advanced maternal age.” However, age alone is a poor screening test, because approximately 70 percent of Down syndrome pregnancies are in women younger than 35 years. Nearly 30 years ago, Merkatz and associates (1984) observed that pregnancies with Down syndrome were characterized by lower maternal serum AFP levels at 15 to 20 weeks, and screening became available for younger women. During the past two decades, there have been four major advances in the area of aneuploidy screening:

1. The addition of other serum analytes to second-trimester screening has improved Down syndrome detection rates to approximately 80 percent for the quadruple marker test (Table 14-5).

2. First-trimester screening at 11 to 14 weeks’ gestation, using the fetal nuchal translucency measurement together with serum analytes, has achieved Down syndrome detection rates comparable to those for second-trimester screening in women younger than 35 years (American College of Obstetricians and Gynecologists, 2013c).

3. Combinations of first- and second-trimester screening yield Down syndrome detection rates as high as 90 to 95 percent (Malone, 2005b).

4. Maternal serum cell-free fetal DNA testing for trisomy 21, 18, and 13 has become available as a screening test for high-risk pregnancies, with a 98-percent detection rate and a false-positive rate of 0.5 percent (American College of Obstetricians and Gynecologists, 2012b; Bianchi, 2012; Palomaki, 2011, 2012).

*Risk applies to one or both fetuses. Adapted from Meyers, 1997.*
With the exception of cell-free fetal DNA testing, each first- and/or second-trimester aneuploidy screening test is based on a composite likelihood ratio, and the maternal age-related risk is multiplied by this ratio. This principle also applies to modification of the Down syndrome risk by selected sonographic findings (p. 292). Each woman is provided with a specific risk, expressed as a ratio—1:X. However, each screening test has a predetermined value at which it is deemed “positive” or abnormal. For second-trimester tests, this threshold has traditionally been set at the risk for fetal Down syndrome in a woman aged 35 years—approximately 1 in 385 at term (see Table 14-3). Women with a positive screening test result should be offered a diagnostic test
Counseling

Because technology advances have resulted in improved aneuploidy detection with available screening tests, the American College of Obstetricians and Gynecologists (2013c) recommends that all women who present for prenatal care before 20 weeks be offered screening. Available screening paradigms are shown in Table 14-5. A positive screening test result indicates increased risk, but it is not diagnostic of aneuploidy. Conversely, a negative screening test indicates that the risk is not increased, but it does not guarantee a normal fetus. Although Down syndrome is the focus of most aneuploidy screening protocols, it accounts for only half of all fetal chromosomal abnormality cases. Invasive diagnostic tests such as chorionic villus sampling and amniocentesis are safe and effective. Regardless of age, all women are counseled regarding the differences between screening and diagnostic tests, and they are given the option of invasive diagnostic testing.

First-Trimester Screening

The most commonly used protocol involves measurement of sonographic nuchal translucency and two maternal serum analytes. This is performed between 11 and 14 weeks’ gestation.

Nuchal Translucency (NT)

This is the maximum thickness of the subcutaneous translucent area between the skin and soft tissue overlying the fetal spine at the back of the neck (Fig. 14-5). It is measured in the sagittal plane, when the crown-rump length measures between 38 and 84 mm. Specific criteria for NT measurement are listed in Table 10-3 (p. 196). The NT measurement is expressed as a multiple of the gestational age-specific median, similar to serum markers used for aneuploidy screening. An increased NT thickness itself is not a fetal abnormality, but rather is a marker that confers increased risk. Approximately one third of fetuses with increased nuchal translucency thickness will have a chromosome abnormality, nearly half of which are Down syndrome (Snijders, 1998).
As shown in Table 14-5, as an isolated marker, NT detects 64 to 70 percent of fetuses with Down syndrome at a false-positive rate of 5 percent, and it has maximal sensitivity at 11 weeks (Malone, 2005b). The risk conferred by an increased NT thickness is independent of that of serum analytes, and combining NT with serum analyte values results in greatly improved aneuploidy detection (Spencer, 1999). Thus, NT is generally used as an isolated marker only in screening for multifetal gestations, in which serum screening is not as accurate or may not be available (American College of Obstetricians and Gynecologists, 2013c). An exception is that if the NT measurement is increased to 3 to 4 mm, then the aneuploidy risk is unlikely to be normalized using serum analyte assessment, and invasive testing should be offered (Comstock, 2006).

Increased NT thickness is also associated with other aneuploidies, genetic syndromes, and various birth defects, especially fetal cardiac anomalies (Atzei, 2005; Simpson, 2007). Because of this, if the NT measurement is 3.5 mm or greater, the patient should be offered targeted sonography, with or without fetal echocardiography, in addition to fetal karyotyping (American College of Obstetricians and Gynecologists, 2013c).

The NT must be imaged and measured with a high degree of precision for aneuploidy detection to be accurate. This has led to standardized training, certification, and ongoing quality review programs. In the United States, training, credentialing, and monitoring are available through the Nuchal Translucency Quality Review (NTQR) program (www.ntqr.org). Training is also available through the Fetal Medicine Foundation (www.fetalmedicineusa.com). In addition to nuchal translucency, NTQR provides an educational process leading to certification in measurement of the fetal nasal bone, which is discussed on page 294 and shown in Figure 14-5.

**Serum Analytes**

Two analytes used for first-trimester aneuploidy screening are human chorionic gonadotropin—either intact or free β-hCG—and pregnancy-associated plasma protein A (PAPP-A). In cases of
fetal Down syndrome, the first-trimester serum free β-hCG level is higher, approximately 2.0 MoM, and the PAPP-A level is lower, approximately 0.5 MoM. With trisomy 18 and trisomy 13 levels of both analytes are lower (Cuckle, 2000; Malone, 2005b; Spencer, 1999, 2000; Tul, 1999). If gestational age is correct, the use of these serum markers—without NT measurement—results in detection rates for fetal Down syndrome up to 67 percent at a false-positive rate of 5 percent (Wapner, 2003). Aneuploidy detection is significantly greater if these first-trimester analytes are either: (1) combined with the sonographic NT measurement or (2) combined with second-trimester analytes, which is termed serum integrated screening (p. 291).

In twin pregnancies, serum free β-hCG and PAPP-A levels are approximately doubled compared with singleton values (Vink, 2012). Even with specific curves, a normal dichorionic cotwin will tend to normalize screening results, and thus, the aneuploidy detection rate is at least 15-percent lower (Bush, 2005).

### Combined First-Trimester Screening

The most commonly used screening protocol combines the NT measurement with serum hCG and PAPP-A. Using this protocol, Down syndrome detection rates in large prospective trials range from 79 to 87 percent, at a false-positive rate of 5 percent (see Table 14-5). The detection rate is approximately 5-percent higher if performed at 11 compared with 13 weeks (Malone, 2005b). The detection rate for trisomies 18 and 13 is approximately 90 percent, at a 2-percent false-positive rate (Nicolaides, 2004; Wapner, 2003).

Maternal age does affect the performance of first-trimester aneuploidy screening tests. In prospective trials, combined first-trimester screening resulted in Down syndrome detection rates of 67 to 75 percent in women younger than 35 years at delivery, which are 10-percent lower than the overall detection rates in these studies (Malone, 2005b; Wapner, 2003). Among women older than 35 at delivery, however, Down syndrome detection rates were 90 to 95 percent, albeit at a higher false-positive rate of 15 to 22 percent.

### Unexplained Abnormalities of First-Trimester Analytes

There is a significant association between serum PAPP-A levels below the 5th percentile and preterm birth, growth restriction, preeclampsia, and fetal demise (Dugoff, 2004). Similarly, low levels of free β-hCG have been associated with fetal demise (Goetzl, 2004). The sensitivity and positive-predictive values of these markers are considered too low to be clinically useful as screening tests. As with other serum analyte level abnormalities, no management strategies have been demonstrated to improve pregnancy outcomes when these marker levels are abnormally low (Dugoff, 2010).

### Second-Trimester Screening

Pregnancies with fetal Down syndrome are characterized by lower maternal serum AFP levels—approximately 0.7 MoM, higher hCG levels—approximately 2.0 MoM, and lower unconjugated estriol levels—approximately 0.8 MoM (Merkatz, 1984; Wald, 1988). This triple test can detect 61 to 70 percent of Down syndrome cases as shown in Table 14-5 (Alldred, 2012). Levels of all three markers are decreased in the setting of trisomy 18, with a detection rate similar to that for Down syndrome at a false-positive rate of only 0.5 percent (Benn, 1999).

Levels of a fourth marker—dimeric inhibin alpha—are elevated in Down syndrome, with an average value of 1.8 MoM (Spencer, 1996). The addition of dimeric inhibin to the other three
markers is the *quadruple* or *quad test*, which has a trisomy 21 detection rate of approximately 80 percent at a false-positive rate of 5 percent (see Table 14-5). As with first-trimester screening, aneuploidy detection rates will be slightly lower in younger women and higher in women older than 35 years at delivery. If second-trimester serum screening is used in twin pregnancies, aneuploidy detection rates are significantly lower (Vink, 2012).

The quad test is the most commonly used second-trimester serum screening test for aneuploidy. As a stand-alone test, it is generally used if women do not begin care until the second-trimester or if first-trimester screening is not available. As subsequently discussed, combining the quad test with first-trimester screening yields even greater aneuploidy detection rates.

### Unexplained Abnormalities of Second-Trimester Analytes

There is a significant association between second-trimester elevation of either hCG or dimeric inhibin alpha levels and adverse pregnancy outcomes. The outcomes reported are similar to those associated with AFP level elevation and include fetal-growth restriction, preeclampsia, preterm birth, fetal demise, and stillbirth. Moreover, the likelihood of adverse outcome is increased when multiple marker levels are elevated (Dugoff, 2005). However, the sensitivity and positive predictive values of these markers are considered too low to be useful for screening or management (Dugoff, 2010).

#### Low Maternal Serum Estriol Levels

A maternal serum estriol level < 0.25 MoM has been associated with two uncommon but important conditions. The first, Smith-Lemli-Opitz syndrome, is an autosomal recessive condition characterized by mutations in the 7-dehydrocholesterol reductase gene. It may be associated with central nervous system, heart, kidney, and extremity abnormalities, with ambiguous genitalia, and with fetal-growth restriction. For this reason, the Society for Maternal-Fetal Medicine has recommended that sonographic evaluation be performed if an unconjugated estriol level is < 0.25 MoM (Dugoff, 2010). If abnormalities are identified, an elevated amniotic fluid 7-dehydrocholesterol level can confirm the diagnosis.

The second condition is steroid sulfatase deficiency, also known as X-linked ichthyosis. It is typically an isolated condition, but it may also occur in the setting of a contiguous gene deletion syndrome (Chap. 13, p. 266). In such cases, it may be associated with Kallmann syndrome, chondrodysplasia punctata, and/or mental retardation (Langlois, 2009). If the estriol level is < 0.25 MoM and the fetus appears to be male, fluorescence in situ hybridization to assess the steroid sulfatase locus on the X-chromosome may be considered (Dugoff, 2010).

### Combined First- and Second-Trimester Screening

Combined screening strategies enhance aneuploidy detection. For this reason, the American College of Obstetricians and Gynecologists (2013c) recommends that a strategy incorporating both first- and second-trimester screening should be offered to women who seek prenatal care in the first trimester. Three types of screening strategies are available:

1. **Integrated screening** combines results of first- and second-trimester tests. This includes a combined measurement of fetal NT and serum analyte levels at 11 to 14 weeks’ gestation plus quadruple markers at 15 to 20 weeks. An aneuploidy risk is then calculated from these seven parameters. As expected, integrated screening has the highest Down syndrome detection rate—94 to 96 percent at a false-positive rate of 5 percent (see Table 14-5). If NT measurement is not available, *serum integrated screening* includes all six serum markers to calculate risk.
This screening, however, is less effective.

2. **Sequential screening** discloses the results of first-trimester screening to women at highest risk, who are then offered invasive testing with chorionic villus sampling or amniocentesis. There are two testing strategies in this category:

   - With *stepwise sequential screening*, women with first-trimester screen results that confer risk for Down syndrome above a particular threshold are offered invasive testing, and the remaining women receive second-trimester screening. The threshold is set at approximately 1 percent, because in a screened population, the 1 percent at highest risk includes approximately 70 percent of Down syndrome pregnancies (Cuckle, 2005). This method of screening may achieve up to a 95-percent detection rate (see Table 14-5).

   - With *contingent sequential screening*, women are divided into high-, moderate-, and low-risk groups. Those at highest risk, for example, the top 1 percent, are offered invasive testing. Women at moderate risk, who comprise 15 to 20 percent of the population, undergo second-trimester screening. The remaining 80 to 85 percent, who are at or below a 1:1000 risk, receive negative screening test results and have no further testing (Cuckle, 2005). Thus, most of those screened are provided with results almost immediately while still maintaining a high detection rate. This rate ranges from 88 to 94 percent (see Table 14-5). This option is also more cost-effective because a second-trimester test is obviated in up to 85 percent of patients.

Integrated and sequential screening strategies require coordination between the provider and laboratory to ensure that the second sample is obtained during the appropriate gestational age window, sent to the same laboratory, and linked to the first-trimester results.

### Cell-Free Fetal DNA Screening

Using *massively parallel sequencing* or *chromosome selective sequencing* to isolate cell-free fetal DNA from maternal plasma, fetal Down syndrome and other autosomal trisomies may be detected as early as 10 weeks’ gestation (Chap. 13, p. 279). Recent trials of these techniques in high-risk pregnancies have yielded detection rates for trisomies 21, 18, and 13 of approximately 98 percent at a false-positive rate of 0.5 percent or less (American College of Obstetricians and Gynecologists, 2012b; Bianchi, 2012; Palomaki, 2011, 2012; Sparks, 2012). This novel technology has recently become clinically available as a screening test, but it is not considered a replacement diagnostic test. Pretest counseling is recommended. If an abnormal result is identified, genetic counseling should be performed, and invasive prenatal diagnostic testing should be offered to confirm the results. The American College of Obstetricians and Gynecologists (2012b) currently recommends that the test may be offered to the following groups:

   - Women 35 years or older at delivery
   - Those with sonographic findings indicating increased risk for fetal aneuploidy
   - Those with a prior pregnancy complicated by trisomy 21, 18, or 13
   - Patient or partner carries a balanced robertsonian translocation indicating increased risk for fetal trisomy 21 or 13
   - Those with an abnormal first-, second-, or combined first- and second-trimester screening test result for aneuploidy.
The College does not recommend offering the test to women with low-risk pregnancies or multifetal gestations (American College of Obstetricians and Gynecologists, 2012b).

**Sonographic Screening**

Major abnormalities and minor sonographic markers contribute significantly to aneuploidy detection. As shown in Table 14-6, with few exceptions, the aneuploidy risk associated with any major abnormality is high enough to warrant offering an invasive test for fetal karyotype and/or chromosomal microarray analysis (Chap. 13, p. 275). Importantly, a fetus with one abnormality may have others that are less likely to be detected sonographically or even undetectable sonographically but that greatly affect the prognosis nonetheless. Most fetuses with aneuploidy that is likely to be lethal in utero—such as trisomy 18 and 13 and triploidy—usually have sonographic abnormalities that can be seen by the second trimester. However, only 25 to 30 percent of second-trimester fetuses with Down syndrome will have a major malformation that can be identified sonographically (Vintzileos, 1995).

**Second-Trimester Sonographic Markers—“Soft Signs”**

For more than two decades, investigators have recognized that the sonographic detection of aneuploidy, particularly Down syndrome, may be improved by minor markers that are collectively
referred to as “soft signs.” Minor markers are normal variants rather than fetal abnormalities, and in the absence of aneuploidy or an associated abnormality, they do not significantly affect prognosis. Examples of these sonographic findings are listed in Table 14-7. Six of these markers have been the focus of genetic sonogram studies, in which likelihood ratios have been derived that allow a numerical risk to be calculated (Table 14-8). They are generally used only from 15 to 20 or 22 weeks’ gestation. The aneuploidy risk increases steeply with the number of markers identified.

### Table 14-8. Likelihood Ratios and False-Positive Rates for Isolated Second-Trimester Markers Used in Down Syndrome Screening Protocols
Unfortunately, at least 10 percent of unaffected pregnancies will have one of these soft signs, significantly limiting their utility for general population screening (Bromley, 2002; Nyberg, 2003). The incorporation of minor markers into second-trimester screening protocols has been studied primarily in high-risk populations. In this setting, detection rates of 50 to 75 percent for Down syndrome have been reported (American College of Obstetricians and Gynecologists, 2013c). With the exception of increased nuchal skinfold thickness, the identification of an isolated second-trimester marker in an otherwise low-risk pregnancy is not generally considered sufficient to warrant “high-risk” status. A metaanalysis concluded that if minor markers were used as a basis to decide whether to offer amniocentesis, more fetal losses would result than cases of Down syndrome identified (Smith-Bindman, 2001). The American College of Obstetricians and Gynecologists (2013c) recommends that risk adjustment based on second-trimester sonographic markers be limited to specialized centers.

The nuchal skinfold is measured in the transcerebellar view of the fetal head, from the outer edge of the skull to the outer border of the skin (Fig. 14-6A). A measurement ≥ 6 mm is typically considered abnormal (Benacerraf, 1985). This finding is present in approximately 1 per 200 pregnancies and confers a more than tenfold risk for Down syndrome (Bromley, 2002; Nyberg, 2001; Smith-Bindman, 2001). Unlike the other markers listed in Table 14-8, nuchal skinfold thickening should prompt targeted sonography and consideration of amniocentesis even as an isolated finding in an otherwise low-risk patient.

\(^a\)Higher in Asian individuals.

Data from Bromley, 2002; Nyberg, 2001; Smith-Bindman, 2001.
FIGURE 14-6 Minor sonographic markers that are associated with increased risk for fetal Down syndrome. **A.** Nuchal skinfold thickening (*bracket*). **B.** Echogenic intracardiac focus (*arrow*). **C.** Mild renal pelvis dilatation (pyelectasis) (*arrows*). **D.** Echogenic bowel (*arrow*). **E.** Clinodactyly—hypoplasia of the 5th finger middle phalanx creates an inward curvature (*arrow*). **F.** “Sandal-gap.”

An *echogenic intracardiac focus (EIF)* is a focal papillary muscle calcification that is neither a structural nor functional cardiac abnormality. It is usually left-sided (Fig. 14-6B). An EIF is present in approximately 4 percent of fetuses, but it may be found in up to 30 percent of Asian individuals (Shipp, 2000). As an isolated finding, an EIF approximately doubles the risk for fetal Down syndrome (see Table 14-8). Particularly if bilateral, they are also common with trisomy 13 (Nyberg, 2001).

As discussed in Chapter 10 (p. 214), mild *renal pelvis dilatation* is usually transient or physiological and does not represent an underlying abnormality (Nguyen, 2010). The renal pelves are measured in a transverse image of the kidneys, anterior-to-posterior, with calipers placed at the inner borders of the fluid collection (Fig. 14-6C). A measurement 4 mm or greater is found in about 2 percent of fetuses and approximately doubles the risk for Down syndrome (see Table 14-8). The degree of pelvic dilatation beyond 4 mm correlates with the likelihood of an underlying renal abnormality, and additional evaluation is generally performed at approximately 34 weeks (Chap. 10, p. 215).

*Echogenic fetal bowel* appears as bright as bone and is seen in approximately 0.5 percent of
pregnancies (Fig. 14-6D). Although typically associated with normal outcomes, it increases the risk for Down syndrome approximately sixfold (see Table 14-8). Echogenic bowel may represent small amounts of swallowed blood and may be seen in the setting of AFP level elevation (p. 287). It has also been associated with fetal cytomegalovirus infection and cystic fibrosis—representing inspissated meconium in the latter.

The femur and humerus are slightly shorter in Down syndrome fetuses, although the femur length to abdominal circumference (FL/AC) ratio is generally within the normal range in the second trimester. The femur is considered “short” for Down syndrome screening if it measures ≤ 90 percent of that expected. The expected femur length is that which correlates with the measured biparietal diameter (Benacerraf, 1987). Although this finding may be identified in approximately 4 percent of fetuses, its sensitivity may vary with ethnicity. As an isolated finding in an otherwise low-risk pregnancy, it is generally not considered to pose great enough risk to warrant counseling modification. Similarly, a humerus shortened to ≤ 89 percent of expected, based on a given biparietal diameter, has also been associated with an increased risk for Down syndrome (see Table 14-8).

First-Trimester Sonographic Findings
Unlike second-trimester soft signs, which may be readily visible during a standard sonogram, first-trimester findings associated with aneuploidy require specialized training. The fetal NT is unique in that it has become a component of aneuploidy screening offered to all women. Other first-trimester findings associated with an increased risk for fetal Down syndrome include an absent fetal nasal bone, wider frontomaxillary facial angle—indicating a flat facial profile, tricuspid regurgitation, and abnormal ductus venosus flow (Borenstein, 2008; Cicero, 2001; Faiola, 2005; Huggon, 2003; Matias, 1998; Sonek, 2007). Each has also been associated with an increased risk for trisomies 18 and 13 and other aneuploidies. However, these signs have not become widely adopted for routine use in the United States.

Fetal Nasal Bone. In approximately two thirds of fetuses with Down syndrome, the nasal bone is not visible at the 11- to 14-week examination (Cicero, 2004; Rosen, 2007; Sonek, 2006). Currently, this is the only first-trimester marker, other than NT, for which the Nuchal Translucency Quality Review Program has established a training program. Criteria for adequate assessment include that the fetus occupies most of the image; that there be a 45-degree angle of insonation with the fetal profile; that the profile be well defined in the midsagittal plane, with the tip of the nose and the third and fourth ventricles visible; and that the nasal bone brightness be greater than or equal to that of the overlying skin (Nuchal Translucency Quality Review Program, 2013). An example is shown in Figure 14-5. Initial optimism for this marker was somewhat dampened when the FASTER (First- and Second-Trimester Evaluation of Risk) trial concluded that difficulty in performing the assessment would limit its usefulness for aneuploidy screening (Malone, 2004, 2005a).

PREGNANCIES AT INCREASED RISK FOR GENETIC DISORDERS
Couples with a personal or family history of a heritable genetic disorder should be offered genetic counseling. They should be given an estimated risk of having an affected infant and provided
information concerning benefits and limitations of available prenatal testing options. As discussed in Chapter 13 (p. 260), the publicly funded GeneTests website contains detailed information regarding hundreds of specific genetic conditions and laboratory testing information for more than 3000 genetic disorders (http://www.ncbi.nlm.nih.gov/sites/GeneTests). Prenatal diagnosis may be available if the disease-causing mutation or mutations are known. That said, many genetic disorders are characterized by a high degree of penetrance but variable expressivity, such that prediction of phenotype—even when family members are affected—is not currently possible. Common examples include neurofibromatosis, tuberous sclerosis, and Marfan syndrome. There are also conditions for which risk may be refined by detection of associated sonographic abnormalities or by gender determination if X-linked.

Ethnicity-based carrier screening is performed for certain autosomal recessive disorders that are found with increased frequency in specific racial or ethnic groups (Table 14-9). When an otherwise rare gene is found with increased frequency within a certain population and can be traced back to a single family member or small group of ancestors, it is called the founder effect. This phenomenon may occur when generations of individuals procreate only within their own groups because of religious or ethnic prohibitions or geographical isolation. Carrier screening should be offered to those at increased risk for selected autosomal recessive conditions, either prior to conception or early in pregnancy.

**Cystic Fibrosis**

This disorder is caused by a mutation in the cystic fibrosis conductance transmembrane regulator (CFTR) gene, which is located on the long arm of chromosome 7 and encodes a chloride-channel protein. Although the most common CFTR gene mutation associated with classic cystic fibrosis (CF) is the ΔF508 mutation, more than 1900 mutations have been identified (Cystic
Cystic fibrosis may be caused by either **homozygosity** or **compound heterozygosity** for mutations in the CFTR gene. In other words, one mutation must be present in each copy of the gene, but they need not be the same mutation. As expected, this results in a tremendous range of clinical disease severity. Median survival is approximately 37 years, but approximately 15 percent have a milder disease form and can survive for decades longer (American College of Obstetricians and Gynecologists, 2011). Care for the pregnant woman with CF is discussed in Chapter 51 (p. 1022).

The current screening panel contains 23 panethnic CF gene mutations, selected because they are present in at least 0.1 percent of patients with classic CF (American College of Obstetricians and Gynecologists, 2011). The CF carrier frequency is approximately 1 in 25 in non-Hispanic white Americans and those of Ashkenazi Jewish descent, who are from Eastern Europe. Thus, the incidence of CF in a child born to a non-Hispanic white couple is approximately $\frac{1}{4} \times \frac{1}{25} \times \frac{1}{25}$, or 1:2500. As shown in Table 14-10, both CF incidence and the sensitivity of the screening test are lower for other ethnicities.

From American College of Obstetricians and Gynecologists, 2011, with permission.

Current recommendations for CF carrier screening from the American College of Obstetricians and Gynecologists (2011) are as follows:

- Information regarding CF carrier screening should be made available to all couples presenting for preconceptional counseling or prenatal care.
- When both partners are from a high-risk ethnicity, carrier screening should be offered before conception or early in pregnancy.
- Acknowledging that it is becoming increasingly difficult to assign individuals a single ethnicity, it is reasonable to offer CF carrier screening to patients of all ethnicities.
- For individuals with a family or personal history of CF, screening with an expanded mutation panel or even complete CFTR gene sequencing may be necessary if not already obtained.
Although a negative screening test result does not preclude the possibility of carrying a less-common mutation, it reduces the risk substantively from the background rate (see Table 14-10). If both parents are carriers, the fetus can be tested using chorionic villus sampling or amniocentesis to determine whether he or she has inherited one or both of the parental mutations. Counseling following identification of two disease-causing mutations is challenging, because phenotype prediction is reasonably accurate only for pancreatic disease, and only then for well-characterized mutations. Prognosis depends most on degree of pulmonary disease, which varies considerably even among individuals with the most common genotype associated with classic disease, that is, those homozygous for the ΔF508 mutation. This likely reflects the effect of genetic modifiers on protein function, which may further vary depending on CFTR mutation and on exposure and susceptibility to environmental factors (Cutting, 2005; Drumm, 2005).

### Sickle Hemoglobinopathies

This group includes sickle-cell anemia, sickle-cell hemoglobin C disease, and sickle-cell β-thalassemia. Sickle-cell anemia is the most common inherited life-shortening disease of childhood onset in the United States. Normal adult hemoglobin consists of two α-chains and two β-chains. As discussed in Chapter 56 (p. 1107), hemoglobin S results from a single point mutation in the gene that encodes the β-chain. A heterozygous individual has one copy each of hemoglobin A and S, that is, hemoglobin AS or sickle-cell trait. A homozygous individual inherits one copy of hemoglobin S from each parent to express hemoglobin SS or sickle-cell anemia. Hemoglobin C is inherited in a similar manner and SC disease results from one copy each of hemoglobin S and C.

African and African American patients are at increased risk to carry hemoglobin S and other hemoglobinopathies and should be offered preconceptional or prenatal screening. One in 12 African Americans has sickle-cell trait, one in 40 carries hemoglobin C, and one in 40 carries the trait for β-thalassemia. Hemoglobin S is also more common among individuals of Mediterranean, Middle Eastern, and Asian Indian descent (Davies, 2000). The American College of Obstetrician and Gynecologists (2013a) recommends that patients of African descent be offered hemoglobin electrophoresis. If a couple is at risk to have a child with a sickle hemoglobinopathy, genetic counseling should be offered. Prenatal diagnosis can be performed with either chorionic villus sampling or amniocentesis.

### Thalassemias

These syndromes are the most common single-gene disorders worldwide, and up to 200 million people carry a gene for one of these hemoglobinopathies. Some individuals with thalassemia have microcytic anemia secondary to decreased synthesis of either α- or β-hemoglobin chains. In general, deletions of α-globin chains cause α-thalassemia, whereas mutations in β-globin chains cause β-thalassemia. Less commonly, an α-globin chain mutation also causes α-thalassemia. Care for the pregnant woman with thalassemia is discussed in Chapter 56 (p. 1112).

### Alpha-Thalassemia

The number of α-globin genes that are deleted may range from one to all four. If two α-globin genes are deleted, both may be deleted from the same chromosome—cis configuration (αα/–), or one may be deleted from each chromosome—trans configuration (α-/α-). Alpha-thalassemia trait is common among individuals of African, Mediterranean, Middle Eastern, West Indian, and...
Southeast Asian descent and results in mild anemia. The *cis* configuration is more prevalent among Southeast Asians, whereas those of African descent are more likely to inherit the *trans* configuration. The clinical significance of this difference is that when both parents carry *cis* deletions, offspring are at risk for the absence of α-hemoglobin, called Hb Barts disease, which typically leads to hydrops and fetal loss (Chap. 15, p. 315).

Detection of α-thalassemia or α-thalassemia trait is based on molecular genetic testing and is not detectable using hemoglobin electrophoresis. Because of this, routine carrier screening is not offered. If there is microcytic anemia in the absence of iron deficiency, and the hemoglobin electrophoresis is normal, then testing for α-thalassemia should be considered, particularly among individuals of Southeast Asian descent (American College of Obstetricians and Gynecologists 2013a).

**Beta-Thalassemia**

Mutations in β-globin genes may cause reduced or absent production of β-globin chains. If the mutation affects one gene, it results in β-thalassemia minor. If both copies are affected, the result is either β-thalassemia major—termed Cooley anemia—or β-thalassemia intermedia. Because of reduced production of hemoglobin A among carriers, electrophoresis demonstrates elevation of hemoglobins that do not contain β-chains, including hemoglobins F and A₂.

Beta-thalassemia minor is more common among individuals of African, Mediterranean, and Southeast Asian descent. The American College of Obstetricians and Gynecologists (2013a) recommends that they be offered carrier screening with hemoglobin electrophoresis, particularly if found to have microcytic anemia in the absence of iron deficiency. Hemoglobin A₂ levels exceeding 3.5 percent confirm the diagnosis. Other ethnicities at increased risk include those of Middle Eastern, West Indian, and Hispanic descent.

**Tay-Sachs Disease**

This autosomal recessive lysosomal-storage disease is characterized by absence of the hexosaminidase A enzyme. This leads to a buildup of GM2 gangliosides in the central nervous system, progressive neurodegeneration, and death in early childhood. Affected individuals have almost complete absence of the enzyme, whereas carriers are asymptomatic but have less than 55-percent hexosaminidase A activity. The carrier frequency of Tay-Sachs disease in Jewish individuals of Eastern European (Ashkenazi) descent is approximately 1 in 30, but it is much lower, only about 1 in 300, in the general population. Other groups at increased risk for Tay-Sachs disease include those of French-Canadian and Cajun descent. An international Tay-Sachs carrier-screening campaign was initiated in the 1970s and met with unprecedented success in the Ashkenazi Jewish population. The incidence of Tay-Sachs disease subsequently declined more than 90 percent (Kaback, 1993). Most cases of Tay-Sachs now occur in non-Jewish individuals.

The American College of Obstetricians and Gynecologists (2010) has the following screening recommendations for Tay-Sachs disease:

- Screening should be offered before pregnancy if both members of a couple are of Ashkenazi Jewish, French-Canadian, or Cajun descent, or if there is a family history of Tay-Sachs disease.
- When only one member of the couple is of one of the above ethnicities, the high-risk partner may be screened first, and if found to be a carrier, the other partner also should be offered screening. If the couple is already pregnant, then both partners may be screened simultaneously.
- Targeted mutation analysis of the *HEXA* gene has a sensitivity of 94 percent in Ashkenazi Jewish
individuals but is not recommended for screening in low-risk groups because the detection rate may be below 50 percent.

- Biochemical analysis by determining the hexosaminidase A serum level has a sensitivity of 98 percent and is the test that should be performed in individuals from low-risk ethnicities. **Leukocyte testing** must be used if the woman is already pregnant or taking oral contraceptives.
- Ambiguous or positive screening test results should be confirmed by biochemical and DNA analysis for the most common mutation. This will detect patients who carry genes associated with mild disease or pseudodeficiency states. Referral to a genetics specialist may be helpful in such cases.
- If both partners are found to be carriers of Tay-Sachs disease, genetic counseling and prenatal diagnosis should be offered. Hexosaminidase activity may be measured from chorionic villus sampling or amniocentesis specimens.

### Other Recessive Diseases in Ashkenazi Jewish Individuals

The carrier rate among individuals of Eastern European (Ashkenazi) Jewish descent is approximately 1 in 30 for Tay-Sachs disease, 1 in 40 for Canavan disease, and 1 in 32 for familial dysautonomia. Fortunately, the detection rate of screening tests for each is at least 98 percent in this population. Because of their relatively high prevalence and consistently severe and predictable phenotype, the American College of Obstetricians and Gynecologists (2009a) recommends that carrier screening for these three conditions be offered to Ashkenazi Jewish individuals, either before conception or during early pregnancy. In addition, other conditions for which carrier screening should be made available include mucolipidosis IV, Niemann-Pick disease type A, Fanconi anemia group C, Bloom syndrome, and Gaucher disease. Features of these conditions are shown in **Table 14-11**. Gaucher disease differs from the other conditions listed in that it has a wide range in phenotype—from childhood illness to absence of symptoms throughout life. Also, there is effective treatment available in the form of enzyme therapy (Zuckerman, 2007).

The American College of Obstetricians and Gynecologists (2009a) has the following recommendations for carrier screening:

• When only one partner is of Ashkenazi Jewish descent, that individual should be screened first, and if found to be a carrier, the other partner is offered screening. With the exception of cystic fibrosis and Tay-Sachs disease, the carrier frequency and detection rate for each of the conditions listed in Table 14-11 is unknown.

• Individuals with a positive family history of one of these disorders should be offered carrier screening for it and may benefit from genetic counseling.

• When both partners are carriers of one of these disorders, they should be referred for genetic counseling and offered prenatal diagnosis.

• When a carrier is identified, they should be encouraged to inform relatives at risk for carrying the same mutation.

Non-Jewish carrier frequency and detection rates are unknown except for Tay-Sachs disease and cystic fibrosis.

†CFTR = cystic fibrosis transmembrane conductance regulator; IKBKAP = inhibitor of kappa light polypeptide gene enhancer in B-cells, kinase complex-associated protein.

Data from the American College of Obstetricians and Gynecologists, 2009a, 2010; National Institute of Neurological Disorders and Stroke, 2012a-d.

Prenatal and Preimplantation Diagnostic Testing
Invasive procedures used in prenatal diagnosis—amniocentesis, chorionic villus sampling, and fetal blood sampling—enable a vast array of sophisticated genetic diagnoses to be made before birth. Preimplantation genetic diagnosis permits similar diagnoses to be made in oocytes or embryos before implantation.

Improvements in aneuploidy screening tests during the past decade as described in the preceding section have resulted in a significant decrease in the number of prenatal diagnostic procedures. In a study of more than 160,000 pregnant women 35 years and older, patient acceptance of amniocentesis procedures decreased from 56 to 36 percent between 2001 and 2008, while that of chorionic villus sampling decreased from 36 to 24 percent (Nakata, 2010). Fetal blood sampling procedures have also decreased, but for different reasons. Namely, amniocentesis with fluorescence in situ hybridization (FISH) has decreased the need for rapid karyotyping from fetal blood (Chap. 13, p. 276); the number of DNA-based tests performed on amnionic fluid has greatly expanded; and fetal middle cerebral artery Doppler studies have improved the accuracy of fetal anemia detection (Chap. 10, p. 221).

Amniocentesis

Transabdominal withdrawal of amnionic fluid remains the most common procedure used to diagnose fetal aneuploidy and other genetic conditions. It is generally performed between 15 and 20 weeks’ gestation but may be performed later as well. The indication is usually to assess fetal karyotype, although use of FISH and array-based comparative genomic hybridization studies have increased considerably as discussed in Chapter 13 (p. 275). Because the amniocytes must be cultured before fetal karyotype can be assessed, the time needed for karyotyping is 7 to 10 days. Outside the context of prenatal genetic analysis, amnionic fluid occasionally may be removed in large amounts therapeutically to relieve symptomatic hydramnios (Chap. 11, p. 236). The same technique described next is also used for this indication.

Technique

Amniocentesis is performed using aseptic technique, under direct sonographic guidance, using a 20- to 22-gauge spinal needle (Fig. 14-7). A standard spinal needle is approximately 9 cm long, and depending on patient habitus, a longer needle may be required. The needle is directed into a clear pocket of amnionic fluid, while avoiding the fetus and umbilical cord and ideally without traversing the placenta. Efforts are made to puncture the chorioamnion rather than to “tent” it away from the underlying uterine wall. Discomfort from the procedure is considered minor, and local anesthetic is not typically used (Mujezinovic, 2011).
The volume of fluid generally needed for commonly performed analyses is shown in Table 14-12. Because the initial 1 to 2 mL of fluid aspirate may be contaminated with maternal cells, it is generally discarded. Approximately 20 mL of fluid is then collected for fetal chromosomal analysis before removing the needle. Sonography is used to observe the uterine puncture site for bleeding, and fetal cardiac motion is documented at the end of the procedure. If the patient is Rh D-negative and unsensitized, anti-D immune globulin is administered following the procedure (Chap. 15, p. 311).

The color and clarity of the fluid are documented. Amnionic fluid should be clear and colorless or pale yellow. Blood-tinged fluid is more frequent if there is transplacental passage of the needle, however, it generally clears with continued aspiration. The placenta is attached to the anterior uterine wall in approximately half of pregnancies, and if this is the case, it will be traversed by the needle about 60 percent of the time (Bombard, 1995). Fortunately, this has not been associated with pregnancy loss (Marthin, 1997). Dark brown or greenish fluid may represent a past episode of intraamnionic bleeding.

### Amniocentesis in Multifetal Pregnancy

For twin gestations, a small quantity of dilute indigo carmine dye is often injected before removing the needle from the first sac. This can be accomplished using 2 mL of a solution in which 1 mL of indigo carmine has been diluted in 10 mL of sterile saline. When the second sac is entered, the return of clear amnionic fluid verifies needle positioning within the second sac. Methylene blue dye is contraindicated because it has been associated with jejunal atresia and neonatal methemoglobinemia (Cowett, 1976; van der Pol, 1992). Because isolated cases of jejunal atresia have also been reported following use of indigo carmine dye, it has been suggested that sonographic visualization should be clear enough to avert the need for dye (Brandenburg, 1997).

### Complications

The procedure-related loss rate following midtrimester amniocentesis is considered to be 1 per 300 to 500 (American College of Obstetricians and Gynecologists, 2012a). The loss rate may be doubled in women with class 3 obesity—those with a body mass index (BMI) ≥ 40 kg/m² (Harper, 2012). In twin pregnancies, Cahill and coworkers (2009) reported an increased loss rate attributable to amniocentesis of 1.8 percent. Some losses are unrelated to the procedure and instead are due to abnormal placental implantation or abortion, uterine abnormalities, fetal anomalies, or infection. Wenstrom and colleagues (1990) analyzed 66 fetal deaths following nearly 12,000 second-trimester amniocenteses and found that 12 percent were caused by...
preexisting intrauterine infection.

Other complications of amniocentesis include amnionic fluid leakage in 1 to 2 percent and chorioamnionitis in less than 0.1 percent (American College of Obstetricians and Gynecologists 2012a). Following leakage of amnionic fluid, which generally occurs within 48 hours of the procedure, fetal survival exceeds 90 percent (Borgida, 2000). Needle injuries to the fetus are rare. Amnionic fluid culture is successful in more than 99 percent of cases, although cells are less likely to grow if the fetus is abnormal (Persutte, 1995).

Early Amniocentesis
If performed between 11 and 14 weeks, amniocentesis is termed “early.” The technique is the same as for traditional amniocentesis, although sac puncture may be more challenging due to lack of membrane fusion to the uterine wall. Also, less fluid is typically withdrawn—approximately 1 mL for each gestational week (Shulman, 1994; Sundberg, 1997).

Early amniocentesis is associated with significantly higher rates of procedure-related complications than other fetal procedures. In the Canadian Early and Mid-Trimester Amniocentesis Trial (1998) that involved more than 4000 women undergoing early amniocentesis, rates of amnionic fluid leakage, fetal loss, and talipes equinovarus (clubfoot) were all significantly higher following early amniocentesis than with traditional amniocentesis. Compared with chorionic villus sampling, early amniocentesis was similarly found to be associated with a fourfold increased rate of talipes equinovarus (Philip, 2004). Another problem with early amniocentesis is that the cell culture failure rate is higher, thus necessitating a second procedure. For all these reasons, the American College of Obstetricians and Gynecologists (2012a) recommends against the use of early amniocentesis.

Chorionic Villus Sampling (CVS)

Biopsy of chorionic villi is generally performed between 10 and 13 weeks’ gestation. Although most procedures are performed to assess fetal karyotype, numerous specialized genetic tests can also be performed by chorionic villus sampling (CVS). Very few analyses specifically require either amnionic fluid or placental tissue. The primary advantage of villus biopsy is that results are available earlier in pregnancy, allowing safer pregnancy termination, if desired. A full karyotype is available in 7 to 10 days, and some laboratories provide preliminary results within 48 hours.

Technique
Chorionic villi may be obtained transcervically or transabdominally, using aseptic technique. Both approaches are considered equally safe and effective (American College of Obstetricians and Gynecologists, 2012a; Jackson, 1992). Transcervical villus sampling is performed using a specifically designed catheter made from flexible polyethylene that contains a blunt-tipped, malleable stylet. Transabdominal sampling is performed using an 18- or 20-gauge spinal needle. With either technique, transabdominal sonography is used to guide the catheter or needle into the early placenta—chorion frondosum, followed by aspiration of villi into a syringe containing tissue culture media (Fig. 14-8). Fetal cardiac motion is documented following the procedure.
Relative contraindications include vaginal bleeding or spotting, active genital tract infection, extreme uterine ante- or retroflexion, or body habitus precluding adequate visualization. If the patient is Rh D-negative and unsensitized, anti-D immune globulin is administered following the procedure as discussed in Chapter 15 (p. 311).

**Complications**

The overall loss rate following CVS is higher than that following midtrimester amniocentesis because of background spontaneous losses, that is, those that would have occurred between the first and second trimester in the absence of a fetal procedure. The procedure-related fetal loss rate is comparable to that with amniocentesis (American College of Obstetricians and Gynecologists 2012a). Caughey and colleagues (2006) found that the overall loss rate following CVS was approximately 2 percent compared with less than 1 percent following amniocentesis. However, the adjusted procedure-related loss rate was about 1 per 400 for either procedure. The indication for CVS will also affect the loss rate. For example, fetuses with increased nuchal translucency thickness have a higher likelihood of demise. Finally, there is a “learning curve” effect associated with safe performance of CVS (Silver, 1990; Wijnberger, 2003).

An early problem with CVS was its association with limb-reduction defects and oromandibular limb hypogenesis (Burton, 1992; Firth, 1991, 1994; Hsieh, 1995). These were subsequently found to be associated with procedures performed at 7 weeks’ gestation (Holmes, 1993). When performed at ≥ 10 weeks’ gestation, as is commonly done today, the incidence of limb defects does not exceed the background rate of 1 per 1000 (Evans, 2005; Kuliev, 1996).

Vaginal spotting is not uncommon following transcervical sampling, but it is self-limited and not associated with pregnancy loss. The incidence of infection is less than 0.5 percent (American College of Obstetricians and Gynecologists, 2012a).
A limitation of CVS is that chromosomal mosaicism is identified in up to 2 percent of specimens. In most cases, the mosaicism reflects confined placental mosaicism rather than a true second cell line within the fetus. Amniocentesis should be offered, and if the result is normal, the mosaicism is presumed to be confined to the placenta. Confined placental mosaicism has been associated with fetal-growth impairment and stillbirth.

**Fetal Blood Sampling**

This procedure is also called cordocentesis or percutaneous umbilical blood sampling (PUBS). It was initially described for fetal transfusion of red blood cells in the setting of anemia from alloimmunization, as discussed in Chapter 15 (p. 310), and fetal anemia assessment remains the most common indication. Fetal blood sampling is also performed for assessment and treatment of platelet alloimmunization and for fetal karyotype determination, particularly in cases of mosaicism identified following amniocentesis or CVS. Fetal blood karyotyping can be accomplished within 24 to 48 hours. Thus, it is significantly quicker than the 7- to 10-day turnaround time with amniocentesis or CVS. Although fetal blood can be analyzed for virtually any test performed on neonatal blood, improvements in tests available with amniocentesis and CVS have eliminated the need for fetal venipuncture in most cases (Society for Maternal-Fetal Medicine, 2013).

**Technique**

Under direct sonographic guidance, using aseptic technique, the operator introduces a 22- or 23-gauge spinal needle into the umbilical vein, and blood is slowly withdrawn into a heparinized syringe. Adequate visualization of the needle is essential. As with amniocentesis, a longer needle may be required depending on patient habitus. Fetal blood sampling is often performed near the placental cord insertion site, where it may be easier to enter the cord if the placenta is anterior (Fig. 14-9). Alternatively, a free loop of cord may be punctured. Because fetal blood sampling requires more time than other fetal procedures, a local anesthetic may be administered. Prophylactic antibiotics are used at some centers, although there are no trials to support this policy. Arterial puncture is avoided, because it may result in vasospasm and fetal bradycardia. After the needle is removed, fetal cardiac motion is documented, and the site is observed for bleeding.
Complications

The procedure-related fetal loss rate following fetal blood sampling is approximately 1.4 percent (Ghidini, 1993; Maxwell, 1991; Tongsong 2001). The actual loss rate varies according to the procedure indication and the fetal status. Other complications may include cord vessel bleeding in 20 to 30 percent of cases, fetal-maternal bleeding in approximately 40 percent of cases in which the placenta is traversed, and fetal bradycardia in 5 to 10 percent (Boupaijit, 2012; Ghidini, 1993; Society for Maternal-Fetal Medicine, 2013). Most complications are transitory, with complete recovery, but some result in fetal loss.

In a series of more than 2000 procedures comparing fetal blood sampling near the placental cord insertion site with puncture of a free loop, there were no differences in rates of procedure success, pregnancy loss, visible bleeding from the cord, or fetal bradycardia. Time to complete the procedure was significantly shorter if the cord was sampled at the placental insertion site rather than at a free loop—5 versus 7 minutes. However, sampling at the insertion site had a higher rate of maternal blood contamination (Tangshewinsirikul, 2011).
For couples undergoing in vitro fertilization (IVF), genetic testing performed on oocytes or embryos before implantation may provide valuable information regarding the chromosomal complement and single-gene disorders. There are two separate categories of testing—preimplantation genetic diagnosis and preimplantation genetic screening—each with different indications. Comprehensive genetic counseling is required before consideration of these procedures. There are three techniques that are used for both categories of preimplantation genetic testing:

1. **Polar body analysis** is a technique used to infer whether a developing oocyte is affected by a maternally inherited genetic disorder. The first and second polar bodies are normally extruded from the developing oocyte following meiosis I and II, and their sampling should not affect fetal development (Fig. 5-8, p. 89). In one recent series, this technique was used to diagnose 146 mendelian disorders, with reported accuracy exceeding 99 percent. The main disadvantages of polar body analysis are that the paternal genetic contribution is not evaluated and that an additional procedure may be required in complex cases (Kuliev, 2011).

2. **Blastomere biopsy** is done at the 6- to 8-cell (cleavage) stage when an embryo is 3 days old, and it is the technique most commonly used for preimplantation testing. One cell is typically removed through a hole made in the zona pellucida, as shown in Figure 14-10. The technique is associated with a 10-percent reduction in the pregnancy rate (Mastenbroek, 2007, 2011; Simpson, 2012). As discussed subsequently, a particular limitation of using this technique for aneuploidy assessment is that mosaicism of the blastomeres may not reflect the chromosomal complement of the developing embryo (American Society for Reproductive Medicine, 2008).

3. **Trophectoderm biopsy** involves removal of 5 to 7 cells from a 5- to 6-day blastocyst (Fig. 14-11). An advantage is that because the trophectoderm cells give rise to the trophoblast—the placenta—no cells are removed from the developing embryo. Disadvantageously, because the procedure is performed later in development, if genetic analysis cannot be performed rapidly, then cryopreservation and embryo transfer during a later IVF cycle may be required.
Preimplantation Genetic Diagnosis (PGD)

A genetic abnormality—rather than infertility—may be the reason why a couple has elected IVF. When either or both members of a couple are known carriers of a specific genetic disease or a
balanced chromosomal rearrangement, preimplantation genetic diagnosis (PGD) may be performed to determine if an oocyte or embryo has the defect (American Society for Reproductive Medicine 2008). Only embryos without the abnormality would be implanted.

This procedure has a vast number of applications. It is used to diagnose single-gene disorders such as cystic fibrosis, β-thalassemia, and hemophilia; to determine gender in X-linked diseases; to identify mutations such as BRCA-1 that do not cause disease but confer significantly increased risk; and to match human leukocyte antigens for umbilical cord stem cell transplantation for a sibling (de Wert, 2007; Flake, 2003; Fragouli, 2007; Grewal, 2004; Jiao, 2003; Rund, 2005; Xu 2004).

To determine whether the known carrier has transmitted a specific genetic mutation, polymerase chain reaction (PCR) is used to amplify the genome region containing the segment of interest (Chap. 13, p. 277). If PGD is performed to identify a translocation or other structural chromosomal rearrangement carried by either parent, FISH is typically used. Because typically only one or two cells are available for analysis and because a rapid completion time is essential, this procedure is technically challenging. Risks include failure to amplify the genetic region of interest, selection of a cell that does not contain a nucleus, and maternal cell contamination. Infrequently, affected embryos thought to be normal are implanted, and unaffected embryos are misdiagnosed as abnormal and discarded. Because of this, the American Society for Reproductive Medicine (2008) encourages further prenatal diagnostic testing—either CVS or amniocentesis—to confirm PGD results.

Preimplantation Genetic Screening (PGS)
This term is used for aneuploidy screening that is performed on oocytes or embryos before IVF transfer. Such screening is used with couples who are not known to have or carry a genetic abnormality. Although preimplantation screening has obvious theoretical advantages, it has faced significant challenges in practice.

Most commonly, FISH is used to identify the copy number of selected chromosomes, and it is performed on a single blastomere (American Society for Reproductive Medicine, 2008). Because the number of chromosome pairs per cell nucleus that can be evaluated with FISH is limited efforts have also focused on the use of chromosomal microarray analysis (Chap. 13, p. 277). Mosaicism is common in cleavage-stage embryo blastomeres, and it may not be clinically significant because it often does not reflect the actual embryonic chromosomal complement (American College of Obstetricians and Gynecologists, 2009b). In addition, among women 35 years or older, pregnancy rates following preimplantation screening are significantly lower than those observed following IVF without it (Mastenbroek, 2007, 2011). For these reasons, the American College of Obstetricians and Gynecologists (2009b) recommends against use of preimplantation screening with FISH for advanced maternal age screening. It also recommends against it for women with recurrent pregnancy loss or recurrent implantation failure outside the setting of a research trial.

Fetal Disorders

FETAL ANEMIA

RED CELL ALLOIMMUNIZATION

FETOMATERNAL HEMORRHAGE

FETAL THROMBOCYTOPENIA

HYDROPS FETALIS

Fetal disorders may be acquired—such as alloimmunization, they may be genetic—congenital adrenal hyperplasia or α4-thalassemia, or they may be sporadic developmental abnormalities—like many structural malformations. Reviewed in this chapter are fetal anemia and thrombocytopenia, along with immune and nonimmune fetal hydrops. Hydrops is perhaps the quintessential fetal disorder, as it can be a manifestation of severe illness from a wide variety of etiologies. Fetal structural malformations are reviewed in Chapter 10; genetic abnormalities are reviewed in Chapters 13 and 14; and other conditions amenable to fetal medical and surgical treatment are reviewed in Chapter 16. Because congenital infections arise as a result of maternal infection or colonization, they are considered in Chapters 64 and 65.

FETAL ANEMIA

Of the many causes of fetal anemia, the most common is red cell alloimmunization, which results from transplacental passage of maternal antibodies that destroy fetal red cells. Alloimmunization leads to overproduction of immature fetal and neonatal red cells—erythroblastosis fetalis—a condition now referred to as hemolytic disease of the fetus and newborn (HDFN). Several congenital infections are also associated with fetal anemia, particularly parvovirus B19, discussed in Chapter 64 (p. 1244). In Southeast Asian populations, α4-thalassemia is a common cause of severe anemia and nonimmune hydrops. Fetomaternal hemorrhage occasionally creates severe fetal anemia and is discussed on page 312. Rare causes of anemia include red cell production disorders—such as Blackfan-Diamond anemia and Fanconi anemia; red cell enzymopathies—glucose-6-phosphate dehydrogenase deficiency and pyruvate kinase deficiency; red cell structural abnormalities—hereditary spherocytosis and elliptocytosis; and myeloproliferative disorders—leukemias. Anemia may be identified through fetal blood sampling as described in
Chapter 14 (p. 300) or by Doppler evaluation of the fetal middle cerebral artery (MCA) peak systolic velocity as described on page 310.

Progressive fetal anemia from any cause leads to heart failure, hydrops fetalis, and ultimately death. Fortunately, the prevention of Rh D alloimmunization with anti-D immune globulin, and the identification and treatment of fetal anemia with MCA Doppler studies and intrauterine transfusions, respectively, have dramatically changed the prevalence and course of this otherwise devastating disorder. Severely anemic fetuses transfused in utero have survival rates exceeding 90 percent, and even in cases of hydrops fetalis, survival rates approach 80 percent (Lindenburg, 2013; van Kamp, 2001).

Red Cell Alloimmunization

There are currently 30 different blood group systems and 328 red cell antigens recognized by the International Society of Blood Transfusion (Storry, 2011). Although some of these are immunologically and genetically important, many are so rare as to be of little clinical significance. Any individual who lacks a specific red cell antigen may produce an antibody when exposed to that antigen. Such antibodies can prove harmful to that individual if she receives an incompatible blood transfusion, and they may be harmful to her fetus during pregnancy. Accordingly, blood banks routinely screen for erythrocyte antigens. These antibodies may also be harmful to a mother’s fetus during pregnancy. As noted, maternal antibodies formed against fetal erythrocyte antigens may cross the placenta to cause fetal red cell lysis and anemia.

Typically, a fetus inherits at least one red cell antigen from the father that is lacking in the mother. Thus, the mother may become sensitized if enough fetal erythrocytes reach her circulation to elicit an immune response. Even so, alloimmunization is uncommon for the following reasons: (1) low prevalence of incompatible red cell antigens; (2) insufficient transplacental passage of fetal antigens or maternal antibodies; (3) maternal-fetal ABO incompatibility, which leads to rapid clearance of fetal erythrocytes before they elicit an immune response; (4) variable antigenicity; and (5) variable maternal immune response to the antigen.

In population-based screening studies, the prevalence of red cell alloimmunization in pregnancy is approximately 1 percent (Howard, 1998; Koelewijn, 2008). Most cases of severe fetal anemia requiring antenatal transfusion are attributable to anti-D, anti-Kell, or anti-c alloimmunization.

Alloimmunization Detection

A blood type and antibody screen are routinely assessed at the first prenatal visit, and unbound antibodies in maternal serum are detected by the indirect Coombs test (Chap. 9, p. 174). With positive results, specific antibodies are identified, their immunoglobulin subtype is determined as either IgG or IgM, and the titer is quantified. Only IgG antibodies are of concern because IgM antibodies do not cross the placenta. Selected antibodies and their potential to cause fetal hemolytic anemia are listed in Table 15-1. The critical titer is the level at which significant fetal anemia could potentially develop. This may be different for each antibody, is determined individually by each laboratory, and usually ranges between 1:8 and 1:32. If the critical titer for anti-D antibodies is 1:16, a titer ≥ 1:16 indicates the possibility of severe hemolytic disease. An important exception is Kell sensitization, which is discussed on page 308.

**CDE (Rh) Blood Group Incompatibility**

The rhesus system includes five red cell proteins or antigens: C, c, D, E, and e. No “d” antigen has
been identified, and Rh D-negativity is defined as the absence of the D antigen. Although most people are Rh D positive or negative, more than 200 D antigen variants exist (Daniels, 2013).

CDE antigens are clinically important. Rh D-negative individuals may become sensitized after a single exposure to as little as 0.1 mL of fetal erythrocytes (Bowman, 1988). The two responsible genes—RHD and RHCE—are located on the short arm of chromosome 1 and are inherited together, independent of other blood group genes. Their incidence varies according to racial and ethnic origin. Nearly 85 percent of non-Hispanic white Americans are Rh D-positive, as are approximately 90 percent of Native Americans, 93 percent of African Americans and Hispanic Americans, and 99 percent of Asian individuals (Garratty, 2004).

The prevalence of Rh D alloimmunization complicating pregnancy ranges from 0.5 to 0.9 percent (Howard, 1998; Koelewijn, 2008; Martin, 2005). Without anti-D immune globulin prophylaxis, an Rh D-negative woman delivered of an Rh D-positive, ABO-compatible infant has a 16-percent likelihood of developing alloimmunization. Two percent will become sensitized by the time of delivery, 7 percent by 6 months postpartum, and the remaining 7 percent will be “sensibilized”—producing detectable antibodies only in a subsequent pregnancy (Bowman, 1985). If there is ABO incompatibility, the Rh D alloimmunization risk is approximately 2 percent without prophylaxis (Bowman, 2006). The reason for the differing rates relative to ABO blood type results from erythrocyte destruction of ABO-incompatible cells and thus limitation of sensitizing opportunities. Rh D sensitization also may occur following first-trimester pregnancy complications, prenatal diagnostic procedures, and maternal trauma (Table 15-2).

For each of the above, anti-D immune globulin is recommended.

Data from The American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012.
The Rh C, c, E, and e antigens have lower immunogenicity than the Rh D antigen, but they too can cause hemolytic disease. Sensitization to E, c, and C antigens complicates approximately 0.3 percent of pregnancies in screening studies and accounts for about 30 percent of red cell alloimmunization cases (Howard, 1998; Koelewijn, 2008). Anti-E alloimmunization is the most common, but the need for fetal or neonatal transfusions is significantly greater with anti-c alloimmunization than with anti-E or anti-C (Hackney, 2004; Koelewijn, 2008).

The Grandmother Effect. In virtually all pregnancies, small amounts of maternal blood enter the fetal circulation. Real-time polymerase chain reaction (PCR) has been used to identify maternal Rh D-positive DNA in peripheral blood from preterm and full-term Rh D-negative newborns (Lazar, 2006). Thus, it is possible for an Rh D-negative female fetus exposed to maternal Rh D-positive red cells to develop sensitization. When such an individual reaches adulthood, she may produce anti-D antibodies even before or early in her first pregnancy. This mechanism is called the grandmother theory because the fetus in the current pregnancy is jeopardized by maternal antibodies that were initially provoked by his or her grandmother’s erythrocytes.

Alloimmunization to Minor Antigens
Because routine administration of anti-D immunoglobulin prevents anti-D alloimmunization, proportionately more cases of hemolytic disease are caused by red cell antigens other than D—also known as minor antigens (see Table 15-1). Kell antibodies are among the most frequent. Duffy group A antibodies—anti-Fy^a—are also fairly common, as are anti-MNSs and anti-Jk^a—Kidd group (Geifman-Holtzman, 1997). Most cases of sensitization to minor antigens result from incompatible blood transfusions (American College of Obstetricians and Gynecologists, 2012). If an IgG red cell antibody is detected and there is any doubt as to its significance, the clinician should err on the side of caution, and the pregnancy should be evaluated for hemolytic disease.

There are only a few blood group antigens that pose no fetal risk. Lewis antibodies—Le^a and Le^b, as well as I antibodies, are cold agglutinins. They are predominantly IgM and are not expressed on fetal red cells. Another antibody that does not cause fetal hemolysis is Duffy group B—Fy^b.

Kell Alloimmunization. Approximately 90 percent of whites and up to 98 percent of African Americans are Kell negative. Kell type is not routinely determined, and approximately 90 percent of Kell sensitization cases result from transfusion with Kell-positive blood. Thus, transfusion history is important.

If Kell sensitization develops from maternal–fetal incompatibility, it may develop more rapidly and may be more severe than with sensitization to Rh D and other blood group antigens. This is because Kell antibodies attach to fetal bone marrow erythrocyte precursors and prevent a hemopoietic response to anemia. With fewer erythrocytes produced, there is less hemolysis. Because of these vicissitudes, severe anemia may not be predicted by either the maternal Kell antibody titer or the amniotic fluid bilirubin level (p. 310). One option is to use a lower critical titer—1:8—for Kell sensitization (Moise, 2012). The American College of Obstetricians and Gynecologists (2012) has recommended that antibody titers not be used to monitor Kell-sensitized pregnancies. Van Wamelen and colleagues (2007) have advocated MCA Doppler studies beginning at 16 to 17 weeks’ gestation for pregnancies with anti-Kell titers ≥ 1:2.

ABO Blood Group Incompatibility
Incompatibility for the major blood group antigens A and B is the most common cause of hemolytic disease in newborn infants, but it does not cause appreciable hemolysis in the fetus. Approximately 20 percent of newborns have ABO blood group incompatibility, however, only 5 percent are clinically affected, and the resulting anemia is usually mild. The condition differs from Rh CDE incompatibility in several respects. First, ABO incompatibility is often seen in firstborn infants, whereas sensitization to other blood group antigens is not. This is because most group O women have developed anti-A and anti-B isoagglutinins before pregnancy from exposure to bacteria displaying similar antigens. Second, ABO alloimmunization can affect future pregnancies, but unlike CDE disease, it rarely becomes progressively more severe. Last, most anti-A and anti-E antibodies are immunoglobulin M (IgM), which do not cross the placenta. Fetal red cells also have fewer A and B antigenic sites than adult cells and are thus less immunogenic. For these reasons, ABO alloimmunization is generally a pediatric disease rather than an obstetrical concern. There is no need to monitor for fetal hemolysis or to deliver the fetus early. Careful neonatal observation is essential, because hyperbilirubinemia may require treatment with phototherapy or occasionally transfusion (Chap. 33, p. 644).

Management of the Alloimmunized Pregnancy

An estimated 25 to 30 percent of fetuses from Rh D-alloimmunized pregnancies will have mild to moderate hemolytic anemia, and without treatment, up to 25 percent will develop hydrops (Tannirandorn, 1990). If alloimmunization is detected and the titer is below the critical value, the titer is generally repeated every 4 weeks for the duration of the pregnancy (American College of Obstetricians and Gynecologists, 2012). Importantly, however, if a woman has had a prior pregnancy complicated by alloimmunization, serial titer assessment is inadequate for surveillance of fetal anemia. In these instances, pregnancy is assumed to be at risk and is followed as discussed on page 310. Once a titer has reached a critical value, there is no benefit to repeating it. The pregnancy is at risk even if the titer decreases, and further evaluation is still required.

Determining Fetal Risk

The presence of maternal anti-D antibodies reflects her sensitization, but it does not necessarily indicate that the fetus will be affected or is even Rh D-positive. For example, in a non-Hispanic white couple in which the woman is Rh D-negative, there is an 85-percent chance that the man is Rh D-positive, but in 60 percent of these cases he will be heterozygous at the D-locus (American College of Obstetricians and Gynecologists, 2012). If he is heterozygous, then only half of his children will be at risk for hemolytic disease. Another consideration is that if a woman became sensitized in a prior pregnancy, her antibody titer might rise to high levels during the current pregnancy even if the current fetus is Rh D-negative. This is termed an amnestic response. Additionally, alloimmunization to a red cell antigen other than Rh D may have occurred following a blood transfusion in the past, and if that antigen is not present on paternal erythrocytes, the pregnancy is not at risk.

Initial evaluation of alloimmunization begins with determining the paternal erythrocyte antigen status. Provided that paternity is certain, if the father is negative for the red cell antigen to which the mother is sensitized, the pregnancy is not at risk. In an Rh D alloimmunized pregnancy in which the father is Rh D-positive, it is helpful to determine prenatal paternal zygosity for the Rh E antigen, and DNA-based analysis will establish this. If the father is heterozygous or if paternity is in question, the patient should be offered assessment of fetal antigen type. In the United States, this has traditionally been done with amniocentesis and PCR testing of uncultured amniocytes to assess...
fetal blood type (Chap. 13, p. 277) (American College of Obstetricians and Gynecologists, 2012). This test has a positive-predictive value of 100 percent and negative-predictive value of approximately 97 percent (Van den Veyver, 1996). Chorionic villus sampling is not generally performed because it is associated with greater risk for fetomaternal hemorrhage and may worsen alloimmunization. Fetal testing for other antigens is also available from reference laboratories using amniocentesis specimens. Examples include testing for E/e, C/c, Duffy, Kell, Kidd, and M/N.

More recently, noninvasive fetal Rh D blood typing has been performed using cell-free fetal DNA from maternal plasma (Chap. 13, p. 279). Accuracy is reported to be as high as 99 to 100 percent (Minon, 2008; Tynan, 2011). In a metaanalysis, only 3 percent of samples had inconclusive results (Geifman-Holtzman, 2006). Fetal Rh D blood typing with cell-free fetal DNA is routinely used in parts of Europe. There are two potential indications in Rh D negative pregnant women: (1) in women with Rh D alloimmunization, testing can identify fetuses who are also Rh D negative and do not require anemia surveillance, and (2) in women without Rh D alloimmunization, anti-D immune globulin might be withheld if the fetus is Rh D negative. However, concerns have been raised that use of the test to limit anti-D immune globulin administration could lead to an increased prevalence of Rh D alloimmunization (Goodspeed, 2013; Szczepura, 2011). As of 2013, cell-free fetal DNA testing for fetal Rh type has not been widely adopted in the United States.

Management of the alloimmunized pregnancy is individualized and may consist of maternal antibody titer surveillance, sonographic monitoring of the fetal MCA peak systolic velocity, amniotic fluid bilirubin studies, or fetal blood sampling. Accurate pregnancy dating is critical. The gestational age at which fetal anemia developed in prior pregnancies is important because anemia tends to occur earlier and be sequentially more severe.

Middle Cerebral Artery Doppler Velocimetry. In most specialized centers, serial measurement of the peak systolic velocity of the fetal middle cerebral artery has replaced amniocentesis for the detection of fetal anemia. The anemic fetus shunts blood preferentially to the brain to maintain adequate oxygenation. The velocity increases because of increased cardiac output and decreased blood viscosity (Moise, 2008a). The technique, which is discussed in Chapter 10 (p. 221), should be used only with adequate training and experience (American College of Obstetricians and Gynecologists, 2012).

In a landmark study, Mari and coworkers (2000) measured the MCA peak systolic velocity serially in 111 fetuses at risk for anemia and in 265 normal control fetuses. Threshold values > 1.5 multiples of the median (MoM) for given gestational ages correctly identified all fetuses with moderate or severe anemia. This provided a sensitivity of 100 percent, with a false-positive rate of 12 percent.

The MCA peak systolic velocity is followed serially, and values are plotted on a curve like the one shown in Figure 15-1. If the velocity is between 1.0 and 1.5 MoM and the slope is increasing—such that the value is approaching 1.5 MoM—surveillance is generally increased to weekly Doppler interrogation. If the MCA peak systolic velocity exceeds 1.5 MoM, further evaluation by fetal blood sampling is necessary to assess need for fetal transfusion. The false-positive rate increases significantly beyond 35 weeks, due to the normal increase in cardiac output that develops at this gestational age (Moise, 2008a; Zimmerman, 2002).
Amnionic Fluid Spectral Analysis. More than 50 years ago, Liley (1961) demonstrated the utility of amnionic fluid spectral analysis to measure bilirubin concentration. This permitted an estimate of hemolysis severity and indirect assessment of anemia. Amnionic fluid bilirubin is measured by a spectrophotometer and is demonstrable as a change in optical density absorbance at 450 nm—ΔOD_{450}. The likelihood of fetal anemia is determined by plotting the ΔOD_{450} value on a graph that is divided into several zones. The original Liley graph is valid from 27 to 42 weeks’ gestation and contains three zones. Zone 1 indicates an Rh D-negative fetus or one with only mild disease. Zone 2 indicates fetal anemia, with hemoglobin concentrations of 11.0 to 13.9 g/dL for values in lower zone 2 and those of 8.0 to 10.9 g/dL for upper zone 2. Zone 3 indicates severe anemia, with hemoglobin concentration < 8.0 g/dL.

The Liley graph was subsequently modified by Queenan and associates (1993) to include gestational ages as early as 14 weeks (Fig. 15-2). The naturally high amnionic fluid bilirubin level at midpregnancy results in a large indeterminate zone. Here, bilirubin concentrations do not accurately predict fetal hemoglobin concentration. For this reason, if evaluation indicated that severe fetal anemia or hydrops before 25 weeks was likely, then fetal blood sampling was often performed.
Middle cerebral artery velocimetry is noninvasive and does not confer the risks for pregnancy loss or increased alloimmunization associated with amniocentesis. Importantly, it is also more accurate than $\Delta OD_{450}$ assessment, particularly early in pregnancy. Oepkes and coworkers (2006) compared MCA Doppler velocimetry and amnionic fluid bilirubin studies. They found that MCA Doppler had significantly greater sensitivity and accuracy. For these reasons, amnionic fluid spectral analysis is currently used only when Doppler velocimetry is not readily available. It also may be considered if the MCA peak systolic velocity exceeds 1.5 MoM after 35 weeks’ gestation. In the latter situation, if $\Delta OD_{450}$ assessment indicates only mild hemolysis, delivery at 37 to 38 weeks has been recommended (American College of Obstetricians and Gynecologists, 2012; Moise, 2008b).

**Fetal Blood Transfusion**

If there is evidence of severe fetal anemia, either because of elevated MCA peak systolic velocity or development of fetal hydrops, management is strongly influenced by gestational age. The preterm fetus is usually evaluated with fetal blood sampling, as described in Chapter 14 (p. 300). Some recommend fetal transfusion until 30 to 32 weeks’ gestation and delivery at 32 to 34 weeks. To decrease neonatal morbidity from prematurity, others suggest intrauterine transfusion up to 36 weeks followed by delivery at 37 to 38 weeks (American College of Obstetricians and Gynecologists, 2012).

Intravascular transfusion into the umbilical vein under sonographic guidance is the preferred method of fetal transfusion. Peritoneal transfusion may be necessary with severe, early-onset hemolytic disease in the early second trimester, a time when the umbilical vein is too narrow to readily permit needle entry (Fox, 2008; Howe, 2007). With hydrops, although peritoneal absorption is impaired, some prefer to transfuse into both the peritoneal cavity and the umbilical vein.

Transfusion is generally recommended if the fetal hematocrit is $< 30$ percent. Once hydrops has developed, however, the hematocrit is generally 15 percent or lower. The red cells transfused are
type O, Rh D negative, cytomegalovirus-negative, packed to a hematocrit of about 80 percent to prevent volume overload, irradiated to prevent fetal graft-versus-host reaction, and leukocyte-poor. The fetal-placental volume allows rapid infusion of a relatively large quantity of blood. Before transfusion, a paralytic agent such as vecuronium may be given to the fetus to minimize movements and potential needle-stick trauma. In a nonhydropic fetus, the target hematocrit is generally 40 to 50 percent. The volume transfused may be estimated by multiplying the estimated fetal weight in grams by 0.02 for each 10-percent increase in hematocrit needed (Giannina, 1998). In the severely anemic fetus, less blood is transfused initially, and another transfusion is planned for about 2 days later.

Subsequent transfusions usually take place every 2 to 4 weeks, depending on the hematocrit. The sensitivity of the MCA peak systolic velocity to detect severe anemia appears to be lower following an initial transfusion, such that it may not be reliable (Scheier, 2006). One schedule is to perform a second transfusion in 10 days, the third 2 weeks later, and any additional transfusions 3 weeks later (Moise, 2012). Following transfusion, the fetal hematocrit generally decreases by approximately 1 volume percent per day. A more rapid initial decline may be seen with hydropic fetuses.

**Outcomes.** Procedure-related complications have been reported in up to 9 percent of transfused pregnancies (van Kamp, 2005). These include fetal death in approximately 3 percent, neonatal death in about 2 percent, need for emergent cesarean delivery in 6 percent, and infection in 1 percent. Considering that fetal transfusion is potentially lifesaving in severely compromised fetuses, these risks should not dissuade therapy.

The overall survival rate following fetal transfusion approximates 90 percent (Lindenberg, 2013; Van Kamp, 2005). If transfusion is required before 20 weeks, survival rates are lower but may reach 80 percent at experienced centers (Canlorde, 2011; Lindenberg, 2013). Van Kamp and colleagues (2001) reported that if hydrops had developed, the survival rate approached 75 to 80 percent. However, of the nearly two thirds with resolution of hydrops following transfusion, more than 95 percent survived. The survival rate was below 40 percent if hydrops persisted.

Lindenberg and associates (2012) recently reviewed long-term outcomes following intrauterine transfusion in a cohort of more than 450 alloimmunized pregnancies. Alloimmunization was secondary to Rh D in 80 percent, Kell in 12 percent, and Rh c in 5 percent. Approximately a fourth of affected fetuses had hydrops, and more than half also required exchange transfusion in the neonatal period. The overall survival rate approximated 90 percent. Among nearly 300 children aged 2 to 17 years who participated in neurodevelopmental testing, fewer than 5 percent had severe impairments. These included severe developmental delay in 3 percent, cerebral palsy in 2 percent, and deafness in 1 percent.

---

**Prevention of Rh D Alloimmunization**

Anti-D immune globulin has been used for more than four decades to prevent Rh E alloimmunization and is one of the success stories of modern obstetrics. In countries without access to anti-D immune globulin, nearly 10 percent of Rh D-negative pregnancies are complicated by hemolytic disease of the fetus and newborn (Zipursky, 2011). With immunoprophylaxis, however, the alloimmunization risk is reduced to < 0.2 percent. Despite longstanding and widespread use, its mechanism of action is not completely understood.

As many as 90 percent of alloimmunization cases occur from fetomaternal hemorrhage at delivery. Routine postpartum administration of anti-D immune globulin to at-risk pregnancies
within 72 hours of delivery decreases the alloimmunization rate by 90 percent (Bowman, 1985). Additionally, provision of anti-D immune globulin at 28 weeks’ gestation reduces the third-trimester alloimmunization rate from approximately 2 percent to 0.1 percent (Bowman, 1988).

Whenever there is doubt whether to give anti–D immunoglobulin, it should be given. Even if not needed, it will cause no harm, but failing to give it when needed can have severe consequences.

Current preparations of anti-D immune globulin are derived from human plasma donated by individuals with high-titer anti-D antibodies. Formulations prepared by cold ethanol fractionation and ultrafiltration can only be administered intramuscularly, because they contain plasma proteins that could result in anaphylaxis if given intravenously. However, newer formulations, prepared using ion exchange chromatography, may be administered either intramuscularly or intravenously. This is important for treatment of significant fetomaternal hemorrhage, which is discussed subsequently. Both preparation methods effectively remove viral particles, including hepatitis and human immunodeficiency viruses. Depending on the preparation, the half-life of anti-D immune globulin ranges from 16 to 24 days, which is why it is given both in the third trimester and following delivery. The standard intramuscular dose of anti-D immune globulin—300 μg or 1500 international units (IU)—will protect the average-sized mother from a fetal hemorrhage of up to 30 mL of fetal whole blood or 15 mL of fetal red cells.

In the United States, anti-D immune globulin is given prophylactically to all Rh D-negative unsensitized women at approximately 28 weeks, and a second dose is given after delivery if the infant is Rh D-positive (American College of Obstetricians and Gynecologists, 2010). Before the 28-week dose of anti-D immune globulin, repeat antibody screening is recommended to identify individuals who have become alloimmunized (American Academy of Pediatrics and American College of Obstetricians and Gynecologists 2012). Following delivery, anti-D immune globulin should be given within 72 hours. Importantly, if immune globulin is inadvertently not administered following delivery, it should be given as soon as the omission is recognized, because there may be some protection up to 28 days postpartum (Bowman, 2006). Anti-D immune globulin is also administered after pregnancy-related events that could result in fetomaternal hemorrhage (see Table 15-2).

Anti-D immune globulin may produce a weakly positive—1:1 to 1:4—indirect Coombs titer in the mother. This is harmless and should not be confused with development of alloimmunization. Additionally, as the body mass index increases above 27 to 40 kg/m^2, serum antibody levels decrease by 30 to 60 percent and may be less protective (MacKenzie, 2006; Woelfer, 2004). Rh D-negative women who receive other types of blood products—including platelet transfusions and plasmapheresis—are also at risk of becoming sensitized, and this can be prevented with anti-D immune globulin. Rarely, a small amount of antibody crosses the placenta and results in a weakly positive direct Coombs test in cord and infant blood. Despite this, passive immunization does not cause significant fetal or neonatal hemolysis.

In approximately 1 percent of pregnancies, the volume of fetomaternal hemorrhage exceeds 30 mL of whole blood (Ness, 1987). A single dose of anti-D immune globulin would be insufficient in such situations. If additional anti-D immune globulin is considered only for women with risk factors—examples include abdominal trauma, placental abruption, placenta previa, intrauterine manipulation, multifetal gestation, or manual placenta removal—half of those who require more than the 1500-IU dose may be missed. Because of these observations, the American Association of Blood Banks recommends that all D-negative women be tested at delivery with a rosette test or Kleihauer-Betke test (Snyder, 1998).

The rosette test is used to identify whether fetal Rh D-positive cells are present in the circulation of an Rh D-negative woman. It is a qualitative test. A sample of maternal blood is
mixed with anti-D antibodies that coat any Rh D-positive fetal cells present in the sample. Indicator red cells bearing the D-antigen are then added, and rosettes form around the fetal cells as the indicator cells attach to them by the antibodies. Thus, if rosettes are visualized, there are fetal Rh D-positive cells in that sample.

The Kleihauer-Betke test is a quantitative test used either in the setting of Rh D incompatibility or any time a large fetomaternal hemorrhage is suspected—regardless of antigen status. It is discussed on page 313.

The dosage of anti-D immune globulin is calculated from the estimated volume of the fetal-to-maternal hemorrhage, as described on page 311. One 1500-IU (300 μg) ampule is given for each 15 mL of fetal red cells or 30 mL of fetal whole blood to be neutralized. If using an intramuscular preparation of anti-D immune globulin, no more than five doses may be given in a 24-hour period. If using an intravenous preparation, two ampules—totaling 3000 IU (600 μg)—may be given every 8 hours. To determine if the administered dose was adequate, the indirect Coombs test may be performed. A positive result indicates that there is excess anti-D immunoglobulin in maternal serum, thus demonstrating that the dose was sufficient. Alternatively, a rosette test may be performed to assess whether circulating fetal cells remain.

**Weak D Antigens**

Women who are positive for weak D antigens, formerly called D\(^u\), are not considered at risk for hemolytic disease and do not require anti-D immune globulin (American College of Obstetricians and Gynecologists, 2010). There are, however, D-antigen variants—termed *partial D antigens*—that can result in Rh D alloimmunization and cause hemolytic disease (Daniels, 2013). If a D-negative woman delivers a weak D-positive infant, she should be given anti-D immune globulin. It is worth emphasizing that if there is any doubt regarding D-antigen status, then immune globulin should be given.

**Fetomaternal Hemorrhage**

It is likely that all pregnant women experience a small fetomaternal hemorrhage, and in two-thirds, this may be sufficient to provoke an antigen-antibody reaction. As shown in Figure 15-3, the incidence increases with gestational age, as does the volume of fetal blood in the maternal circulation. Large volumes of blood loss—true fetomaternal hemorrhage—are fortunately rare. In a series of more than 30,000 pregnancies, de Almeida and Bowman (1994) found evidence of fetomaternal hemorrhage > 80 mL in approximately 1 per 1000 births, and hemorrhage > 150 mL in 1 per 5000 births.
Fetomaternal hemorrhage may follow maternal trauma, may occur with placenta previa or vasa previa, and may follow amniocentesis or external cephalic version (Giacoia, 1997; Rubod, 2007). In more than 80 percent of cases, however, no cause is identified. With significant hemorrhage, the most common presenting complaint is decreased fetal movement (Eichbaum, 2006; Hartung, 2000; Wylie, 2010). A sinusoidal fetal heart rate pattern, although uncommon, is occasionally seen and warrants immediate evaluation (Chap. 24, p. 482). Sonography may demonstrate elevated MCA peak systolic velocity, and hydrops may be identified (Eichbaum, 2006; Giacoia, 1997; Hartung, 2000). If fetomaternal hemorrhage is suspected based on either a sinusoidal fetal heart rate pattern or positive Kleihauer-Betke test result, then the finding of an elevated MCA peak systolic velocity or hydrops should prompt consideration of either fetal transfusion or delivery.

One limitation of quantitative tests for fetal cells in the maternal circulation is that they do not provide information regarding hemorrhage timing or chronicity (Wylie, 2010). In general, anemia developing gradually or chronically, as in alloimmunization, is better tolerated by the fetus than acute anemia. Chronic anemia may not produce fetal heart rate abnormalities until the fetus is moribund. In contrast, significant acute hemorrhage is poorly tolerated by the fetus and may cause profound fetal neurological impairment from cerebral hypoperfusion, ischemia, and infarction. In some cases, fetomaternal hemorrhage is identified during stillbirth evaluation (Chap. 35, p. 664).

Tests for Fetomaternal Hemorrhage
Once fetomaternal hemorrhage is recognized, the volume of fetal blood loss can be estimated. The volume may influence obstetrical management and is essential to determining the appropriate dose of anti D-immune globulin if the woman is Rh D-negative.

The most commonly used quantitative test for fetal red cells in the maternal circulation is the acid elution or Kleihauer-Betke (KB) test (Kleihauer, 1957). Fetal erythrocytes contain
hemoglobin F, which is more resistant to acid elution than hemoglobin A. After exposure to acid, only fetal hemoglobin remains, such that after staining, the fetal erythrocytes appear red and adult cells appear as “ghosts” (Fig. 15-4). Fetal cells are counted and expressed as a percentage of adult cells. The test is labor intensive. Moreover, it may be less accurate in two situations: (1) cases of maternal hemoglobinopathy in which maternal red cells carry excess fetal hemoglobin and (2) cases near or at term, at which time the fetus has already started to produce hemoglobin A.

![Figure 15-4](image)

**FIGURE 15-4** Kleihauer-Betke test demonstrating massive fetal-to-maternal hemorrhage. After acid-elution treatment, fetal red cells rich in hemoglobin F stain darkly, whereas maternal red cells with only very small amounts of hemoglobin F stain lightly.

The hemorrhaged fetal blood volume is calculated from the Kleihauer-Betke test result using the following formula:

\[
\text{Fetal blood volume} = \frac{\text{MBV} \times \text{maternal Hct} \times \% \text{fetal cells in KB}}{\text{newborn Hct}}
\]

One method is to estimate the maternal blood volume (MBV) as 5000 mL for a normal-size normotensive women at term. Thus, for 1.7-percent positive KB-stained cells in a woman of average size with a hematocrit of 35 percent giving birth to a term infant weighing 3000 g and whose hematocrit is 50 percent:

\[
\text{Fetal blood volume} = \frac{5000 \times 0.35 \times 0.017}{0.5} = 60 \text{ mL}
\]

The fetal-placental blood volume at term approximates 125 mL/kg. For this 3000-g fetus, that would equate to 375 mL. Thus, this fetus has lost approximately 15 percent (60 ÷ 375 mL) of the fetal-placental volume. Because the hematocrit is 50 percent in a term fetus, this 60 mL of whole blood represents 30 mL of red cells lost over time into the maternal circulation. This loss should be well tolerated hemodynamically but would require two 300-µg doses of anti-D immunoglobulin to prevent alloimmunization. A more precise method to estimate the maternal blood volume includes a calculation based on the maternal height, weight, and anticipated blood volume increase due to gestational age (Chap. 41, p. 781).

Fetomaternal hemorrhage can also be quantified using flow cytometry to measure red cell size...
This is an automated test and is unaffected by maternal levels of fetal hemoglobin F or by fetal levels of hemoglobin A. In direct comparison studies with the Kleihauer-Betke test, flow cytometry has been reported to be more sensitive and accurate (Chambers, 2012; Fernandes, 2007).

**FETAL THROMBOCYTOPENIA**

**Alloimmune Thrombocytopenia**

This condition is also referred to as neonatal alloimmune thrombocytopenia (NAIT) or fetal and neonatal alloimmune thrombocytopenia (FNAIT). Alloimmune thrombocytopenia (AIT) is the most common cause of severe thrombocytopenia among term newborns, with a frequency of 1 to 2 per 1000 (Kamphuis, 2010; Pacheco, 2013; Risson, 2012). AIT is caused by maternal alloimmunization to paternally inherited fetal platelet antigens. The resulting maternal antiplatelet antibodies cross the placenta in a manner similar to red cell alloimmunization (p. 306). Unlike immune thrombocytopenia, the maternal platelet count is normal. And unlike Rh-D alloimmunization, severe sequelae may affect the first at-risk pregnancy.

Maternal platelet alloimmunization is most commonly against human platelet antigen-1a (HPA-1a). This is followed by HPA-5b, HPA-1b, and HPA-3a, and alloimmunization to other antigens accounts for only 1 percent of reported cases. Alloimmunization to HPA-1a accounts for 80 to 90 percent of cases and is associated with the greatest severity (Bussel, 1997; Knight, 2011; Tiller, 2013).

Approximately 85 percent of white individuals are positive for HPA-1a. Two percent are homozygous for HPA-1b and thus are at risk for alloimmunization. But, only 10 percent of homozygous HPA-1b mothers carrying an HPA-1a fetus will produce anti-platelet antibodies. Approximately a third of affected fetuses or neonates will develop severe thrombocytopenia, and 10 to 20 percent with severe thrombocytopenia sustain an intracranial hemorrhage (ICH) (Kamphuis, 2010). As a result, population-based screening studies have identified FNAIT-associated ICH in 1 per 25,000 to 60,000 pregnancies (Kamphuis, 2010; Knight, 2011).

FNAIT has a broad spectrum of presentation. In some, neonatal thrombocytopenia may be an incidental finding or the infant may present with petechiae. Alternatively, the fetus or neonate may develop devastating ICH—often before birth. Of 600 pregnancies with alloimmune thrombocytopenia identified through a large international registry, fetal or neonatal ICH complicated 7 percent of cases (Tiller, 2013). Hemorrhage affected the first-born child in 60 percent and occurred before 28 weeks’ gestation in half. A third of affected children died soon after birth, and 50 percent of survivors had severe neurological disabilities. Bussel and coworkers (1997) evaluated fetal platelet counts before therapy in 107 fetuses with FNAIT. Thrombocytopenia severity was predicted by a prior sibling with perinatal ICH, and 98 percent of cases were identified this way. The initial platelet count was < 20,000/mL in 50 percent. In cases in which the platelet count was initially > 80,000/mL, they noted that it dropped by more than 10,000/mL each week without therapy.

**Diagnosis and Management**

The diagnosis of alloimmune thrombocytopenia is usually made after the first affected pregnancy in a woman with a normal platelet count whose neonate is found to have unexplained severe thrombocytopenia. Rarely, the diagnosis is ascertained after finding fetal ICH. The condition
recurs in 70 to 90 percent of subsequent pregnancies, is often severe, and usually develops earlier with each successive pregnancy. Traditionally, fetal blood sampling was performed to detect fetal thrombocytopenia and tailor therapy, and platelets were transfused if the fetal platelet count was < 50,000/mL. But, concern with procedure-related complications has led experts to recommend abandoning routine fetal platelet sampling in favor of empiric treatment with intravenous immune globulin (IVIG) and prednisone (Berkowitz, 2006; Pacheco, 2011).

Therapy is stratified according to whether a prior affected pregnancy was complicated by perinatal ICH, and if so, at what gestational age (Table 15-3). Pioneering work by Bussel (1996) and Berkowitz (2006) and their colleagues demonstrated the efficacy of such treatment. In one series of 50 pregnancies with fetal thrombocytopenia secondary to FNAIT, IVIG resulted in an increased platelet count of approximately 50,000/mL, and no fetus developed ICH (Bussel, 1996). Among pregnancies at particularly high risk—based on platelet count < 20,000/mL or sibling with FNAIT-associated ICH—the addition of corticosteroids to IVIG increased the platelet count in 8 percent of cases (Berkowitz, 2006). Cesarean delivery has been recommended at or near term. A noninstrumental vaginal delivery may be considered only if fetal blood sampling has demonstrated a platelet count > 100,000/mL (Pacheco, 2011).

HPA = human platelet antigen; ICH = intracerebral hemorrhage; IVIG = intravenous immunoglobulin G. Adapted from Pacheco, 2011.

Additional considerations include risks and costs associated with therapy. Side effects of IVIC may include fever, headache, nausea/vomiting, myalgia, and rash. Maternal hemolysis also has...
been described (Rink, 2013). As of 2011, costs for various preparations of IVIG were approximately $70 per gram or nearly $10,000 for each weekly 2-g/kg infusion for an average-size pregnant woman (Pacheco, 2011).

## Immune Thrombocytopenia

In pregnant women with immune thrombocytopenia (ITP), autoimmune antiplatelet IgG antibodies may cross the placenta and cause fetal thrombocytopenia. Maternal ITP is discussed in Chapter 56 (p. 1114). Fetal thrombocytopenia is usually mild. However, neonatal platelet levels may fall rapidly after birth and reach a nadir at 48 to 72 hours of life. Neither the maternal platelet count or identification of antiplatelet antibodies, nor treatment with corticosteroids is predictive of fetal or neonatal platelet counts. Importantly, fetal platelet counts are usually adequate to allow vaginal delivery without an increased risk of ICH. Fetal bleeding complications are considered rare, and fetal blood sampling is not recommended (Neunert, 2011). Delivery mode is based on standard obstetrical indications.

## HYDROPS FETALIS

The term *hydrops* refers to excessive accumulation of serous fluid in the body, and strictly defined, *hydrops fetalis* is edema of the fetus. Traditionally, the diagnosis was made after delivery of a massively edematous neonate, often stillborn (Fig. 15-5). With sonography, hydrops has become a prenatal diagnosis. It is defined as two or more fetal effusions—pleural, pericardial, or ascites—or one effusion plus anasarca. With condition progression, edema is invariably a component, often accompanied by placentomegaly and hydramnios. Hydrops may result from a wide range of conditions with varying pathophysiologies, each with the potential to make the fetus severely ill. It is divided into two categories. If found in association with red cell alloimmunization, it is termed *immune*, otherwise, it is *nonimmune*. 
Immune Hydrops

The incidence of immune hydrops has dramatically decreased with the advent of anti-D immune globulin, MCA Doppler studies for detection of severe anemia, and prompt fetal transfusion when needed. Only an estimated 10 percent of hydrops cases are caused by red cell alloimmunization (Bellini, 2009, 2012; Santolaya, 1992).

The pathophysiology underlying hydrops remains unknown. Immune hydrops is postulated to share several physiological abnormalities with nonimmune hydrops. As shown in Figure 15-6, these include decreased colloid oncotic pressure, increased hydrostatic (or central venous) pressure, and increased vascular permeability. Immune hydrops results from transplacental passage of maternal antibodies that destroy fetal red cells. Resultant anemia stimulates marrow erythroid hyperplasia and extramedullary hematopoiesis in the spleen and liver. The latter likely causes portal hypertension and impaired hepatic protein synthesis, which decreases plasma oncotic pressure (Nicolaides, 1985). Fetal anemia also may raise central venous pressure (Weiner, 1989). Finally, tissue hypoxia from anemia may increase capillary permeability, such that fluid collects in the fetal thorax, abdominal cavity, and/or subcutaneous tissue.
The degree of anemia in immune hydrops is typically severe. Nicolaides and associates (1988) reported that the hemoglobin concentration was 7 to 10 g/dL below the normal mean for gestational age in a cohort of 48 fetuses with immune hydrops. Similarly, in a series of 70
pregnancies with fetal anemia from red cell alloimmunization, Mari and coworkers (2000) found that all those with immune hydrops had hemoglobin values below 5 g/dL. As discussed on page 310, immune hydrops is treated with fetal blood transfusions (van Kamp, 2001).

### Nonimmune Hydrops

Currently, nearly 90 percent of cases of hydrops are nonimmune (Bellini, 2009, 2012; Santolaya, 1992). The prevalence estimate is 1 per 1500 second-trimester pregnancies (Heinonen, 2000). The number of specific disorders that can lead to nonimmune hydrops is extensive. Etiologies and the proportion of births within each hydrops category from a review of more than 5400 affected pregnancies are summarized in Table 15-4. A cause is identified in at least 60 percent prenatally and in more than 80 percent postnatally (Bellini, 2009; Santo, 2011). As shown in Figure 15-6, there are several different pathophysiological processes proposed to account for the final common pathway of hydrops fetalis.

**TABLE 15-4. Some Etiologies of Nonimmune Hydrops Fetalis**
Cardiovascular 22
Structural defects: Ebstein anomaly, Fallot tetralogy with absent pulmonary valve, hypoplastic left or right heart, premature closure of ductus arteriosus, arteriovenous malformation (vein of Galen aneurysm)
Cardiomyopathies
Tachyarrhythmias
Bradycardia, as may occur in heterotaxy syndrome with endocardial cushion defect or in maternal SLE with anti-Ro/La antibodies

Chromosomal 13
Turner syndrome (45,X), triploidy, trisomies 21, 18, and 13

Hematological 10
Hemoglobinopathies, such as α4-thalassemia
Erythrocyte enzyme and membrane disorders
Erythrocyte aplasia/dyserythropoiesis
Decreased erythrocyte production (myeloproliferative disorders)
Fetomteral hemorrhage

Infections 7
Parvovirus B19, syphilis, cytomegalovirus, toxoplasmosis, rubella, enterovirus, varicella, herpes simplex, coxsackievirus, listeriosis, leptospirosis, Chagas disease, Lyme disease

Thoracic Abnormalities 6
Cystic adenomatoid malformation
Pulmonary sequestration
Diaphragmatic hernia
Hydro/chylothorax
Congenital high airway obstruction sequence
Mediastinal tumors
Skeletal dysplasia with very small thorax

Lymphatic Abnormalities
Importantly, the etiology of nonimmune hydrops varies according to when in gestation it is identified. Of those diagnosed prenatally, aneuploidy accounts for approximately 20 percent, cardiovascular abnormalities for 15 percent, and infections for 14 percent—the most common of these being parvovirus B19 (Santo, 2011). Overall, only 40 percent of pregnancies with nonimmune hydrops result in a liveborn neonate. For these, the neonatal survival rate is only about 50 percent. Sohan and colleagues (2001) reviewed 87 pregnancies with hydrops and found that 45 percent of those diagnosed before 24 weeks’ gestation had a chromosomal abnormality. The most common was 45, X—Turner syndrome (Chap. 10, p. 205), and in such cases, the survival rate was < 5 percent. If hydrops is detected in the first trimester, the aneuploidy risk is nearly 50 percent, and most have cystic hygromas (Fig. 10-16, p. 206) (Has, 2001).

Thus, the prognosis of nonimmune hydrops is guarded but is heavily dependent on etiology. In large series from Thailand and Southern China, α4-thalassemia is the predominant cause of nonimmune hydrops, accounting for 30 to 50 percent of cases and conferring an extremely poor
prognosis (Liao, 2007; Ratanasiri, 2009; Suwanrath-Kengpol, 2005). In contrast, Sohan and associates (2001) found that treatable causes of nonimmune hydrops—parvovirus, chylothorax, and tachyarrhythmias—each comprised about 10 percent of cases, and with fetal therapy, two thirds of fetuses with these etiologies survived.

**Diagnostic Evaluation**

Hydrops is readily detected sonographically. As noted, two effusions or one effusion plus anasarca are required for diagnosis. Edema may be particularly prominent around the scalp, or equally obvious around the trunk and extremities. Effusions are visible as fluid outlining the lungs, heart, or abdominal viscera (Fig. 15-7).
FIGURE 15-7 Hydropic features. A. This profile of a 23-week fetus with nonimmune hydrops secondary to B19 parvovirus infection depicts scalp edema (arrowheads) and ascites (*). B. In this coronal image, prominent pleural effusions (*) outline the lungs (L). This 34-week fetus had hydrops secondary to an arteriovenous malformation in the brain, known as a vein of Galen aneurysm. Fetal ascites is also present (arrows), as is anasarca. C. This axial (transverse) image depicts a pericardial effusion (arrows) in a 23-week fetus with hydrops from B19 parvovirus infection. The degree of cardiomegaly is impressive, and the ventricular hypertrophy raises
concern for myocarditis, which can accompany parvovirus infection. **D.** This axial (transverse) image depicts fetal ascites (*) in a 15-week fetus with hydrops secondary to large cystic hygromas. Anasarca is also seen (*brackets*).

In many cases, targeted sonographic and laboratory evaluation will identify the underlying cause of fetal hydrops. These include cases due to fetal anemia, arrhythmia, structural abnormality, aneuploidy, placental abnormality, or complications of monochorionic twinning. Depending on the circumstances, initial evaluation includes the following:

1. Indirect Coombs test for alloimmunization
2. Targeted sonographic fetal and placental examination, including:
   - A detailed anatomic survey to assess for the structural abnormalities listed in Table 15-4
   - MCA Doppler velocimetry to assess for fetal anemia
   - Fetal echocardiography with M-mode evaluation
3. Amniocentesis for fetal karyotype and for B19 parvovirus, cytomegalovirus, and toxoplasmosis testing as discussed in Chapter 64. Consideration of chromosomal microarray analysis if fetal anomalies are present
4. Consideration of Kleihauer-Betke test for fetomaternial hemorrhage if anemia is suspected, depending on findings and test results
5. Consideration of testing for α-thalassemia and/or inborn errors of metabolism.

**Isolated Effusion or Edema.** Although one effusion or anasarca alone is not diagnostic for hydrops, the above evaluation should be considered if these are encountered, as hydrops may develop. For example, an isolated pericardial effusion may be the initial finding in fetal B19 parvovirus infection (Chap. 64, p. 1244). An isolated pleural effusion may represent a chylothorax, which is amenable to prenatal diagnosis, and for which fetal therapy may be lifesaving if hydrops develops (Chap. 16, p. 329). Isolated ascites also may be the initial finding in fetal B19 parvovirus infection or it may result from a gastrointestinal abnormality such as meconium peritonitis. Finally, isolated edema, particularly involving the upper torso or the dorsum of the hands and feet, may be found in Turner or Noonan syndrome or may represent congenital lymphedema syndrome (Chap. 13, p. 264).

**Mirror Syndrome**

An association between fetal hydrops and development of maternal edema in which the fetus mirrors the mother is attributed to Ballantyne. He called the condition *triple edema* because the fetus, mother, and placenta all became edematous. The etiology of the hydrops is not related to development of mirror syndrome. It has been associated with hydrops from Rh D alloimmunization, twin-twin transfusion syndrome, placental chorioangioma, and with fetal cystic hygroma, Ebstein anomaly, sacrococcygeal teratoma, chylothorax, bladder outlet obstruction, supraventricular tachycardia, vein of Galen aneurysm, and various congenital infections (Braun, 2010).

In a review of more than 50 cases of mirror syndrome, Braun and coworkers (2010) found that approximately 90 percent of women had edema, 60 percent had hypertension, 40 percent had proteinuria, 20 percent had liver enzyme elevation, and nearly 15 percent had headache and visual disturbances. Based on these findings, it is reasonable to consider mirror syndrome a form of severe preeclampsia (Espinoza, 2006; Midgley, 2000). Others, however, have suggested that it is
a separate disease process with hemodilution rather than hemoconcentration (Carbillon, 1997; Livingston, 2007). There have been recent reports describing the same imbalance of angiogenic and antiangiogenic factors observed with preeclampsia and thus supporting a common pathophysiology (Espinoza, 2006; Goa, 2013; Llurba, 2012). These findings, which include elevated concentrations of soluble fms-like tyrosine kinase-1 (sFlt-1), decreased placental growth factor (PIGF) levels, and elevation of soluble vascular endothelial growth factor receptor-1 (sVEGFR-1) concentrations, are discussed further Chapter 40 (p. 735).

In most cases with mirror syndrome, prompt delivery is indicated and followed by resolution of maternal edema and other findings in approximately 9 days (Braun, 2010). There are, however, isolated cases of fetal anemia, supraventricular tachycardia, hydrothorax, and bladder outlet obstruction in which successful fetal treatment resulted in resolution of both fetal hydrops and maternal mirror syndrome (Goa, 2013; Livingston, 2007; Llurba, 2012; Midgley, 2000). In two of these cases, normalization of the angiogenic imbalance also occurred following fetal transfusion for B19 parvovirus infection (Goa, 2013; Llurba, 2012). Fetal therapy for these conditions is reviewed in Chapter 16. Given the parallels to severe preeclampsia, delaying delivery to effect fetal therapy should be considered only with caution. If the maternal condition deteriorates, delivery is recommended.

Fetal Therapy

MEDICAL THERAPY

Interventions developed during the past three decades have dramatically altered the course of selected fetal anomalies and conditions. Reviewed in this chapter are fetal disorders amenable to treatment with either maternal medication or surgical procedures. The treatment of fetal anemia and thrombocytopenia is reviewed in Chapter 15, and the treatment of some fetal infections is discussed in Chapters 64 and 65.

MEDICAL THERAPY

Fetal pharmacotherapy, administered to the mother and transported transplacentally, can be used to treat an array of serious conditions. Two well-described examples are fetal tachyarrhythmia treatment with medications such as digoxin, and corticosteroid therapy to prevent virilization of female fetuses with congenital adrenal hyperplasia. More recently, a course of corticosteroid therapy—the same used to promote lung maturity before preterm birth—has been used to stabilize the growth of large fetal lung masses and avoid fetal surgery.

Arrhythmias

Fetal cardiac rhythm disturbances may be broadly categorized as tachyarrhythmias, heart rates > 180 beats per minute (bpm); bradyarrhythmia, heart rate < 110 bpm; and ectopy, typically premature atrial contractions. Fetal M-mode sonography (p. 322) should be performed to determine the atrial and ventricular rate to clarify the relationship between atrial and ventricular beats, thereby diagnosing the rhythm disturbance type.
Premature Atrial Contractions

This is by far the most common arrhythmia. Premature atrial contractions are identified in 1 to 2 percent of pregnancies and are generally a benign finding (Hahurij, 2011; Strasburger, 2010). They represent immaturity of the cardiac conduction system and typically resolve either with advancing gestation or in the neonatal period. Although they may be conducted, they are more commonly blocked, and with handheld Doppler or fetoscope, they sound like a dropped beat. Premature atrial contractions are not associated with major structural cardiac abnormalities, but they sometimes occur with an atrial septal aneurysm. As shown in Figure 10-24 (p. 212), M-mode evaluation demonstrates that the dropped beat is a compensatory pause following the premature atrial contraction. They may occur as frequently as every other beat, known as blocked atrial bigeminy. This results in an auscultated fetal ventricular rate as low as 60 to 80 beats per minute. Unlike other causes of bradycardia, this carries a benign prognosis and does not require treatment (Strasburger, 2010).

Approximately 2 percent of fetuses with premature atrial contractions are later identified to develop supraventricular tachycardia (SVT) and require urgent treatment to prevent development of hydrops (Copel, 2000; Srinivasan, 2008). Given the importance of identifying such tachycardia, the fetus with premature atrial contractions is often monitored with heart rate assessment every 1 to 2 weeks until ectopy resolution.

Tachyarrhythmias

The two most common are supraventricular tachycardia and atrial flutter. SVT is characterized by an abrupt increase in the fetal heart rate to 180 to 300 bpm with 1:1 atrioventricular concordance. The typical range is 200 to 240 bpm. SVT may develop secondary to an ectopic focus or to an accessory atrioventricular pathway leading to a reentrant tachycardia. Atrial flutter is characterized by a much higher atrial rate—300 to 500 bpm. There are varying degrees of atrioventricular block, such that the ventricular rate may range from below normal to approximately 250 bpm (Fig. 16-1). In contrast, fetal sinus tachycardia typically presents with a gradual heart rate rise to a rate slightly above normal. There is often a readily discernible cause such as maternal fever or hyperthyroidism, or rarely, fetal anemia or infection.
FIGURE 16-1 Atrial flutter. In this M-mode image at 28 weeks, calipers mark the ventricular rate, which is approximately 225 bpm. There are two atrial beats (A) for each ventricular beat (V), such that the atrial rate is approximately 450 bpm with 2:1 atrioventricular block.

If a tachyarrhythmia is identified, it is important to determine whether it is sustained—defined as present for at least 50 percent of the time. It may be necessary to monitor the fetal heart rate for 12 to 24 hours upon initial detection, and then periodically to reassess (Srinivasan, 2008). Nonsustained or intermittent tachyarrhythmias generally do not require treatment, provided that fetal surveillance is reassuring.

Sustained fetal tachyarrhythmia with ventricular rates exceeding 200 bpm impairs ventricular filling to such a degree that the risk of hydrops is significant. With atrial flutter, lack of coordinated atrioventricular contractions may further compound this risk. Maternal administration of antiarrhythmic agents that cross the placenta may convert the rhythm to normal or lower the baseline heart rate to forestall heart failure. Therapy may require dosages at the upper end of the therapeutic adult range. A maternal electrocardiogram should be performed before and during therapy. If the fetus has become hydropic, the drug may need to be administered directly via the umbilical vein (Mangione, 1999; Simpson, 2006).

Various antiarrhythmic medications have been used, most commonly digoxin, sotalol (Betapace), flecainide (Tambocor), and procainamide (Pronestyl). Their selection depends on the type of tachyarrhythmia as well as provider familiarity and experience with the drug. Digoxin is usually the first-line agent. Amiodarone (Cordarone) has been associated with fetal and neonatal hypothyroidism, which may be severe (Niinikoski, 2007; Simpson, 2006).
In a review of 485 cases of fetal tachyarrhythmia, hydrops was reported in approximately 40 percent of those with either SVT or atrial flutter (Krapp, 2003). Digoxin was the first-line agent selected in two thirds with either tachyarrhythmia. Treatment was more effective in nonhydropic fetuses than in those in whom hydrops had already developed. With therapy, the neonatal survival rate with either arrhythmia exceeded 90 percent (Krapp, 2003).

Bradyarrhythmia

The most common etiology of pronounced fetal bradycardia is congenital heart block. Approximately 50 percent of cases occur in the setting of a structural cardiac abnormality involving the conduction system. These include heterotaxy, in particular left-atrial isomerism; endocardial cushion defect; and corrected transposition of the great vessels (Srinivasan, 2008). The prognosis of heart block secondary to a structural cardiac anomaly is extremely poor, and fetal loss rates exceed 80 percent (Glatz, 2008; Strasburger, 2010). In a structurally normal heart, 85 percent of cases of atrioventricular block develop secondary to transplacental passage of maternal anti-SSA/Ro or anti-SSB/La antibodies (Buyon, 2009). Many of these women have, or subsequently develop, systemic lupus erythematosus or another connective-tissue disease (Chap. 59, p. 1172). The risk of third-degree heart block with these antibodies is only 2 to 5 percent, but it may be up to 20 percent if a prior infant has been affected. Immune-mediated congenital heart block confers a mortality rate of 20 to 30 percent, requires permanent pacing in two thirds of surviving children, and also poses a risk for cardiomyopathy (Buyon, 2009). If associated with effusions, bradyarrhythmias, or endocardial fibroelastosis, neonatal status may progressively worsen after birth (Cuneo, 2007).

Research efforts have focused on maternal corticosteroid therapy to reverse fetal heart block or forestall it. Friedman and colleagues (2008, 2009) conducted a prospective multicenter trial of pregnancies with anti-SSA/Ro antibodies—the PR Interval and Dexamethasone (PRIDE) study. Weekly sonography was used to monitor for fetal heart block. If identified, maternal treatment was dexamethasone 4 mg orally daily. There were several important findings. First-degree block was rare and did not generally precede to more advanced block; progression from second- to third-degree block was not prevented with maternal dexamethasone therapy; and third-degree atrioventricular block was irreversible (Friedman, 2008, 2009). In rare cases, there was a potential benefit in reversing first-degree atrioventricular block. However, the authors cautioned that there was a need to weigh this potential benefit against the risks of chronic antepartum corticosteroid treatment, including impaired fetal growth (Friedman, 2009).

Maternal terbutaline has also been administered to increase the fetal heart rate in cases with sustained bradycardia of any cause in which the fetal heart rate is ≤ 55 bpm. Cuneo and associates (2007) reported reversal of hydrops with this therapy in a few cases. However, outcomes in those with structural abnormalities remained poor.

Congenital Adrenal Hyperplasia

Several autosomal recessive enzyme deficiencies cause impaired fetal synthesis of cortisol from cholesterol by the adrenal cortex, resulting in congenital adrenal hyperplasia (CAH). This is the most common etiology of androgen excess in females with pseudohermaphroditism (Chap. 7, p. 148). Lack of cortisol stimulates adrenocorticotropic hormone (ACTH) secretion by the anterior pituitary, and the resulting androstenedione and testosterone overproduction leads to virilization of female fetuses. Sequelae may include formation of labioscrotal folds, development of a urogenital sinus, or even creation of a penile urethra and scrotal sac (Fig. 7-18, p. 149).
More than 90 percent of CAH cases are caused by 21-hydroxylase deficiency, which is found in classic and nonclassic forms. The incidence of classic CAH is approximately 1:15,000 overall and is higher in selected populations. For example, it develops in approximately 1:300 Yupik Eskimos (Nimkarn, 2010). Among those with classic CAH, 75 percent are at risk for salt-wasting adrenal crises and require postnatal treatment with mineralocorticoids and glucocorticoids. The remaining 25 percent with classic CAH have the simple virilizing type and require glucocorticoid supplementation. Without prompt recognition and treatment, infants with the salt-wasting form can develop hyponatremia, dehydration, hypotension, and cardiovascular collapse. As discussed in Chapter 32 (p. 631), all states mandate newborn screening for CAH.

The efficacy of maternal dexamethasone treatment to suppress fetal androgen overproduction and either obviate or ameliorate virilization of female fetuses has been recognized for nearly 30 years (David, 1984; New, 2012). Prenatal corticosteroid therapy is considered successful in 80 to 85 percent of cases (Miller, 2013; Speiser, 2010). The alternative is consideration of postnatal genitoplasty, a complex and somewhat controversial surgical procedure, which may involve vaginoplasty, clitoroplasty, and labioplasty (Braga, 2009).

If treatment is elected, the typical regimen is oral dexamethasone given to the mother at a dosage of 20 μg/kg/d—up to 1.5 mg per day, divided in three doses. The critical period for external genitalia development is 7 to 12 weeks’ gestation. To prevent virilization, treatment should be initiated by 9 weeks, before it is known whether the fetus is at risk. Because this is an autosomal recessive condition, affected females comprise only 1 in 8 at-risk conceptions.

Typically, carrier parents are identified after the birth of an affected child. Molecular genetic testing is clinically available for common mutations and deletions of the CYP21A2 gene, which encodes the 21-hydroxylase enzyme. It is informative in 80 to 98 percent of cases, and for the remainder, gene sequencing may detect rarer alleles (Nimkarn, 2010). Women who elect treatment do so with a plan to undergo prenatal diagnosis and stop therapy if the fetus is male or an unaffected female. Prenatal diagnosis with molecular genetic testing may be performed on chorionic villi—at 10 to 12 weeks’ gestation—or on amniocytes after 15 weeks. Ideally, the goal is to limit dexamethasone exposure in males and in unaffected females.

Recently, maternal treatment with dexamethasone has become a topic of significant controversy. The Endocrine Society has recommended that treatment be given only in the context of research protocols (Miller, 2013; Speiser, 2010). If therapy is initiated shortly before 9 weeks, the dosage of dexamethasone used is not considered to have significant teratogenic potential because organogenesis of major organs has already taken place (McCullough, 2010). There are ongoing concerns, however, about the potential effects of either excess endogenous androgens or excess exogenous dexamethasone on the developing brain. Although maternal dexamethasone has been used for many years to prevent virilization of female fetuses with CAH, long-term safety data are relatively limited.

Development of cell-free fetal DNA testing of maternal serum has potential to replace invasive tests such as chorionic villus sampling and amniocentesis for CAH (Chap. 13, p. 279). Determination of fetal gender using cell-free fetal DNA is reported to have at least 95-percent sensitivity when performed at or beyond 7 weeks’ gestation (Devaney, 2011). Although not yet clinically available in 2013, DNA analysis of the CYP21A2 gene has also been reported using cell-free fetal DNA testing.

### Congenital Cystic Adenomatoid Malformation

Also called congenital pulmonary airway malformation (CPAM), this lung mass is a...
hamartomatous overgrowth of terminal bronchioles. Sonographically, congenital cystic adenomatoid malformation (CCAM) is a well-circumscribed mass that may appear solid and echogenic or may have one or multiple variably sized cysts (Fig. 10-18, p. 207). Lesions with cysts 5 mm or larger are generally termed macrocystic, whereas microcystic lesions have smaller cysts or appear solid (Adzick, 1985). Therapy for macrocystic CCAM is discussed on page 330.

Infrequently, a microcystic CCAM may demonstrate rapid growth between 18 and 26 weeks’ gestation. The mass may become so large that it causes mediastinal shift, compromised cardiac output and venous return, and resultant hydrops (Cavoretto, 2008). A CCAM-volume ratio (CVR) has been used to quantify size and risk for hydrops in these severe cases (Crombleholme, 2002). The CVR is an estimate of the CCAM volume—length × width × height × 0.52—divided by the head circumference. In the absence of a dominant cyst, a CVR exceeding 1.6 has been associated with a hydrops risk of approximately 75 percent, whereas the risk is < 5 percent with a smaller CVR.

If the CVR exceeds 1.4 or 1.6 or if signs of hydrops develop, corticosteroid treatment has been advocated to improve outcome. Regimens include dexamethasone—6.25 mg every 12 hours for four doses, or betamethasone—12.5 mg intramuscularly every 24 hours for two doses. In some reports, hydrops has resolved in nearly 80 percent of cases, and approximately 85 percent of these treated cases survived (Curran, 2010; Loh, 2012; Peranteau, 2007). However, others found that high-risk CCAMs displayed a variable response to corticosteroid treatment, and perinatal mortality rates were > 40 percent (Morris, 2009c).

Thyroid Disease

Identification of fetal thyroid disease is rare and usually prompted by sonographic detection of a fetal goiter. There are several possibilities to consider. If a woman has previously been treated for Graves disease with either thyroid ablation or surgical resection, she may continue to produce IgG thyroid-stimulating immunoglobulins. These cross the placenta to cause fetal thyrotoxicosis. In a woman receiving medication for Graves disease, transplacental passage of propylthiouracil or methimazole usually prevents this, as discussed in Chapter 58 (p. 1149). Occasionally, maternal treatment—or overtreatment—for thyrotoxicosis may cause fetal hypothyroidism (Bliddal, 2011a). Other potential causes of fetal hypothyroidism resulting in goiter include transplacental passage of thyroid peroxidase antibodies and fetal thyroid dyshormonogenesis (Agrawal, 2002).

If a goiter is identified, it is important to determine whether the fetus is hyper- or hypothyroid. Thyroid hormone levels may be measured in amniotic fluid, but fetal blood sampling, discussed in Chapter 14 (p. 300), is preferred for guiding treatment (Abuhamad, 1995; Ribault, 2009). A primary purpose of therapy—in addition to correcting the physiological abnormality—is to decrease goiter size. The goiter may compress the trachea and esophagus to such a degree that the fetus may develop severe hydramnios and the neonate may develop airway compromise. Hyperextension of the fetal neck by a goiter may result in labor dystocia.

Fetal Thyrotoxicosis

Untreated fetal thyrotoxicosis may present with goiter, tachycardia, growth restriction, hydramnios, accelerated bone maturation, and even heart failure and hydrops (Huel, 2009; Peleg, 2002). The cause is usually Graves disease with transplacental passage of thyroid-stimulating immunoglobulins. Most recommend fetal blood sampling to confirm the diagnosis (Duncombe, 2001; Heckel, 1997; Srisupundit, 2008). Confirmed fetal thyrotoxicosis is followed by maternal antithyroid treatment, and if the mother develops hypothyroidism, she is given supplemental
levothyroxine (Hui, 2011).

**Fetal Hypothyroidism**

Goitrous hypothyroidism may lead to hydramnios, neck hyperextension, and delayed bone maturation. If the mother is receiving antithyroid medication, discontinuation is generally recommended, along with intraamnionic levothyroxine injection (Bliddal, 2011a; Ribault, 2009). There have been numerous case reports of intraamnionic levothyroxine treatment. However, optimal dosage and frequency have not been established, and reported dosages range from 50 to 800 mg every 1 to 4 weeks (Abuhamad, 1995; Bliddal, 2011b; Ribault, 2009).

**Fetal Stem-Cell Transplantation**

In theory, stem-cell transplantation could be used to treat various hematological, metabolic, and immunological diseases. It could also serve as a delivery vehicle for gene transfer to treat other genetic conditions. The fetal period is ideal for this because in the first and early second trimesters, the fetus lacks an adaptive immune response to foreign antigens—described as *preimmune* (Tiblad, 2008). Also, pretreatment chemotherapy or radiation is not necessary before transplantation, and graft-versus-host disease is less likely.

Fetal stem-cell transplantation has been most successful in the treatment of immunodeficiency syndromes. Engraftment has been achieved in fetuses with severe combined immunodeficiency and bare lymphocyte syndrome (Tiblad, 2008). Treatment of red blood cell and metabolic disorders, however, has not been successful (Mummery, 2011). Stem-cell transplantation has been attempted to treat hemoglobinopathies without success. Some children with α- and β-thalassemia have remained transfusion dependent despite achieving engraftment (Tiblad, 2008; Westgren, 1996). One fetus with osteogenesis imperfecta, type II, was transplanted with fetal mesenchymal stem cells and developed both engraftment and chimerism (Le Blanc, 2005; Mummery, 2011). Although long-term outcomes of such cases remain uncertain, the technology holds great promise.

**SURGICAL THERAPY**

Also called *maternal-fetal surgery*, these procedures are offered for selected congenital abnormalities in which the likelihood of fetal deterioration is so great that delaying treatment until after delivery would risk fetal death or substantially greater postnatal morbidity (Walsh, 2011). Open fetal surgery is a highly specialized, multidisciplinary intervention performed at relatively few centers in the United States and for only a few fetal conditions. It was pioneered more than three decades ago by Harrison and coworkers (1982) at the University of California, San Francisco. Criteria for consideration of fetal surgery are listed in Table 16-1. In many cases, data regarding the safety and efficacy of these procedures are lacking. The Agency for Healthcare Research and Quality has stressed that when considering fetal surgery, the overriding concern must be maternal and fetal safety. Accomplishing the fetal goals of the procedure are secondary (Walsh, 2011).

<tr>
<td>Accurate prenatal diagnosis for the defect is available, with staging if applicable</td>
</tr>
</tbody>
</table>
The defect appears isolated, with no evidence of other abnormality or underlying genetic syndrome that would significantly worsen survival or quality of life. The defect results in a high likelihood of death or irreversible organ destruction, and postnatal therapy is inadequate. The procedure is technically feasible, and a multidisciplinary team is in agreement regarding the treatment plan. Maternal risks from the procedure are well documented and considered acceptable. There is comprehensive parental counseling. It is recommended that there is an animal model for the defect and procedure.

Some abnormalities amenable to fetal surgical treatment, antepartum or intrapartum, are shown in Table 16-2. Information regarding the procedures, their indications, and complications is provided to assist patient evaluation and counseling. It is beyond the scope of this text to provide technical information necessary to perform these procedures or address individual circumstances in which their benefits may outweigh potential risks.

**TABLE 16-2. Selected Fetal Abnormalities Amenable to Fetal Surgery**

**Open Fetal Surgery**
- Myelomeningocele
- Congenital cystic adenomatoid malformation (CCAM)
- Extralobar pulmonary sequestration
- Sacrococcygeal teratoma

**Fetoscopic Surgery**
- Twin-twin transfusion: laser of placental anastomoses
- Diaphragmatic hernia: fetal endoscopic tracheal occlusion (FETO)
- Posterior urethral valves: cystoscopic laser
- Congenital high airway obstruction: vocal cord laser
- Amnionic band release

**Percutaneous Procedures**
- Shunt therapy
  - Posterior-urethral valves/bladder outlet obstruction
  - Pleural effusion: chylothorax or sequestration
  - Dominant cyst in CCAM
- Radiofrequency ablation
  - Twin-reversed arterial perfusion (TRAP) sequence
  - Monochorionic twins with severe anomaly(ies) of 1 twin
  - Chorioangioma
- Fetal intracardiac catheter procedures
  - Aortic or pulmonic valvuloplasty for stenosis
Atrial septostomy for hypoplastic left heart with restrictive atrial septum

**Ex-Utero Intrapartum Treatment (EXIT) Procedures**
- Congenital diaphragmatic hernia after FETO
- Congenital high airway obstruction sequence (CHAOS)
- Severe micrognathia
- Tumors involving neck or airway
- EXIT-to-resection: resection of fetal thoracic or mediastinal mass
- EXIT-to-extracorporeal membrane oxygenation (ECMO): congenital diaphragmatic hernia

---

**Open Fetal Surgery**

These procedures require a highly-skilled multidisciplinary team and extensive preoperative counseling. The mother must undergo general endotracheal anesthesia to suppress both uterine contractions and fetal responses. Using sonographic guidance to avoid the placental edge, a hysterotomy incision is made with a stapling device that seals the edges for hemostasis. To replace amnionic fluid losses, warmed fluid is continuously infused into the uterus through a rapid infusion device. The fetus is gently manipulated to permit pulse oximetry monitoring and venous access, in case fluids or blood are emergently needed. The surgical procedure is then performed. After completion, the hysterotomy is closed and tocolysis begun. Tocolysis typically includes intravenous magnesium sulfate for 24 hours, oral indomethacin for 48 hours, and at some centers, oral nifedipine until delivery (Wu, 2009). Prophylactic antibiotics are also administered and generally continued for 24 hours following the procedure. Cesarean delivery will be needed later in gestation and for all future deliveries.

**Risks**

Morbidities associated with fetal surgery have been well characterized. In a review of 87 open procedures from the University of California, San Francisco, Golombeck and colleagues (2006) reported the following morbidities: pulmonary edema—28 percent, placental abruption—9 percent, blood transfusion—13 percent, premature rupture of membranes—52 percent, and preterm delivery—33 percent. Wilson and associates (2010) from Children’s Hospital of Philadelphia reviewed subsequent pregnancy outcomes following open fetal surgery and reported that 14 percent experienced uterine rupture and 14 percent had uterine dehiscence. Morbidities identified in the recent *Management of Myelomeningocele Study—MOMS*—are shown in Table 16-3 (Adzick, 2011). Other potential risks include maternal sepsis and fetal death during or following the procedure.

---

**TABLE 16-3. Benefits and Risks of Fetal Myelomeningocele Surgery versus Postnatal Repair**
Myelomeningocele Surgery

As depicted and described in Chapters 10 (p. 202) and 14 (p. 287), spina bifida, that is, a congenital open vertebral defect, may be associated with herniation of meninges alone (meningocele) or of meninges and spinal cord nerve roots (myelomeningocele). Despite postnatal repair, affected individuals may have varying degrees of paralysis, bladder and bowel dysfunction, developmental delays, and brainstem dysfunction from the Arnold-Chiari II malformation. Evidence from animal and human studies supports a two-hit hypothesis. Spinal cord damage results from both failure of neurulation during embryonic development and ongoing exposure throughout gestation of the neural elements to amnionic fluid (Adzick, 2010; Meuli, 1995, 1997).

<sup>a</sup>Each primary outcome had two components. The perinatal death components of the primary outcomes as well as the Bayley Mental Development Index at 30 months did not differ between the two study cohorts.

Data from Adzick, 2011.
Spina bifida is the first nonlethal birth defect for which fetal surgery has been offered. It meets all of the criteria listed in Table 16-1. Preliminary reports demonstrated that compared with historical controls, infants who had undergone fetal myelomeningocele surgery had reversal of the Arnold-Chiari II malformation and were less likely to require ventriculoperitoneal shunt placement (Bruner, 1999; Sutton, 1999).

Based on this evidence, the National Institutes of Health sponsored a randomized multicenter trial of prenatal versus postnatal myelomeningocele repair—the Management of Myelomeningocele Study—MOMS (Adzick, 2011). Criteria for participation in the MOMS trial included: (1) singleton fetus at 19.0 to 25.9 weeks’ gestation; (2) upper myelomeningocele boundary between T1 and S1 as confirmed by fetal magnetic resonance (MR) imaging; (3) evidence of hindbrain herniation; and (4) normal karyotype and no evidence of a fetal anomaly unrelated to the myelomeningocele. Women at risk for preterm birth or placental abruption, those with a contraindication to fetal surgery, and women with body mass index $\geq 35$ kg/m$^2$ were excluded. Using these criteria and following comprehensive multidisciplinary counseling, only 15 percent of screened patients underwent the procedure.

The MOMS trial demonstrated improved infant outcomes in the prenatal surgery cohort (see Table 16-3). Infants who had undergone prenatal surgery were twice as likely to walk independently by 30 months. They had significantly less hindbrain herniation and were only half as likely to undergo ventriculoperitoneal shunting by the age of 1 year. A primary outcome was a composite score that was derived from the Bayley Mental Development Index and from the difference between the functional and anatomical level of the lesion at 30 months. This outcome was also significantly better in the prenatal surgery group.

When counseling prospective families, however, it is essential to place these results into context. For example, despite improvements in the proportion with independent ambulation, most children who received fetal surgery were not able to ambulate independently, and nearly 30 percent were not able to ambulate at all. Prenatal surgery did not confer improvements in fetal or neonatal death rates or in the Bayley Mental Development Index score at age 30 months. And, as shown in Table 16-3, surgery was associated with a small but significant risk for placental abruption and maternal pulmonary edema. Moreover, nearly half were delivered $\leq 34$ weeks, which significantly increased the risk for respiratory distress syndrome (Adzick, 2011). Long-term data from this trial are pending.

Since publication of the MOMS trial, fetal myelomeningocele has become the most common indication for open fetal surgery at the University of California, San Francisco (Vrecenak, 2013). This is not unexpected, as myelomeningocele is more common than other defects for which open fetal surgery is offered. Also, with other abnormalities, surgery is offered only in the most severe cases—usually prompted by development of hydrops. Rapid expansion of centers offering fetal myelomeningocele surgery has raised concerns about the importance of training and ongoing experience, adherence to the MOMS trial criteria, and need for a registry to ensure that future cases achieve the same success as in the MOMS trial (Cohen, 2014; Vrecenak, 2013).

Thoracic Masses

In the past, if hydrops developed in a fetus with a large extralobar pulmonary sequestration or cystic adenomatoid malformation without a dominant cyst, open fetal surgery with lobectomy was the only treatment available other than preterm delivery (Chap. 10, p. 207). Because most thoracic masses are small and have a benign prognosis, fetal surgery is rarely necessary for fetuses with such masses. Also, larger masses are generally treated with a trial of corticosteroids, and open fetal surgery is reserved for those cases prior to 32 weeks in which hydrops is developing. In...
fetuses with early hydrops and minimal placentomegaly, the survival rate following open lobectomy approximates 60 percent (Vrecenak, 2013). Use of the ex-utero intrapartum treatment procedure in the treatment of fetal lung masses is discussed on page 331.

Sacrococcygeal Teratoma

This germ cell tumor has a birth prevalence of about 1 per 28,000 (Derikx, 2006; Swamy, 2008). Sonographically, a sacrococcygeal teratoma (SCT) is a solid and/or cystic mass that arises from the anterior sacrum (Fig. 16-2). It may grow rapidly, usually extending inferiorly and externally (Fig. 10-12, p. 204). Hydramnios is common, and hydrops may develop from high-output cardiac failure, either as a consequence of tumor vascularity or secondary to bleeding within the tumor and resultant anemia. Mirror syndrome—maternal preeclampsia developing along with fetal hydrops—may occur in this setting (Chap. 15, p. 318). Fetal MR imaging may be helpful in evaluating the extent of the internal tumor component.

FIGURE 16-2 Photograph of open fetal surgery for resection of a sacrococcygeal teratoma. Hysterotomy has been completed, and the caudal portion of the fetus has been delivered onto the surgical field. The tumor is held by the surgeon’s hand. (Photograph contributed by Dr. Timothy M. Crombleholme.)

In 30 pregnancies with a prenatal diagnosis of SCT, the perinatal mortality rate exceeded 40 percent (Hedrick, 2004). Fetal loss approaches 100 percent if hydrops or placentomegaly develop (Vrecenak, 2013). The group at the Children’s Hospital of Philadelphia has recommended consideration of open fetal surgery for SCT only in cases in which the tumor is completely external (Type I) and in which high cardiac output with early hydrops has developed in the second trimester (Vrecenak, 2013). As shown in Figure 16-2, hysterotomy is performed and the external component resected. The coccyx and any deep tumor are left in place for postnatal removal. Because tumor debulking interrupts the vascular steal, normal fetal physiology may be restored.
Fetoscopic Surgery

These procedures use fiberoptic endoscopes only 1 to 2 mm in diameter to cross the maternal abdominal wall, the uterine wall, and membranes. Instruments such as lasers fit through 3- to 5-mm cannulae that surround the endoscope. Thus, fetoscopic surgeries are usually performed at highly specialized centers, and many are considered investigational. Morbidities are generally lower than with open fetal surgery, but they still may be formidable, particularly if maternal laparotomy is required for access (Golombeck, 2006). Examples of some conditions treated by fetoscopy are listed in Table 16-2.

Twin-Twin Transfusion Syndrome

As discussed in Chapter 45 (p. 907), fetoscopic laser ablation of placental anastomoses has become the preferred management for many cases of severe twin-twin transfusion syndrome (TTTS). It is generally performed between 16 and 26 weeks’ gestation for monochorionic-diamnionic twin pregnancies with stage II to stage IV TTTS. These categories of the Quintero Staging System are described in Chapter 45 (Quintero, 1999; Society for Maternal-Fetal Medicine, 2013). In this country, pregnancies with stage I TTTS are not routinely offered laser ablation. However, following a consensus conference held by the North American Fetal Therapy Network (NAFTNet), as of 2013, a randomized trial that includes laser therapy for stage I TTTS is underway (Stamilio, 2010).

Technique. The procedure is typically performed under epidural analgesia with intravenous sedation. A fetoscope is used to view the vascular equator that separates the placental cotyledons supplying each twin to permit selective laser photocoagulation of arteriovenous anastomoses that cross this equator (Fig. 16-3).

FIGURE 16-3 Laser therapy for twin-twin transfusion syndrome (TTTS). Fetoscopic photograph
of the fetal surface of the placenta. **A.** Vascular anastomoses (arrows) are shown before selective laser ablation. **B.** Sites of ablation are seen as blanched yellow-white areas (arrows). (Photographs contributed by Dr. Timothy M. Crombleholme.)

The randomized trial of TTTS conducted in the United States and reported by Crombleholme and associates (2007) used the following methodology. First, a small skin incision allows ultrasound-guided placement of a 3.3-mm fetoscope containing separate ports for the lens, the laser, and rapid infusion of saline as needed. More recently, fetoscopes as small as 1.2 mm have been used (Chalouhi, 2011). Next, the choric plate of the placenta is mapped three times: first to identify all anastomoses at the vascular equator, then to mark and record the location of each connecting vessel, and after photocoagulation, to verify that no connecting vessels were missed or had recanalized. Vessels are photocoagulated with 60 watts of power using a 600-μm diameter diode laser with the endostat placed 1 cm from the vessel surface. A 400-μm neodymium:yttrium-aluminum-garnet (Nd:YAG) laser also may be used. At the end of the procedure, amnioreduction is performed to decrease the single deepest pocket of amniotic fluid to below 5 cm, and antibiotics are injected into the amniotic cavity.

If cardiomyopathy has been identified in the recipient twin, nifedipine, 20 mg every 6 hours, may be given to the mother 24 to 48 hours before photocoagulation and continued following the procedure, in an effort to improve recipient twin survival (Crombleholme, 2010).

**Complications.** Families should have reasonable expectations of procedural success and potential complications. Without treatment, the perinatal mortality rate for severe TTTS is 70 to 100 percent (Society for Maternal-Fetal Medicine, 2013). Following laser therapy, the anticipated perinatal mortality rate approximates 30 to 50 percent, with a 5- to 20-percent risk for long-term neurological handicap (Society for Maternal-Fetal Medicine, 2013). Cystic periventricular leukomalacia and grade III to IV interventricular hemorrhage are identified neonatally in up to 10 percent of laser-treated cases (Lopriore, 2006).

Procedure-related complications include preterm prematurely ruptured membranes in up to 25 percent, placental abruption in 8 percent, vascular laceration in 3 percent, amniotic band syndrome resulting from laser laceration of the membranes in 3 percent, and twin-anemia polycythemia sequence in 2 to 12 percent (Habli, 2009; Robyr, 2006). Finally, almost 85 percent of laser-treated TTTS pregnancies deliver before 34 weeks (Habli, 2009).

Twin anemia polycythemia sequence (TAPS) is a type of chronic fetofetal transfusion. It is characterized by large differences in hemoglobin concentrations between the twins of a monochorionic pair in the absence of amniotic fluid volume differences. It may occur spontaneously in 3 to 5 percent of monochorionic twins, although it has been recognized more frequently as a complication of laser-treated TTTS. Differences in middle cerebral artery peak systolic velocity, described in Chapter 10 (p. 221), between the twins may assist in identifying this complication (Robyr, 2006; Slaghekke, 2010).

**Congenital Diaphragmatic Hernia**

Fetal therapy for this anomaly is more controversial than for others. The prevalence of congenital diaphragmatic hernia (CDH) is approximately 1 in 3000 to 4000 births, and the overall survival rate is 50 to 60 percent (Chap. 10, p. 206). Associated anomalies occur in 40 percent of cases and confer a considerably lower survival rate. With isolated CDH, the major causes of mortality are pulmonary hypoplasia and pulmonary hypertension. The major risk factor is liver herniation, which complicates at least half of cases and is associated with a 30-percent reduction in the
Lung-to-Head Ratio. This sonographic ratio was developed by investigators from the University of California, San Francisco to improve prediction of survival in fetuses with isolated left-sided CDH diagnosed before 25 weeks’ gestation (Metkus, 1996). The lung-to-head ratio (LHR) is a measurement of the right lung area, taken at the level of the four-chamber view of the heart (Fig. 10-20, p. 209), divided by the head circumference. Investigators found that the survival rate was 100 percent if the LHR was above 1.35, and there were no survivors if it was below 0.6. Nearly three fourths of pregnancies had values between 0.6 and 1.35, and prediction was difficult in this large group because the overall survival rate was about 60 percent (Metkus, 1996).

Jani and coworkers (2006) evaluated the LHR in 184 cases from an international registry of isolated CDH between 22 and 28 weeks’ gestation. The survival rate was 15 percent if the LHR was 0.8 to 1.0, 65 percent with LHRs 1.0 to 1.5, and 80 percent with LHRs 1.6 or more. There were no survivors with LHRs below 0.8. As of 2013, trials underway in the United States and Europe have selected a threshold LHR of 1.0 or lower for inclusion.

Magnetic Resonance Imaging. This has been used to estimate the volume of lung tissue ipsilateral and contralateral to the diaphragmatic hernia, which may then be compared with a gestational age-matched reference. Mayer and colleagues (2011) performed a metaanalysis of 19 studies involving more than 600 pregnancies in which isolated CDH was evaluated with fetal MR imaging. Factors significantly associated with neonatal survival included the side of the defect, total fetal lung volume, observed-to-expected lung volume, and fetal liver position.

Fetal MR imaging has also been used to quantify the volume of herniated liver (Fig. 10-44, p. 225). Two reasons underlie the rationale for assessing liver volume. The first is that liver herniation is perhaps the strongest predictor of outcome in fetuses with isolated CDH. Second, liver volume might be a more reliable predictor because lungs are inherently more compressible than liver. In preliminary reports, MR assessment of the degree of liver herniation has been found to correlate with postnatal survival rates and may even be more useful as a predictor than lung volume (Cannie, 2008; Walsh, 2000; Worley, 2009).

Tracheal Occlusion. Early attempts to treat severe diaphragmatic herniation used open fetal surgery. Unfortunately, repositioning of the liver into the abdomen resulted in kinking of the umbilical vein with subsequent fetal demise (Harrison, 1993).

Knowledge that fetal lungs normally produce fluid and that fetuses with upper airway obstruction develop hyperplastic lungs formed the rationale for tracheal occlusion (Hedrick, 1994). Initially, the trachea was occluded with an external clip (Harrison, 1993). Currently, a detachable silicone balloon is placed within the trachea endoscopically, using a 3-mm operating sheath and fetoscopes as small as 1 mm (Deprest, 2011; Ruano, 2012). The ex-utero intrapartum treatment procedure (p. 331) was developed in tandem with these procedures, and it is used at delivery during reversal of the tracheal occlusion.

A randomized trial of the fetal endoscopic tracheal occlusion (FETO) technique was conducted in pregnancies with isolated CDH, liver herniation, and LHR below 1.4 (Harrison, 2010). Because of maternal and fetal risks associated with fetal surgical intervention, efforts have focused on identifying those least likely to survive with postnatal therapy alone. Cases with associated anomalies are typically excluded, as are those without liver herniation. Prediction is further hampered because of improvements in neonatal care for infants with CDH. These include permissive hypercapnia, “gentle ventilation” to avoid barotrauma, and delayed surgery.
Pregnancies included had a predicted survival rate < 40 percent with conventional postnatal therapy based on historical data. The trial was stopped after only 24 women had been enrolled because no benefit was identified. Survival rates 90 days after birth were unexpectedly high in both groups and approximated 75 percent. Potential benefits of FETO may have been offset by the high rate of early preterm birth. The mean age at delivery was just older than 30 weeks, and fetuses were delivered an average of 6 weeks after the procedure. This left less time for catch-up growth (Wenstrom, 2003).

Following this study, there has been continued enthusiasm for the technique, particularly outside the United States. Using a lower lung-to-head ratio threshold of 1.0 for inclusion, significantly higher postnatal survival rates have been reported. Rates improved from < 25 percent with postnatal therapy to approximately 50 percent with FETO (Jani, 2009; Ruano, 2012).

Percutaneous Procedures

Sonographic guidance can be used to permit therapy with a shunt, radiofrequency ablation needle, or angioplasty catheter. With these procedures, desired instruments cross the maternal abdominal wall, uterine wall, and membranes to reach the amnionic cavity and fetus. Risks include maternal infection, preterm labor or prematurely ruptured membranes, and fetal injury or loss. Percutaneous shunts are used to drain fluid in cases of selected urinary and thoracic abnormalities. Radiofrequency ablation has become increasingly available for selected indications such as twin-reversed arterial perfusion sequence. Fetal cardiac catheterization procedures hold promise for pregnancies with severe hypoplastic left heart syndrome but currently remain investigational.

Thoracic Shunts

A shunt placed from the fetal pleural cavity into the amnionic cavity may be used to drain pleural fluid. A large effusion may cause a significant mediastinal shift, resulting in pulmonary hypoplasia or in heart failure and hydrops. The most common etiology of a primary effusion is chylothorax—caused by lymphatic obstruction. Pleural effusions may also be secondary to congenital viral infection or aneuploidy, or they may be associated with a malformation such as extralobar pulmonary sequestration. Yinon and associates (2010) reported aneuploidy in approximately 5 percent and associated anomalies in 10 percent of cases.

Typically, the effusion is first drained using a 22-gauge needle under sonographic guidance. Tests for aneuploidy and infection are performed, as well as a cell count. A pleural-fluid cell count with greater than 80-percent lymphocytes, in the absence of infection, is diagnostic of chylothorax. If the fluid reaccumulates, a trocar and cannula may be inserted through the fetal chest wall, and a double-pigtail shunt may be placed to drain the effusion (Fig. 16-4). If the effusion is right-sided, the shunt is placed in the lower third of the chest to permit maximum expansion of the lung. If left-sided, the shunt is placed along the upper axillary line to allow the heart to return to normal position (Mann, 2010). The overall survival rate is reported to be 70 percent, and that of hydropic fetuses approximates 50 percent (Mann, 2010; Yinon, 2010). Shunt displacement into the amnionic cavity is not uncommon. If the shunt remains in place, it must be clamped immediately upon delivery of the infant to avoid pneumothorax.
FIGURE 16-4 Thoraco-amnionic shunt placement. A. A large, right-sided fetal pleural effusion (asterisks) and ascites were identified at 18 weeks’ gestation. The effusion was drained but rapidly reaccumulated. The xanthochromic fluid contained 95-percent lymphocytes, consistent with chylothorax. B. A double-pigtail shunt (arrow) was inserted under ultrasound guidance. Following shunt placement, the effusion and ascites resolved.

Shunts have also been used to drain a dominant cyst in fetuses with macrocystic congenital cystic adenomatoid malformation. Fortunately, cysts rarely are large enough to pose a risk for hydrops or pulmonary hypoplasia. Shunt placement may reduce the volume of the CCAM by as much as 70 percent and may reverse hydrops and improve survival rates (Knox, 2006; Mann, 2010). Survival rates following shunt placement for CCAM approximate 70 percent (Wilson, 2004).

Urinary Shunts
Vesicoamnionic shunts are used in fetuses with bladder-outlet obstruction that would otherwise have a grim prognosis. Distal obstruction of the urinary tract occurs more often in male fetuses, and the most common etiology is posterior urethral valves, followed by urethral atresia and by prune belly syndrome, which is also called Eagle-Barrett syndrome. Diagnosis is discussed in Chapter 10 (p. 216). Sonographic findings include dilatation of the bladder and proximal urethra, termed the “keyhole” sign, along with bladder wall thickening (Fig. 10-33, p. 217). Oligohydramnios before midpregnancy leads to pulmonary hypoplasia. Unfortunately, the outcome may be poor even when amnionic fluid volume is normal. Evaluation includes a careful search for
associated anomalies, which may coexist in 40 percent of cases, and for aneuploidy, which has been reported in 5 to 8 percent of cases (Hayden, 1988; Hobbins, 1984; Mann, 2010; Manning 1986).

Shunt placement allows urine to drain from the bladder into the amnionic cavity. This attempts to preserve renal function and improve oligohydramnios to prevent pulmonary hypoplasia. Potential candidates are fetuses without other severe anomalies or aneuploidy and without sonographic features that confer poor prognosis, for example, renal cortical cysts. Therapy is generally offered only if the fetus is male, because in females, the type of anomaly tends to be even more severe. Serial bladder drainage—vesicocentesis—is performed at 24- to 48-hour intervals under sonographic guidance to determine the urine electrolyte and protein content. This permits classification of the renal prognosis as good or poor (Table 16-4).

Good or poor prognosis is based on values from serial vesicocentesis performed between 18 and 22 weeks’ gestation, using the last specimen obtained. Data from Mann, 2010.

Amnioinfusion is usually performed before shunting to aid placement of the distant end of the catheter into the amnionic cavity. Amnioinfusion also assists sonographic fetal anatomical survey to ensure than no other abnormalities are present. A small trocar and cannula are then inserted into the fetal bladder under sonographic guidance. The shunt is placed as low as possible within the bladder to avoid dislodgement after bladder decompression. A double-pigtail catheter is used, with the distal end within the fetal bladder and the proximal end within the amnionic cavity.

Complications include displacement of the shunt out of the fetal bladder in up to 40 percent of cases, urinary ascites in about 20 percent, and development of gastoschisis in 10 percent (Freedman, 2000; Mann, 2010). Preterm delivery is common, and infant survival rates have ranged from 50 to 90 percent (Biard, 2005; Walsh, 2011). It is not known whether vesicoamnionic shunt placement confers a benefit in terms of long-term renal function (Holmes, 2001). A third of surviving children have required dialysis or renal transplantation, and almost half have respiratory problems (Biard, 2005).

Radiofrequency Ablation

With this procedure, high-frequency alternating current is used to coagulate and desiccate tissue. Radiofrequency ablation (RFA) has become a favored modality for the treatment of twin-reversed
arterial perfusion (TRAP) sequence, also known as acardiac twin (Chap. 45, p. 908). Without treatment, the mortality rate for the normal or pump twin in TRAP sequence exceeds 50 percent. The procedure is also used for selective termination with other monochorionic twin complications (Bebbington, 2012).

The procedure is performed under sonographic guidance, and a 17- or 19-gauge RFA needle is placed into the base of the umbilical cord of the acardiac twin and into its abdomen. After a 2-cm area of coagulation is achieved, color Doppler sonography is used to verify absent flow into this twin. Several centers have reported a significantly improved rate of survival for the normal twin following RFA for TRAP sequence (Lee, 2007; Livingston, 2007). RFA was performed at approximately 20 weeks in 98 pregnancies with TRAP sequence reported by the North American Fetal Therapy Network (Lee, 2013). The median gestational age at delivery was 37 weeks, and the neonatal survival rate was 80 percent. The major complication was prematurely ruptured membranes and preterm birth—12 percent were delivered at about 26 weeks.

RFA has generally been offered to TRAP sequence pregnancies when the volume of the acardiac twin is large. In the NAFTNet series cited above, the median size of the acardius relative to the pump twin was 90 percent (Lee, 2013). Considering procedure-related risks, expectant management with close fetal surveillance is recommended if the estimated weight of the acardius is < 50 percent of the pump twin (Jelin, 2010).

Fetal Intracardiac Catheter Procedures

Selected fetal cardiac lesions may worsen during gestation, further complicating, or even obviating, options for postnatal repair. Severe narrowing of a cardiac outflow tract may result in progressive myocardial damage in utero, but intervention may permit muscle growth and preserve ventricular function (Walsh, 2011). Possible fetal procedures include aortic valvuloplasty for critical aortic stenosis; atrial septostomy for hypoplastic left heart syndrome with intact interatrial septum; and pulmonary valvuloplasty for pulmonary atresia with intact interventricular septum. There is a registry for these cases—the International Fetal Cardiac Intervention Registry (www.ifcir.org).

Of these, fetal aortic valvuloplasty is the most commonly performed. It is offered for selected cases of critical aortic stenosis in which the left ventricle is either normal sized or dilated. The goal is to prevent development of hypoplastic left heart and permit postnatal biventricular repair (McElhinney, 2010). Under sonographic guidance, an 18-gauge needle is inserted into the left ventricle with the tip positioned in front of the stenotic aortic valve. A 2.5- to 4.5-mm balloon catheter is then guided into the aortic annulus and inflated several times. Arzt and Tulzer (2011) reviewed the collective experience of two major centers that perform fetal cardiac procedures—one in Boston and the other in Linz, Austria. Technical procedural success was achieved in 75 percent of cases, and there was a 9-percent fetal loss rate. All required postnatal aortic valvuloplasty, two thirds needed early aortic valve replacement, and less than half achieved the goal of postnatal biventricular repair.

Fetal atrial septostomy, also using a percutaneous balloon catheter, has been offered in selected cases of hypoplastic left heart with an intact or highly restrictive interatrial septum. This condition has a postnatal mortality rate of approximately 80 percent (Glantz, 2007). In one report of 21 cases, the procedure-related loss was about 10 percent, and the short-term neonatal survival rate was 58 percent (Marshall, 2008).

Fetal pulmonary valvuloplasty has been offered in cases of pulmonary atresia with intact interventricular septum to prevent development of hypoplastic right heart syndrome. Success has been reported in approximately two thirds of cases. However, it is not yet clear whether outcomes
are improved compared with standard postnatal repair (Artz, 2011; McElhinney, 2010).

**Ex-Utero Intrapartum Treatment**

This procedure is designed to allow the fetus to remain perfused by the placental circulation after being partially delivered, so that life-saving treatment can be performed before completing the delivery. The technique was first developed to obtain an airway with fetal tumors involving the oropharynx and neck (Catalano, 1992; Kelly, 1990; Langer, 1992). It was refined when tracheal occlusion was developed to treat congenital diaphragmatic hernia, because it was necessary to reestablish an airway after the trachea had been “plugged” or “clipped” (Mychaliska, 1997). Components of the procedure are shown in Table 16-5.

Adapted from Moldenhauer, 2013.

Some indications for the ex-utero intrapartum treatment (EXIT) procedure are listed in Table 16-2. It is the procedure of choice for intrapartum management of giant neck masses such as the one shown in Figure 16-5. Also, it is frequently used to remove the endotracheal balloon following fetal surgery for congenital diaphragmatic hernia (Laje, 2012; Ruano, 2012). Less common indications include treatment of congenital high airway obstruction sequence (CHAOS, and selected cases of severe fetal micrognathia, both discussed in Chapter 10 (Figs. 10-14 and 10-19, p. 205). Morris and coworkers (2009b) have proposed that in addition to a fetal jaw measurement below the 5th percentile, cases to be considered for EXIT procedures are those with indirect evidence of obstruction, including hydramnios, an absent stomach bubble, or glossoptosis. Fetal MR imaging may be helpful in this setting (Chap. 10, p. 226).
This procedure can also be used as a bridge to other procedures. For example, during an EXIT procedure, resection of large thoracic masses may be accomplished by fetal thoracotomy performed with the placental circulation intact. In a series of 16 fetuses with CCAM volume ratio $> 1.6$ or hydrops, all of whom had mediastinal compression, Cass and colleagues (2013) reported that nine undergoing EXIT-to-resection survived. In contrast, there were no survivors with urgent postnatal surgery done alone. Similarly, Moldenhauer (2013) reported that 20 of 22 infants treated with EXIT-to-resection for lung masses survived. The EXIT procedure has also been used as a bridge to extracorporeal membrane oxygenation—EXIT-to-ECMO—in pregnancies with severe congenital diaphragmatic hernia. However, it has not been found to clearly confer survival benefit in such cases (Morris, 2009a; Stoffan, 2012).

An EXIT procedure is performed by a multidisciplinary team, which may include an obstetrician, maternal-fetal medicine specialist, pediatric surgeon(s), pediatric otolaryngologist, pediatric cardiologist, anesthesiologists for the mother and fetus, and neonatologists, as well as nursing personnel from many of these specialties. Counseling should include procedure-related risks such as hemorrhage from placental abruption or uterine atony, need for cesarean delivery in future pregnancies, increased risk for subsequent uterine rupture or dehiscence, possible need for hysterectomy, and fetal death or permanent neonatal disability. Compared with cesarean delivery, the EXIT procedure is also associated with a longer operating time—approximately 40 minutes longer depending on the procedure, increased blood loss, and a higher incidence of wound
complications (Noah, 2002).

Krapp M, Kohl T, Simpson JM, et al: Review of diagnosis, treatment, and outcome of fetal atrial flutter compared with
supraventricular tachycardia. Heart 89:913, 2003
Available techniques employed to forecast fetal well-being focus on fetal biophysical findings that include heart rate, movement, breathing, and amnionic fluid production. These findings are used to perform antepartum fetal surveillance to accomplish the stated goals of the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2012), which includes prevention of fetal death and avoidance of unnecessary interventions. In most cases, a negative, that is, normal test result is highly reassuring, because fetal deaths within 1 week of a normal test are rare. Indeed, negative-predictive values—a true negative test—for most of the tests described are 99.8 percent or higher. In contrast, estimates of the positive-predictive values—a true positive test—for abnormal test results are low and range between 10 and 40 percent. Importantly, the widespread use of antepartum fetal surveillance is primarily based on circumstantial evidence because there have been no definitive randomized clinical trials (Grivell, 2012; Hofmeyr, 2012).

**FETAL MOVEMENTS**

Passive unstimulated fetal activity commences as early as 7 weeks’ gestation and becomes more sophisticated and coordinated by the end of pregnancy (Vindla, 1995). Indeed, beyond 8 menstrual weeks, fetal body movements are never absent for periods exceeding 13 minutes (DeVries, 1985).
Between 20 and 30 weeks, general body movements become organized, and the fetus starts to show rest-activity cycles (Sorokin, 1982). Fetal movement maturation continues until approximately 36 weeks, when behavioral states are established in most normal fetuses. Nijhuis and colleagues (1982) described four fetal behavioral states:

- State 1F is a quiescent state—quiet sleep—with a narrow oscillatory bandwidth of the fetal heart rate.
- State 2F includes frequent gross body movements, continuous eye movements, and wider oscillation of the fetal heart rate. This state is analogous to rapid eye movement (REM) or active sleep in the neonate.
- State 3F includes continuous eye movements in the absence of body movements and no heart rate accelerations. The existence of this state is disputed (Pillai, 1990a).
- State 4F is one of vigorous body movement with continuous eye movements and heart rate accelerations. This state corresponds to the awake state in newborns.

Fetuses spend most of their time in states 1F and 2F. For example, at 38 weeks, 75 percent of time is spent in these two states. These behavioral states—particularly 1F and 2F, which correspond to quiet sleep and active sleep—have been used to develop an increasingly sophisticated understanding of fetal behavior. In a study of fetal urine production, as shown in Figure 17-1, bladder volumes increased during state 1F quiet sleep. During state 2F, the fetal heart rate baseline bandwidth increased appreciably, and bladder volume was significantly diminished due to fetal voiding as well as decreased urine production. These phenomena were interpreted to represent reduced renal blood flow during active sleep. Knight and coworkers (2012) studied 456 term pregnancies with the prenatal diagnosis of oligohydramnios and compared them with matched controls without oligohydramnios. Oligohydramnios was associated with lower birthweight and small-for-gestational age infants, as well as renal malformations, congenital torticollis, and congenitally dislocated hips.

**FIGURE 17-1** Fetal bladder volume measurements together with fetal heart rate (FHR) variation
recorded in relation to 1F or 2F behavior states. State 1F fetal heart rate has a narrow bandwidth consistent with quiet sleep. State 2F heart rate shows wide oscillation of the baseline consistent with active sleep. (Modified from Oosterhof, 1993.)

An important determinant of fetal activity appears to be sleep-awake cycles, which are independent of the maternal sleep-awake state. Sleep cyclicity has been described as varying from approximately 20 minutes to as much as 75 minutes. Timor-Tritsch and associates (1978) reported that the mean length of the quiet or inactive state for term fetuses was 23 minutes. Patrick and associates (1982) measured gross fetal body movements with real-time sonography for 24-hour periods in 31 normal pregnancies and found the longest period of inactivity to be 75 minutes. Amnionic fluid volume is another important determinant of fetal activity. Sherer and colleagues (1996) assessed the number of fetal movements in 465 pregnancies during biophysical profile testing in relation to amnionic fluid volume. They observed decreased fetal activity with diminished amnionic volumes and suggested that a restricted uterine space might physically limit fetal movements.

Sadovsky and coworkers (1979b) studied fetal movements in 120 normal pregnancies and classified the movements into three categories according to both maternal perceptions and independent recordings using piezoelectric sensors. Weak, strong, and rolling movements were described, and their relative contributions to total weekly movements throughout the last half of pregnancy were quantified. As pregnancy advances, weak movements decrease and are superseded by more vigorous movements, which increase for several weeks and then subside at term. Presumably, declining amnionic fluid and space account for diminishing activity at term. Figure 17-2 shows fetal movements during the last half of gestation in 127 pregnancies with normal outcomes. The mean number of weekly movements calculated from 12-hour daily recording periods increased from approximately 200 at 20 weeks to a maximum of 575 movements at 32 weeks. Fetal movements then declined to an average of 282 at 40 weeks. Normal weekly maternal counts of fetal movements ranged between 50 and 950, with large daily variations that included counts as low as 4 to 10 per 12-hour period in normal pregnancies.

FIGURE 17-2 Graph depicts averages of fetal movements counted during 12-hour periods (mean ± SEM). (Data from Sadovsky, 1979a.)

Clinical Application
Diminished fetal activity may be a harbinger of impending fetal death (Sadovsky, 1973). Because of this, various methods have been described to quantify movement of the fetus to forecast its well-being. Methods include use of a tocodynamometer, visualization with sonography, and maternal subjective perceptions. Most, but not all, investigators have reported excellent correlation between maternally perceived fetal motion and movements documented by instrumentation. For example, Rayburn (1980) found that 80 percent of all movements observed during sonographic monitoring were perceived by the mother. In contrast, however, Johnson and colleagues (1992) reported that beyond 36 weeks, mothers perceived only 16 percent of fetal body movements. Fetal motions lasting more than 20 seconds were more likely to be identified than shorter episodes. Although several fetal-movement counting protocols have been used, neither the optimal number of movements nor the ideal duration for counting them has been defined. For example, in one method, perception of 10 fetal movements in up to 2 hours is considered normal (Moore, 1989). In another, women are instructed to count fetal movements for 1 hour a day, and the count is accepted as reassuring if it equals or exceeds a previously established baseline count (Neldam, 1983).

Commonly, women may present in the third trimester complaining of subjectively reduced fetal movement. Harrington and associates (1998) reported that 7 percent of nearly 6800 women presented with a complaint of decreased fetal movement. Fetal heart rate monitoring tests were employed if sonographic scans for fetal growth or Doppler velocimetry were abnormal. Pregnancy outcomes for women who complained of decreased fetal movement were not significantly different from those for women without this complaint. Nonetheless, the authors recommended evaluation to reassure the mother.

Grant and coworkers (1989) performed an unparalleled investigation of maternally perceived fetal movements and pregnancy outcome. More than 68,000 pregnancies were randomly assigned between 28 and 32 weeks. Women in the fetal movement arm of the study were instructed by specially employed midwives to record the time needed to feel 10 movements each day. This required an average of 2.7 hours each day. Women in the control group were informally asked about movements during prenatal visits. Reports of decreased fetal motion were evaluated with tests of fetal well-being. Antepartum death rates for otherwise normal singleton fetuses were similar in the two study groups. Despite the counting policy, most stillborn fetuses were dead by the time the mothers reported for medical attention. Importantly, rather than concluding that maternal perceptions of fetal activity were meaningless, these investigators concluded that informal maternal perceptions were as valuable as formally recorded fetal movement.

The most recent randomized study of fetal movements was performed in Norway by Saastad and colleagues (2011). A total of 1076 women were randomly assigned to standardized fetal movement counting from gestational week 28 or to no counting. Growth-restricted fetuses were identified before birth significantly more often when fetal movement counting was used. There was also a significant reduction (0.4 versus 2.3 percent) in 1-minute Apgar scores ≤ 3 when counting was used. Also, Warrander and associates (2012) performed the first study of placental pathology in pregnancies complicated by decreased fetal movements. Decreased movement was associated with a variety of placental abnormalities including infarction.

**FETAL BREATHING**

After decades of uncertainty as to whether the fetus normally breathes, Dawes and coworkers (1972) showed small inward and outward flows of tracheal fluid in fetal sheep, indicating thoracic movement. These chest wall movements differed from those following birth in that they were
discontinuous. Another interesting feature of fetal respiration was *paradoxical chest wall movement*, which is depicted in Figure 17-3. In the newborn or adult, the opposite occurs. One interpretation of the paradoxical respiratory motion might be coughing to clear amnionic fluid debris. Although the physiological basis for the breathing reflex is not completely understood, such exchange of amnionic fluid appears to be essential for normal lung development.

**FIGURE 17-3** Paradoxical chest movement with fetal respiration. During inspiration (**A**), the chest wall paradoxically *collapses* and the abdomen protrudes, whereas during expiration (**B**), the chest wall *expands*. (Adapted from Johnson, 1988.)

Dawes (1974) identified two types of respiratory movements. The first are *gasps* or *sighs*, which occurred at a frequency of 1 to 4 per minute. The second, *irregular bursts of breathing*, occurred at rates up to 240 cycles per minute. These latter rapid respiratory movements were associated with rapid eye movements–REM. Badalian and associates (1993) studied the maturation of normal fetal breathing using color flow and spectral Doppler analysis of nasal fluid flow as an index of lung function. They suggested that fetal respiratory rate decreased in conjunction with increased respiratory volume at 33 to 36 weeks and coincidental with lung
maturation.

Many investigators have examined fetal breathing movements using sonography to determine whether chest wall movements might reflect fetal health. Several variables in addition to hypoxia were found to affect fetal respiratory movements. These included hypoglycemia, sound stimuli, cigarette smoking, amniocentesis, impending preterm labor, gestational age, the fetal heart rate itself, and labor—during which it is normal for respiration to cease.

Because fetal breathing movements are episodic, interpretation of fetal health when respirations are absent may be tenuous. Patrick and associates (1980) performed continuous 24-hour observation using sonography to characterize fetal breathing patterns during the last 10 weeks of pregnancy. There was a total of 1224 hours of fetal observation in 51 pregnancies. Figure 17-4 displays the percentages of time spent breathing near term. Clearly, there is diurnal variation, because breathing substantially diminishes during the night. In addition, breathing activity increases somewhat following maternal meals. Total absence of breathing was observed in some of these normal fetuses for up to 122 minutes, indicating that fetal evaluation to diagnose absent respiratory motion may require long periods of observation.

![Figure 17-4](image)

**FIGURE 17-4** The percentage of time spent breathing by 11 fetuses at 38 to 39 weeks demonstrated a significant increase in fetal breathing activity after breakfast. Breathing activity diminished during the day and reached its minimum between 8 PM and midnight hours. There was a significant increase in the percentage of time spent breathing between 4 and 7 AM, when mothers were asleep. (Adapted from Patrick, 1980.)

The potential for breathing activity to be an important marker of fetal health is unfulfilled because of the multiplicity of factors that normally affect breathing. Most clinical applications have included assessment of other fetal biophysical indices, such as heart rate. As will be discussed, fetal breathing has become a component of the **biophysical profile**.

**CONTRACTION STRESS TESTING**
As amniotic fluid pressure increases with uterine contractions, myometrial pressure exceeds collapsing pressure for vessels coursing through uterine muscle. This ultimately decreases blood flow to the intervillous space. Brief periods of impaired oxygen exchange result, and if uteroplacental pathology is present, these elicit late fetal heart rate decelerations (Chap. 24, p. 483). Contractions also may produce a pattern of variable decelerations as a result of cord compression, suggesting oligohydramnios, which is often a concomitant of placental insufficiency.

Ray and colleagues (1972) used this concept in 66 complicated pregnancies and developed the oxytocin challenge test, which was later called the contraction stress test. Intravenous oxytocin was used to stimulate contractions, and the fetal heart rate response was recorded. The criterion for a positive test result, that is, an abnormal result, was uniform repetitive late fetal heart rate decelerations. These reflected the uterine contraction waveform and had an onset at or beyond the contraction acme. Such late decelerations could be the result of uteroplacental insufficiency. The tests were generally repeated on a weekly basis, and the investigators concluded that negative contraction stress test results, that is, normal results, forecasted fetal health. One disadvantage cited was that the average contraction stress test required 90 minutes to complete.

To perform the test, the fetal heart rate and uterine contractions are recorded simultaneously with an external monitor. If at least three spontaneous contractions of 40 seconds or longer are present in 10 minutes, no uterine stimulation is necessary (American College of Obstetricians and Gynecologists, 2012a). Contractions are induced with either oxytocin or nipple stimulation if there are fewer than three in 10 minutes. For oxytocin use, a dilute intravenous infusion is initiated at a rate of 0.5 mU/min and doubled every 20 minutes until a satisfactory contraction pattern is established (Freeman, 1975). The results of the contraction stress test are interpreted according to the criteria shown in Table 17-1.

<table>
<thead>
<tr>
<th>TABLE 17-1. Criteria for Interpretation of the Contraction Stress Test</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Negative:</strong> no late or significant variable decelerations</td>
</tr>
<tr>

<tr>
<td><strong>Equivocal-suspicious:</strong> intermittent late decelerations or significant variable decelerations</td>
</tr>
<tr>
<td><strong>Equivocal-hyperstimulatory:</strong> fetal heart rate decelerations that occur in the presence of contractions more frequent than every 2 minutes or lasting longer than 90 seconds</td>
</tr>
<tr>
<td><strong>Unsatisfactory:</strong> fewer than three contractions in 10 minutes or an uninterpretable tracing</td>
</tr>
</tbody>
</table>

Nipple stimulation to induce uterine contractions is usually successful for contraction stress testing (Huddleston, 1984). One method recommended by the American College of Obstetricians and Gynecologists (2012a) involves a woman rubbing one nipple through her clothing for 2 minutes or until a contraction begins. This 2-minute nipple stimulation ideally will induce a pattern of three contractions per 10 minutes. If not, after a 5-minute interval, she is instructed to retry nipple stimulation to achieve the desired pattern. If this is unsuccessful, then dilute oxytocin may be used. Advantages include reduced cost and shortened testing times. Some have reported unpredictable uterine hyperstimulation and fetal distress, whereas others did not find excessive activity to be harmful (Frager, 1987; Schellpfeffer, 1985).
Freeman (1975) and Lee and colleagues (1975) introduced the nonstress test to describe fetal heart rate acceleration in response to fetal movement as a sign of fetal health. This test involved the use of Doppler-detected fetal heart rate acceleration coincident with fetal movements perceived by the mother. By the end of the 1970s, the nonstress test had become the primary method of testing fetal health. The nonstress test was easier to perform, and normal results were used to further discriminate false-positive contraction stress tests. Simplistically, the nonstress test is primarily a test of fetal condition, and it differs from the contraction stress test, which is a test of uteroplacental function. Currently, nonstress testing is the most widely used primary testing method for assessment of fetal well-being and has also been incorporated into the biophysical profile testing system subsequently discussed.

Fetal Heart Rate Acceleration

There are autonomic influences mediated by sympathetic or parasympathetic impulses from brainstem centers that normally increase or decrease the fetal heart rate. Beat-to-beat variability is also under the control of the autonomic nervous system (Matsuura, 1996). Consequently, pathological loss of acceleration may be seen in conjunction with significantly decreased beat-to-beat variability of the fetal heart rate (Chap. 24, p. 479). Loss of such reactivity, however, is most commonly associated with sleep cycles as discussed on page 335. It also may be caused by central depression from medications or cigarette smoking (Jansson, 2005).

The nonstress test is based on the hypothesis that the heart rate of a fetus that is not acidemic as a result of hypoxia or neurological depression will temporarily accelerate in response to fetal movement. Fetal movements during testing are identified by maternal perception and recorded. As hypoxia develops, these fetal heart rate accelerations diminish (Smith, 1988).

Gestational age influences acceleration or reactivity of the fetal heart rate. Pillai and James (1990b) studied the development of fetal heart rate acceleration patterns during normal pregnancy. The percentage of body movements that is accompanied by accelerations and the amplitude of these accelerations increase with gestational age (Fig. 17-5). Guinn and colleagues (1998) studied nonstress test results between 25 and 28 weeks in 188 normal fetuses. Only 70 percent of these normal fetuses demonstrated the required 15 beats per minute (bpm) or more of heart rate acceleration. Lesser degrees of acceleration, that is, 10 bpm, occurred in 90 percent of the fetuses.
Normal Nonstress Tests

There have been many different definitions of normal nonstress test results. They vary as to the number, amplitude, and duration of acceleration, as well as the test duration. The definition currently recommended by the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2012) is two or more accelerations that peak at 15 bpm or more above baseline, each lasting 15 seconds or more, and all occurring within 20 minutes of beginning the test (Fig. 17-6). It was also recommended that accelerations with or without fetal movements be accepted, and that a 40-minute or longer tracing—to account for fetal sleep cycles—should be performed before concluding that there was insufficient fetal reactivity. Miller and coworkers (1996b) reviewed outcomes in fetuses with nonstress tests considered as nonreactive because there was only one acceleration. They concluded that one acceleration was just as reliable as two in predicting healthy fetal status.
FIGURE 17-6 Reactive nonstress test. In the upper panel, notice the increase of fetal heart rate by more than 15 beats/min for longer than 15 seconds following fetal movements, which are indicated by the vertical marks (lower panel).

Although a normal number and amplitude of accelerations seems to reflect fetal well-being, their absence does not invariably predict fetal compromise. Indeed, some investigators have reported 90-percent or higher false-positive rates (Devoe, 1986). Because healthy fetuses may not move for periods of up to 75 minutes, some have considered that a longer duration of nonstress testing might increase the positive-predictive value of an abnormal, that is, nonreactive, test (Brown, 1981). In this scheme, either the test became reactive during a period up to 80 minutes or the test remained nonreactive for 120 minutes, which indicated that the fetus was very ill.

Not only are there many different definitions of normal nonstress test results, but the reproducibility of interpretations is problematic. For example, Hage (1985) mailed five nonstress tests, blinded to specific patient clinical data, to a national sample of obstetricians for their interpretations. He concluded that although nonstress testing is popular, the reliability of test interpretation needs improvement.

Abnormal Nonstress Tests

Based on the foregoing, an abnormal nonstress test is not always malignant. The example shown in Figure 17-7, however, was ominous. Such a pattern can also be seen with a sleeping fetus. Also, an abnormal test can revert to normal as the fetal condition changes, such as the example shown in Figure 17-8. Importantly, a normal nonstress test can become abnormal if the fetal condition deteriorates. There are abnormal patterns that reliably forecast severe fetal jeopardy. Devoe and coworkers (1985) concluded that nonstress tests that were nonreactive for 90 minutes were almost invariably—93 percent—associated with significant perinatal pathology. Hammacher and
coworkers (1968) described tracings with what they termed a *silent oscillatory pattern* that he considered dangerous. This pattern consisted of a fetal heart rate baseline that oscillated less than 5 bpm and presumably indicated absent acceleration and beat-to-beat variability.

**FIGURE 17-7** Nonreactive nonstress test (*left side of tracing*) followed by contraction stress test showing mild, late decelerations (*right side of tracing*). Cesarean delivery was performed, and the severely acidemic fetus could not be resuscitated.
FIGURE 17-8 Two antepartum fetal heart rate (FHR) tracings in a 28-week pregnant woman with diabetic ketoacidosis. A. FHR tracing (upper panel) and accompanying contraction tracing (second panel). Tracing, obtained during maternal and fetal acidemia, shows absence of accelerations, diminished variability, and late decelerations with weak spontaneous contractions. B. FHR tracing shows return of normal accelerations and variability of the fetal heart rate following correction of maternal acidemia.

Visser and associates (1980) described a terminal cardiotocogram, which included: (1) baseline oscillation of less than 5 bpm, (2) absent accelerations, and (3) late decelerations with spontaneous uterine contractions. These results were similar to experiences from Parkland Hospital in which absence of accelerations during an 80-minute recording period in 27 fetuses was associated consistently with evidence of uteroplacental pathology (Leveno, 1983). The latter included fetal-growth restriction in 75 percent, oligohydramnios in 80 percent, fetal acidemia in 40 percent, meconium in 30 percent, and placental infarction in 93 percent.

Interval between Testing

Set originally rather arbitrarily at 7 days, the interval between tests appears to have been shortened as experience evolved with nonstress testing. According to the American College of Obstetricians and Gynecologists (2012a), more frequent testing is advocated by some investigators for women with postterm pregnancy, multifetal gestation, type 1 diabetes mellitus, fetal-growth restriction, or gestational hypertension. In these circumstances, some investigators perform twice-weekly tests, with additional testing completed for maternal or fetal deterioration regardless of the time elapsed since the last test. Others perform nonstress tests daily or even more frequently, such
Decelerations During Nonstress Testing

Fetal movements commonly produce heart rate decelerations. Timor-Tritsch and associates (1978) reported this during nonstress testing in half to two thirds of tracings, depending on the vigor of the fetal motion. This high incidence of decelerations inevitably makes interpretation of their significance problematic. Indeed, Meis and coworkers (1986) reported that variable fetal heart rate decelerations during nonstress tests were not a sign of fetal compromise. The American College of Obstetricians and Gynecologists (2012a) has concluded that variable decelerations, if nonrepetitive and brief—less than 30 seconds—do not indicate fetal compromise or the need for obstetrical intervention. In contrast, repetitive variable decelerations—at least three in 20 minutes—even if mild, have been associated with an increased risk of cesarean delivery for fetal distress. Decelerations lasting 1 minute or longer have been reported to have an even worse prognosis (Bourgeois, 1984; Druzin, 1981; Pazos, 1982).

Hoskins and associates (1991) attempted to refine interpretation of testing that shows variable decelerations by adding sonographic estimation of amnionic fluid volume. The incidence of cesarean delivery for intrapartum fetal distress progressively increased concurrently with the severity of variable decelerations and decline of amnionic fluid volume. Severe variable decelerations during a nonstress test plus an amnionic fluid index of ≤ 5 cm resulted in a 75-percent cesarean delivery rate. Fetal distress in labor, however, also frequently developed in those pregnancies with variable decelerations but with normal amounts of amnionic fluid. Similar results were reported by Grubb and Paul (1992).

False-Normal Nonstress Tests

Smith and associates (1987) performed a detailed analysis of the causes of fetal death within 7 days of normal nonstress tests. The most common indication for testing was postterm pregnancy. The mean interval between testing and death was 4 days, with a range of 1 to 7 days. The single most common autopsy finding was meconium aspiration, often associated with some type of umbilical cord abnormality. They concluded that an acute asphyxial insult had provoked fetal gasping. They also concluded that nonstress testing was inadequate to preclude such an acute asphyxial event and that other biophysical characteristics might be beneficial. Importantly, assessment of amnionic fluid volume was considered valuable. Other ascribed frequent causes of fetal death included intrauterine infection, abnormal cord position, malformations, and placental abruption.

ACOUSTIC STIMULATION TESTS

Loud external sounds have been used to startle the fetus and thereby provoke heart rate acceleration—an acoustic stimulation nonstress test. A commercially available acoustic stimulator is positioned on the maternal abdomen, and a stimulus of 1 to 2 seconds is applied (Eller, 1995). This may be repeated up to three times for up to 3 seconds (American College of Obstetricians and Gynecologists, 2012a). A positive response is defined as the rapid appearance of a qualifying acceleration following stimulation (Devoe, 2008). In a randomized trial of 113
women undergoing nonstress testing, vibroacoustic stimulation shortened the average time of
testing from 24 to 15 minutes (Perez-Delboy, 2002). Similar results were reported by Turitz and
coworkers (2012). Laventhal and colleagues (2003) reported that fetal tachyarrhythmia was
provoked with vibroacoustic stimulation.

**BIOPHYSICAL PROFILE**

Manning and colleagues (1980) proposed the combined use of five fetal biophysical variables as a
more accurate means of assessing fetal health than a single element. Typically, these tests require
30 to 60 minutes of examiner time. Shown in Table 17-2 are the five fetal biophysical components
assessed: (1) heart rate acceleration, (2) breathing, (3) movements, (4) tone, and (5) amnionic
fluid volume. Normal variables were assigned a score of 2 each, and abnormal variables were
given a score of 0. Thus, the highest score possible for a normal fetus is 10. Maternal medications
such as morphine can significantly decrease the score (Kopecky, 2000). Ozkaya and associates
(2012) found that biophysical test scores were higher if a test was performed in late evening (8 to
10 PM) compared with 8 to 10 AM.

Manning and colleagues (1987) tested more than 19,000 pregnancies using the biophysical
profile interpretation and management shown in Table 17-3. More than 97 percent of the
pregnancies tested had normal test results. They reported a false-normal test rate—defined by an
antepartum death of a structurally normal fetus—of approximately 1 per 1000. The most common
identifiable causes of fetal death after a normal biophysical profile include fetomaternal
hemorrhage, umbilical cord accidents, and placental abruption (Dayal, 1999).

**TABLE 17-3. Interpretation of Biophysical Profile Score**
Manning and coworkers (1993) published a remarkable description of 493 fetuses in which biophysical scores were performed immediately before measurement of umbilical venous blood pH values obtained via cordocentesis. Approximately 20 percent of tested fetuses had growth restriction, and the remainder had alloimmune hemolytic anemia. As shown in Figure 17-9, a biophysical score of 0 was almost invariably associated with significant fetal acidemia, whereas a normal score of 8 or 10 was associated with normal pH. An equivocal test result—a score of 6—was a poor predictor of abnormal outcome. As the abnormal score decreased from 2 or 4 down to a very abnormal score of zero, this was a progressively more accurate predictor of abnormal fetal outcome.
In a similar study in 41 diabetic pregnancies, Salvesen and associates (1993) correlated the biophysical profile with umbilical venous blood pH obtained at cordocentesis. They too found that an abnormal pH was significantly associated with abnormal biophysical profile scores. They concluded, however, that the biophysical profile was of limited value in the prediction of fetal pH, because nine mildly acidemic fetuses had normal biophysical profile scores. Weiner and coworkers (1996) assessed 135 overtly growth-restricted fetuses and came to a similar conclusion. Morbidity and mortality in these latter fetuses were linked primarily to gestational age and birthweight and not to abnormal fetal test results. Lalor and associates (2008) performed a Cochrane review and concluded that there is insufficient evidence to support the use of the biophysical profile as a fetal well-being test in high-risk pregnancies. Kaur and colleagues (2008) performed daily biophysical profiles to ascertain the optimal delivery time in 48 growth-restricted preterm fetuses who weighed < 1000 g. Despite scores of 8 in 27 fetuses and 6 in 13, there were six deaths and 21 acidemic fetuses. These investigators concluded that a high incidence of false-positive and -negative results is seen in very preterm fetuses.

**Modified Biophysical Profile**

Because the biophysical profile is labor intensive and requires a person trained in sonography, Clark and coworkers (1989) used an abbreviated biophysical profile as a first-line screening test in 2628 singleton pregnancies. Specifically, a vibroacoustic nonstress test was performed twice
weekly and combined with amnionic fluid index determination for which < 5 cm was considered abnormal (Chap. 11, p. 233). This abbreviated biophysical profile required approximately 10 minutes to perform, and they concluded that it was a superb antepartum surveillance method because there were no unexpected fetal deaths.

Nageotte and colleagues (1994) also combined biweekly nonstress tests with the amnionic fluid index and considered ≤ 5 cm to be abnormal. They performed 17,429 modified biophysical profiles in 2774 women and concluded that such testing was an excellent fetal surveillance tool. Miller and associates (1996a) reported results with more than 54,000 modified biophysical profiles performed in 15,400 high-risk pregnancies. They described a false-negative rate of 0.8 per 1000 and a false-positive rate of 1.5 percent.

The American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2012) have concluded that the modified biophysical profile test is as predictive of fetal well-being as other approaches to biophysical fetal surveillance.

**AMNIONIC FLUID VOLUME**

The importance of amnionic fluid volume estimation is indicated by its inclusion into virtually all schemes by which fetal health is assessed (Frøen, 2008). This is based on the rationale that decreased uteroplacental perfusion may lead to diminished fetal renal blood flow, decreased urine production, and ultimately, oligohydramnios. As discussed in Chapter 11 (p. 232), the amnionic fluid index, the deepest vertical pocket, and the 2 × 2-cm pocket used in the biophysical profile are some sonographic techniques used to estimate amnionic fluid volume. The American College of Obstetricians and Gynecologists (2011) has concluded that either an amnionic fluid index < 5 cm or a maximum deepest vertical pocket < 2 cm are acceptable criteria for diagnosis of oligohydramnios.

In their review of 42 reports on the amnionic fluid index published between 1987 and 1997, Chauhan and coworkers (1999) concluded that an index ≤ 5.0 cm significantly increased the risk of either cesarean delivery for fetal distress or a low 5-minute Apgar score. Similarly, in a retrospective analysis of 6423 pregnancies managed at Parkland Hospital, Casey and colleagues (2000) found that an amnionic fluid index ≤ 5 cm was associated with significantly increased perinatal morbidity and mortality rates. Locatelli and associates (2004) also reported an increased rate of low-birthweight infants if there was oligohydramnios.

Not all investigators agree with the concept that an index of ≤ 5 cm portends adverse outcomes. Magann and colleagues (2011) recommend use of the single deepest pocket. They note that use of the amnionic fluid index leads to an increased diagnosis of oligohydramnios and results in more labor inductions and cesarean deliveries without neonatal outcome improvement. Driggers and coworkers (2004) and Zhang and associates (2004) did not find a correlation with poor outcomes in pregnancies in which the index was < 5 cm. In a randomized trial, Conway and colleagues (2000) concluded that nonintervention to permit spontaneous onset of labor was as effective as induction in term pregnancies with amnionic fluid index values ≤ 5 cm. Similar results were reported by Trudell and coworkers (2012). Patrelli and colleagues (2012) studied 68 women with amnionic fluid indices < 5 cm who were given 7 days of 1500-mL isotonic solution infusions plus daily oral hydration. The amnionic fluid index was significantly increased in hydrated women.
Blood flow velocity measured by Doppler ultrasound reflects downstream impedance (Chap. 10, p. 219). Three fetal vascular circuits—umbilical artery, middle cerebral artery, and ductus venosus—are currently assessed to determine fetal health and to aid in the decision to intervene for growth-restricted fetuses. Maternal uterine artery Doppler velocimetry has also been evaluated to predict placental dysfunction, with the goal to balance stillbirth against the risks of preterm delivery (Ghidini, 2007).

**Doppler Blood Flow Velocity**

Waveforms were first studied systematically in the umbilical arteries late in pregnancy, and abnormal waveforms correlated with placental villous hypovascularity, such as shown in Figure 17-10. Of the small placental arterial channels, 60 to 70 percent need to be obliterated before the umbilical artery Doppler waveform becomes abnormal. Such extensive placental vascular pathology has a major effect on fetal circulation.
FIGURE 17-10 Acrylic casts of the umbilical arterial vascular tree within a placental lobule. They were prepared by injection of the umbilical artery at the site of cord insertion and later acid digestion of the tissue. **A.** Normal placenta. **B.** Placenta from a pregnancy with absent end-diastolic flow in the umbilical artery recorded before delivery. (From Trudinger, 2007, with permission.)
According to Trudinger (2007), because more than 40 percent of the combined fetal ventricular output is directed to the placenta, obliteration of placental vascular channel increases afterload and leads to fetal hypoxemia. This in turn leads to dilatation and redistribution of middle cerebral artery blood flow. Ultimately, pressure rises in the ductus venosus due to afterload in the right side of the fetal heart. In this scheme, placental vascular dysfunction results in increased umbilical artery blood flow resistance, which progressively decreases middle cerebral artery impedance followed ultimately by abnormal flow in the ductus venosus (Baschat, 2004). Clinically, abnormal Doppler waveforms in the ductus venosus are a late finding in the progression of fetal deterioration due to chronic hypoxemia.

### Umbilical Artery Velocimetry

The umbilical artery systolic-diastolic (S/D) ratio is considered abnormal if it is above the 95th percentile for gestational age or if diastolic flow is either absent or reversed (Chap. 10, p. 219). Absent or reversed end-diastolic flow signifies increased impedance to umbilical artery blood flow (Fig. 10-39, p. 220). It is reported to result from poorly vascularized placental villi and is seen in extreme cases of fetal-growth restriction (Todros, 1999). According to Zelop and colleagues (1996), the perinatal mortality rate for absent end-diastolic flow was approximately 10 percent, and for reversed end-diastolic flow, it approximated 33 percent. Spinillo and associates (2005) studied neurodevelopmental outcome at 2 years of age in 266 growth-restricted fetuses delivered between 24 and 35 weeks’ gestation. Of infants with absent or reversed umbilical artery flow, 8 percent had evidence of cerebral palsy compared with 1 percent of those in whom Doppler flow was either normal or > 95th percentile but without reversed flow.

Doppler ultrasound of the umbilical artery has been subjected to more extensive assessment with randomized controlled trials than has any previous test of fetal health. Williams and colleagues (2003) randomized 1360 high-risk women to either nonstress testing or Doppler velocimetry. They found a significantly increased incidence of cesarean delivery for fetal distress in the nonstress test group compared with that for those tested with Doppler velocimetry—8.7 versus 4.6 percent, respectively. One interpretation of this finding is that the nonstress test more frequently identified fetuses in jeopardy. Conversely, Gonzalez and associates (2007) found that abnormal umbilical artery Doppler findings in a cohort of growth-restricted fetuses were the best predictors of perinatal outcomes.

The utility of umbilical artery Doppler velocimetry was reviewed by the American College of Obstetricians and Gynecologists (2013). It was concluded that no benefit has been demonstrated other than in pregnancies with suspected fetal-growth restriction. Specifically, no benefits have been demonstrated for velocimetry for other conditions such as postterm pregnancy, diabetes, systemic lupus erythematosus, or antiphospholipid antibody syndrome. Similarly, velocimetry has not proved valuable as a screening test for fetal compromise in the general obstetrical population.

### Middle Cerebral Artery

Doppler velocimetry interrogation of the middle cerebral artery (MCA) has received particular attention because of observations that the hypoxic fetus attempts brain sparing by reducing cerebrovascular impedance and thus increasing blood flow. Such brain sparing in growth-restricted fetuses has been documented to undergo reversal (Konje, 2001). Investigators reported that 8 of 17 fetuses with this reversal died. Ott and coworkers (1998) randomized 665 women undergoing modified biophysical profile evaluation to either the profile alone or combined with
middle cerebral and umbilical artery velocity flow assessment. There were no significant differences in pregnancy outcomes between these two study groups.

In a different application, Oepkes and colleagues (2006) used middle cerebral artery Doppler velocimetry to detect severe fetal anemia in 165 fetuses with D alloimmunization. They prospectively compared serial amniocentesis for measurement of bilirubin levels with Doppler measurement of peak systolic velocity in the middle cerebral artery. These investigators concluded that Doppler could safely replace amniocentesis in the management of alloimmunized pregnancies. And as discussed in Chapter 15 (p. 310), middle cerebral artery Doppler velocimetry is useful for detection and management of fetal anemia of any cause (Moise, 2008). The American College of Obstetricians and Gynecologists (2012b) also concluded that such use of Doppler is appropriate in centers with personnel trained in the procedure.

### Ductus Venosus

The use of Doppler ultrasound to assess the fetal venous circulation is the most recent application of this technology. Bilardo and colleagues (2004) prospectively studied umbilical artery and ductus venosus Doppler velocimetry in 70 growth-restricted fetuses at 26 to 33 weeks’ gestation. They concluded that ductus venosus velocimetry was the best predictor of perinatal outcome. Importantly, negative or reversed flow in the ductus venosus was a late finding because these fetuses had already sustained irreversible multiorgan damage due to hypoxemia. Also, gestational age at delivery was a major determinant of perinatal outcome independent of ductus venosus flow. Specifically, 36 percent of growth-restricted fetuses delivered between 26 and 29 weeks succumbed compared with only 5 percent delivered from 30 to 33 weeks.

Baschat and coworkers (2007) systemically studied 604 growth-restricted fetuses using umbilical artery, middle cerebral artery, and ductus venosus Doppler velocimetry and reached similar conclusions. Specifically, absent or reversed flow in the ductus venosus was associated with profound generalized fetal metabolic collapse. They too reported that gestational age was a powerful cofactor in ultimate perinatal outcome for growth-restricted fetuses delivered before 30 weeks. Put another way, by the time severely abnormal flow is seen in the ductus venosus, it is too late because the fetus is already near death. Conversely, earlier delivery puts the fetus at risk for death due to preterm delivery. Ghidini (2007) concluded that these reports do not support routine use of ductus venosus Doppler in the monitoring of growth-restricted fetuses and recommended further study.

### Uterine Artery

Vascular resistance in the uterine circulation normally decreases in the first half of pregnancy due to invasion of maternal uterine vessels by trophoblastic tissue (Chap. 5, p. 93). This process can be detected using Doppler flow velocimetry, and uterine artery Doppler may be most helpful in assessing pregnancies at high risk of uteroplacental insufficiency (Abramowicz, 2008). Persistence or development of high-resistance patterns has been linked to a variety of pregnancy complications (Lees, 2001; Yu, 2005). In a study of 30,519 unselected British women, Smith and colleagues (2007) assessed uterine artery velocimetry at 22 to 24 weeks. The risk of fetal death before 32 weeks when associated with abruption, preeclampsia, or fetal-growth restriction was significantly linked to high-resistance flow. This has led to suggestions for continued research of uterine artery Doppler velocimetry as a screening tool to detect pregnancies at risk for stillbirth (Reddy, 2008). Sciscione and Hayes (2009) reviewed the use of uterine artery Doppler flow studies in obstetrical...
practice. Because standards for the study technique and criteria for an abnormal test are lacking, they noted that uterine artery Doppler studies should not be considered standard practice in either low- or high-risk populations.

CURRENT ANTENATAL TESTING RECOMMENDATIONS

According to the American College of Obstetricians and Gynecologists (2012a), there is no “best test” to evaluate fetal well-being. Three testing systems—contraction stress test, nonstress test, and biophysical profile—have different end points to consider depending on the clinical situation.

The most important consideration in deciding when to begin antepartum testing is the prognosis for neonatal survival. The severity of maternal disease is another important consideration. In general, with the majority of high-risk pregnancies, most authorities recommend that testing begin by 32 to 34 weeks. Pregnancies with severe complications might require testing as early as 26 to 28 weeks. The frequency for repeating tests has been arbitrarily set at 7 days, but more frequent testing is often done.

Significance of Fetal Testing

Does antenatal fetal testing really improve fetal outcome? Platt and coworkers (1987) reviewed its impact between 1971 and 1985 at Los Angeles County Hospital. During this 15-year period, more than 200,000 pregnancies were managed, and nearly 17,000 of these women underwent antepartum testing of various types. Fetal surveillance increased from less than 1 percent of pregnancies in the early 1970s to 15 percent in the mid-1980s. These authors concluded that such testing was clearly beneficial because the fetal death rate was significantly less in the tested high-risk pregnancies compared with the rate in those not tested. The study, however, did not consider other innovations incorporated into practice during those 15 years. Preliminary results from Ghana suggest that nonstress testing may be beneficial in low-resource countries (Anderson, 2012). In an observational study of 316 pregnancies complicated by gestational hypertension, women undergoing nonstress testing had a nonsignificant decreased risk for stillbirth compared with those not tested—3.6 versus 9.2 percent, respectively.

The benefits of antenatal fetal testing have not been sufficiently evaluated in randomized controlled trials according to Thacker and Berkelman (1986). This was concluded after reviewing 600 reports, which included only four randomized trials and all conducted with nonstress testing without a contraction stress test. The numbers in these four trials were considered too small to permit detection of important benefits and did not support a specific test. Enkin and colleagues (2000) reviewed evidence in the Cochrane Library database from controlled trials of antepartum fetal surveillance and concluded that “despite their widespread use, most tests of fetal well-being should be considered of experimental value only rather than validated clinical tools.”

Another important and unanswered question is whether antepartum fetal surveillance identifies fetal asphyxia early enough to prevent brain damage. Todd and coworkers (1992) attempted to correlate cognitive development in infants up to age 2 years following either abnormal umbilical artery Doppler velocimetry or nonstress test results. Only abnormal nonstress tests were associated with marginally poorer cognitive outcomes. These investigators concluded that by the time fetal compromise is diagnosed with antenatal testing, fetal damage has already been sustained. Low and colleagues (2003) reached a similar conclusion in their study of 36 preterm infants delivered based on antepartum test results. Manning and coworkers (1998) studied the
incidence of cerebral palsy in 26,290 high-risk pregnancies managed with serial biophysical profile testing. These outcomes were compared with those of 58,657 low-risk pregnancies in which antepartum testing was not performed. The rate of cerebral palsy was 1.3 per 1000 in tested pregnancies compared with 4.7 per 1000 in untested women.

Antenatal forecasts of fetal health have clearly been the focus of intense interest for four decades. When such testing is reviewed, several themes emerge:

1. Methods of fetal forecasting have evolved continually, a phenomenon that at least suggests dissatisfaction with the precision or efficacy of any given method.
2. The fetal biophysical performance is characterized by wide ranges of normal biological variation, resulting in difficulty determining when such performance should be considered abnormal. How many movements, respirations, or accelerations? In what time period? Unable to easily quantify normal fetal biophysical performance, most investigators have resorted to somewhat arbitrary answers to such questions.
3. Despite the invention of increasingly complex testing methods, abnormal results are seldom reliable, prompting many clinicians to use antenatal testing to forecast fetal wellness rather than illness.

The word *abortion* derives from the Latin *aboriri*—to miscarry. Abortion is defined as the spontaneous or induced termination of pregnancy before fetal viability. It thus is appropriate that miscarriage and abortion are terms used interchangeably in a medical context. But because popular use of *abortion* by laypersons implies a deliberate intact pregnancy termination, many prefer *miscarriage* for spontaneous fetal loss. Newer terms made possible by widespread use of sonography and human chorionic gonadotropin measurements that identify extremely early pregnancies include *early pregnancy loss, wastage, or failure*. Throughout this book, these are all used at one time or another.
Terminology used to define fetal viability and thus an abortus has tremendous medical, legal, and social import. Viability lies between the lines that separate abortion from preterm birth. It is usually defined by pregnancy duration and fetal birthweight for statistical and legal purposes (Chap. 1, p. 2). This has led to incongruities in definitions from authoritative organizations. Importantly, the National Center for Health Statistics, the Centers for Disease Control and Prevention, and the World Health Organization all define \textit{abortion} as pregnancy termination before 20 weeks’ gestation or with a fetus born weighing < 500 g. These criteria, however, are somewhat contradictory because the mean birthweight of a 20-week fetus is 320 g, whereas 500 g is the mean for 22 to 23 weeks (Moore, 1977). Further confusion may derive from criteria set by state laws that define abortion even more widely.

As indicated above, technological developments have revolutionized current abortion terminology. Transvaginal sonography (TVS) and precise measurement of serum human chorionic gonadotropin (hCG) concentrations are used to identify extremely early pregnancies as well as those with an intrauterine versus ectopic location. Ubiquitous application of these practices makes it possible to distinguish between a \textit{chemical} and a \textit{clinical} pregnancy. An ad hoc international consensus group has proposed the term \textit{pregnancy of unknown location—PUL}—with the goal of early identification and management of ectopic pregnancy (Barnhart, 2011; Doubilet, 2013). Management options for ectopic gestation are described in Chapter 19 (p. 384). Uterine pregnancies that eventuate in a spontaneous abortion are also termed \textit{early pregnancy loss} or \textit{early pregnancy failure}.

Terms that have been in clinical use for many decades are generally used to describe later pregnancy losses. These include:

1. Spontaneous abortion—this category includes threatened, inevitable, incomplete, complete, and missed abortion. Septic abortion is used to further classify any of these that are complicated further by infection.
2. Recurrent abortion—this term is variably defined, but it is meant to identify women with repetitive spontaneous abortions so that an underlying factor(s) can be treated to achieve a viable newborn.
3. Induced abortion—this term is used to describe surgical or medical termination of a live fetus that has not reached viability.

\section*{FIRST-TRIMESTER SPONTANEOUS ABORTION}

\subsection*{Pathogenesis}

More than 80 percent of spontaneous abortions occur within the first 12 weeks of gestation. With first-trimester losses, death of the embryo or fetus nearly always precedes spontaneous expulsion. Death is usually accompanied by hemorrhage into the decidua basalis. This is followed by adjacent tissue necrosis that stimulates uterine contractions and expulsion. An intact gestational sac is usually filled with fluid and may or may not contain an embryo or fetus. Thus, the key to determining the cause of early miscarriage is to ascertain the cause of fetal death. In contradistinction, in later pregnancy losses, the fetus usually does not die before expulsion, and
thus other explanations are sought.

## Incidence

Statistics regarding the incidence of spontaneous abortion vary according to the diligence used for its recognition. Wilcox and colleagues (1988) studied 221 healthy women through 707 menstrual cycles and found that 31 percent of pregnancies were lost after implantation. They used highly specific assays for minute concentrations of maternal serum $\beta$-hCG and reported that two thirds of these early losses were *clinically silent*.

Currently, there are factors known to influence clinically apparent spontaneous abortion, however, it is unknown if these same factors affect clinically silent miscarriages. By way of example, the rate of clinical miscarriages is almost doubled when either parent is older than 40 years (Gracia, 2005; Kleinhaus, 2006). But, it is not known if clinically silent miscarriages are similarly affected by parental age.

## Fetal Factors

As shown in Table 18-1, approximately half of miscarriages are *anembryonic*, that is, with no identifiable embryonic elements. Less accurately, the term *blighted ovum* may be used (Silver, 2011). The other 50 percent are *embryonic* miscarriages, which commonly display a developmental abnormality of the zygote, embryo, fetus, or at times, the placenta. Of embryonic miscarriage, half of these—25 percent of all abortuses—have chromosomal anomalies and thus are *aneuploid abortions*. The remaining cases are *euploid abortions*, that is, carrying a normal chromosomal complement.

Both abortion rates and chromosomal anomalies decrease with advancing gestational age. As shown in Figure 18-1, 50 percent of embryonic abortions are aneuploid, but chromosomal abnormalities are found in just a third of second-trimester fetal losses and in only 5 percent of third-trimester stillbirths. Aneuploid abortion occurs at earlier gestational ages. Kajii and associates (1980) noted that 75 percent of aneuploid abortions occurred by 8 weeks. Of these, 95 percent of chromosomal abnormalities are caused by maternal gametogenesis errors, and 5 percent by paternal errors (Jacobs, 1980). Some found most common are listed in Table 18-1.

**FIGURE 18-1** Frequency of chromosomal anomalies in abortuses and stillbirths during each trimester. Approximate percentages for each group are shown. (Data from Eiben, 1990; Fantel, 1980; Warburton, 1980.)

With first-trimester miscarriages, *autosomal trisomy* is the most frequently identified chromosomal anomaly. Although most trisomies result from *isolated nondisjunction*, balanced structural chromosomal rearrangements are found in one partner in 2 to 4 percent of couples with recurrent miscarriages. Trisomies have been identified in abortuses for all except chromosome number 1, and those with 13, 16, 18, 21, and 22 are most common. A previous miscarriage increases the baseline risk for aneuploidy in a subsequent fetus from 1.4 to 1.7 percent (Bianco, 2006). With two or three previous miscarriages, the risk increases to 1.8 and 2.2 percent, respectively.

*Monosomy X (45,X)* is the single most frequent specific chromosomal abnormality. This is *Turner syndrome*, which usually results in abortion, but liveborn females are described (Chap. 13, p. 264). Conversely, *autosomal monosomy* is rare and incompatible with life.

*Triploidy* is often associated with hydropic or molar placental degeneration (Chap. 20, p. 398). The fetus within a partial hydatidiform mole frequently aborts early, and the few carried longer are all grossly deformed. Advanced maternal and paternal age do not increase the incidence of triploidy. *Tetraploid* fetuses most often abort early in gestation, and they are rarely liveborn. Last, *chromosomal structural abnormalities* infrequently cause abortion.

**Euploid Abortion**
Chromosomally normal fetuses abort later than those that are aneuploid. Specifically, the rate of euploid abortions peaks at approximately 13 weeks (Kajii, 1980). In addition, the incidence of euploid abortions increases dramatically after maternal age exceeds 35 years (Stein, 1980).

### Maternal Factors

The causes of euploid abortions are poorly understood, but various medical disorders, environmental conditions, and developmental abnormalities have been implicated. One example is the well-known influence of maternal age just described.

### Infections

Some common viral, bacterial, and other infectious agents that invade the normal human can cause pregnancy loss. Many are systemic and infect the fetoplacental unit by blood-borne organisms. Others may infect locally through genitourinary infection or colonization. However, despite the numerous infections acquired in pregnancy, these uncommonly cause early abortion. *Brucella abortus*, *Campylobacter fetus*, and *Toxoplasma gondii* infections cause abortion in livestock, but their role in human pregnancy is less clear (Feldman, 2010; Hide, 2009; Mohammad, 2011; Vilchez, 2014). There appear to be no abortifacient effects of infections caused by *Listeria monocytogenes*, parovirus, cytomegalovirus, or herpes simplex virus (Brown, 1997; Feldman, 2010). One possible exception is infection with *Chlamydia trachomatis*, which was found to be present in 4 percent of abortuses compared with < 1 percent of controls (Baud, 2011). Another is polymicrobial infection from periodontal disease that has been linked with a two- to fourfold increased risk (Holbrook, 2004; Moore, 2004; Xiong, 2007).

Data concerning a link between some other infections and increased abortion are conflicting. Examples are *Mycoplasma* and *Ureaplasma* (Quinn, 1983a,b; Temmerman, 1992). Another is an association with human immunodeficiency virus (HIV) (Quinn, 1983a,b; van Benthem, 2000). Oakeshott and coworkers (2002) reported an association between second-, but not first-, trimester miscarriage and *bacterial vaginosis*.

### Medical Disorders

In general, early abortions are rarely due to chronic wasting diseases such as tuberculosis or carcinomatosis. There are a few specific disorders possibly linked with increased early pregnancy loss. Those associated with diabetes mellitus and thyroid disease are discussed subsequently. Another example is *celiac disease*, which has been reported to cause recurrent abortions as well as both male and female infertility (Sharshiner, 2013; Sher, 1994). Unrepaired cyanotic heart disease is likely a risk for abortion, and in some, this may persist after repair (Canobbio, 1996). Eating disorders—*anorexia nervosa* and *bulimia nervosa*—have been linked with subfertility, preterm delivery, and fetal-growth restriction. Their association with miscarriage, however, is less well studied (Andersen, 2009; Sollid, 2004). Inflammatory bowel disease and systemic lupus erythematosus may increase the risk (Al Arfaj, 2010; Khashan, 2012). *Chronic hypertension* does not appear to confer significant risk (Ankumah, 2013). Perhaps related, women with a history of recurrent miscarriages were reported to be at increased risk for fetal-growth restriction (Catov, 2008). Another possible link with vascular disease is that women with multiple miscarriages are more likely to later suffer a myocardial infarction (Kharazmi, 2011).

### Medications

Only a few medications have been evaluated concerning a role with early pregnancy
loss. Oral contraceptives or spermicidal agents used in contraceptive creams and jellies are not associated with an increased miscarriage rate. Similarly, nonsteroidal antiinflammatory drugs or ondansetron are not linked (Edwards, 2012; Pasternak, 2013). A pregnancy with an intrauterine device (IUD) in situ has an increased risk of abortion and specifically of septic abortion (Chap. 38, p. 700). With the newer IUDs, Moschos and Twickler (2011) reported that only 6 of 26 intact pregnancies aborted before 20 weeks. Finally, studies have shown no increase in pregnancy loss rates with meningococcal conjugate or trivalent inactivated influenza vaccines (Irving, 2013; Zheteyeva, 2013).

Cancer. Therapeutic doses of radiation are undeniably abortifacient, but doses that cause abortion are not precisely known (Chap. 46, p. 930). According to Brent (2009), exposure to < 5 rads does not increase the risk.

Cancer survivors who were previously treated with abdominopelvic radiotherapy may later be at increased risk for miscarriage. Wo and Viswanathan (2009) reported an associated two- to eightfold increased risk for miscarriages, low-birthweight and growth-restricted infants, preterm delivery, and perinatal mortality in women previously treated with radiotherapy. Hudson (2010) found an associated increased risk for miscarriage in those given radiotherapy and chemotherapy in the past for a childhood cancer.

The effects of chemotherapy in causing abortion are not well defined (Chap. 12, p. 248). Particularly worrisome are women with an early normal gestation erroneously treated with methotrexate for an ectopic pregnancy (Chap. 19, p. 384). In a report of eight such cases, two viable-size fetuses had multiple malformations. In the remaining six cases, three each had a spontaneous or induced abortion (Nurmohamed, 2011).

Diabetes Mellitus
The abortifacient effects of uncontrolled diabetes are well-known. Optimal glycemic control will mitigate much of this loss and is discussed in Chapters 8 (p. 157) and 57 (p. 1128). Spontaneous abortion and major congenital malformation rates are both increased in women with insulin-dependent diabetes. This is directly related to the degree of periconceptional glycemic and metabolic control.

Thyroid Disorders
These have long been suspected to cause early pregnancy loss and other adverse pregnancy outcomes. Severe iodine deficiency, which is infrequent in developed countries, has been associated with increased miscarriage rates (Castañeda, 2002). Varying degrees of thyroid hormone insufficiency are common in women. Although the worst—overt hypothyroidism—is infrequent in pregnancy, subclinical hypothyroidism has an incidence of 2 to 3 percent (Casey, 2005; Garber, 2012). Both are usually caused by autoimmune Hashimoto thyroiditis, in which both incidence and severity accrue with age. Despite this common prevalence, any increased risks for miscarriage due to hypothyroidism are still unclear (Krassas, 2010; Negro, 2010). That said, De Vivo (2010) reported that subclinical thyroid hormone deficiency may be associated with very early pregnancy loss.

The prevalence of abnormally high serum levels of antibodies to thyroid peroxidase or thyroglobulin is nearly 15 percent in pregnant women (Abbassi-Ghanavati, 2010; Haddow, 2011). Although most of these women are euthyroid, those with clinical hypothyroidism tend to have higher concentrations of antibodies. Even in euthyroid women, however, antibodies are a marker for increased miscarriage (Benhadi, 2009; Chen, 2011; Thangaratinam, 2011). This has been
confirmed by two prospective studies, and preliminary data from one suggest that thyroxine supplementation decreases this risk (Männistö, 2009; Negro, 2006). Effects associated with thyroid disorders in women with *recurrent miscarriage* are considered further on page 359.

**Surgical Procedures**

The risk of miscarriage caused by surgery is not well studied. There is extensive interest in pregnancy outcomes following *bariatric surgery*, because as discussed on page 353, obesity is an uncontested risk factor for miscarriage. However, currently, it is not known if this risk is mitigated by weight-reduction surgery (Guelinckx, 2009).

It is likely that *uncomplicated* surgical procedures performed during early pregnancy do not increase the risk for abortion (Mazze, 1989). Ovarian tumors can generally be resected without causing miscarriage (Chap. 63, p. 1227). An important exception involves early removal of the corpus luteum or the ovary in which it resides. If performed before 10 weeks’ gestation, supplemental progesterone should be given. Between 8 and 10 weeks, a single 150-mg intramuscular injection of 17-hydroxyprogesterone caproate is given at the time of surgery. If between 6 to 8 weeks, then two additional 150-mg injections should be given 1 and 2 weeks after the first. Other progesterone regimens include: (1) oral micronized progesterone (Prometrium), 200 or 300 mg orally once daily, or (2) 8-percent progesterone vaginal gel (Crinone) given intravaginally as one premeasured applicator daily plus micronized progesterone 100 or 200 mg orally once daily continued until 10 weeks’ gestation.

Trauma seldom causes first-trimester miscarriage, and although Parkland Hospital is a busy trauma center, this is an infrequent association. Major trauma—especially abdominal—can cause fetal loss, but is more likely as pregnancy advances (Chap. 47, p. 950).

**Nutrition**

Extremes of nutrition—severe dietary deficiency and morbid obesity—are associated with increased miscarriage risks. Dietary quality may also be important, as this risk may be reduced in women who consume fresh fruit and vegetables daily (Maconochie, 2007).

Sole deficiency of one nutrient or moderate deficiency of all does not appear to increase risks for abortion. Even in extreme cases—for example, *hyperemesis gravidarum*—abortion is rare (Maconochie, 2007). Other examples discussed on page 352 are *anorexia* and *bulimia nervosa*. Importantly, Bulik and colleagues (2010) reported that half of pregnancies in women with anorexia nervosa were unplanned.

Obesity is associated with a litany of adverse pregnancy outcomes (Chap. 48, p. 965). These include subfertility and an increased risk of miscarriage and recurrent abortion (Jarvie, 2010; Lashen, 2004; Satpathy, 2008). In a study of 6500 women who conceived with in vitro fertilization (IVF), live birth rates were reduced progressively for each body mass index (BMI) unit increase (Bellver, 2010a). As noted earlier, although the risks for many adverse late-pregnancy outcomes are decreased after bariatric surgery, any salutary effects on the miscarriage rate are not clear (Guelinckx, 2009).

**Social and Behavioral Factors**

Lifestyle choices reputed to be associated with an increased miscarriage risk are most commonly related to chronic and especially heavy use of legal substances. The most common used is alcohol, with its potent teratogenic effects discussed in Chapter 12 (p. 245). That said, an increased miscarriage risk is only seen with regular or heavy use (Floyd, 1999; Maconochie, 2007). In fact,
low-level alcohol consumption does not significantly increase the abortion risk (Cavallo, 1995; Kesmodel, 2002).

At least 15 percent of pregnant women admit to cigarette smoking (Centers for Disease Control and Prevention, 2013). It seems intuitive, but unproven, that cigarettes could cause early pregnancy loss by a number of mechanisms that cause adverse late-pregnancy outcomes (Catov, 2008).

Excessive caffeine consumption—not well defined—has been associated with an increased abortion risk. There are reports that heavy intake of approximately five cups of coffee per day—about 500 mg of caffeine—slightly increases the abortion risk (Armstrong, 1992; Cnattingus, 2000; Klebanoff, 1999). Studies of “moderate”—less than 200 mg daily—did not increase the risk (Savitz, 2008; Weng, 2008). Currently, the American College of Obstetricians and Gynecologists (2013b) has concluded that moderate consumption likely is not a major abortion risk and that any associated risk with higher intake is unsettled. Adverse effects of illicit drugs are discussed in Chapter 12 (p. 253).

**Occupational and Environmental Factors**

It is intuitive to limit exposure of pregnant women to any toxin. That said, although some environmental toxins such as benzene are implicated in fetal malformations, data with miscarriage risk is less clear (Lupo, 2011). The major reason is that it is not possible to accurately assess environmental exposures. Earlier reports that implicated some chemicals as increasing miscarriage risk include arsenic, lead, formaldehyde, benzene, and ethylene oxide (Barlow, 1982). More recently, there is evidence that DDT—dichlorodiphenyltrichloroethane—may cause excessive miscarriage rates (Eskenazi, 2009). In fact, use of DDT-containing insecticides had been suspended. But in 2006, it was again and is still endorsed by the World Health Organization (2011) for mosquito control for malaria prevention.

There are even fewer studies of occupational exposures and abortion risks. In a follow-up of the Nurses Health Study II, Lawson and associates (2012) reported slightly increased miscarriage risks in nurses exposed to antineoplastic drugs, sterilizing agents, and x-rays. Some of these found that exposure to video display terminals or to ultrasound did not increase miscarriage rates (Schnorr, 1991; Taskinen, 1990). Increased miscarriage risk was found for dental assistants exposed to more than 3 hours of nitrous oxide daily if there was no gas-scavenging equipment (Boivin, 1997; Rowland, 1995). Conclusions from a metaanalysis were that there is a small incremental risk for spontaneous abortion in women who worked with cytotoxic antineoplastic chemotherapeutic agents (Dranitsaris, 2005).

**Immunological Factors**

The immune tolerance of the mother to the paternal-haploid fetal combination remains enigmatic (Calleja-Agius, 2011; Williams, 2012). This is discussed in greater detail in Chapter 5 (p. 97). There is, however, an increased risk for early pregnancy loss with some immune-mediated disorders. The most potent of these are antiphospholipid antibodies directed against binding proteins in plasma (Erkan, 2011). These along with clinical and laboratory findings provide criteria for the antiphospholipid antibody syndrome—APS (American College of Obstetricians and Gynecologists, 2012). Because associated pregnancy loss can be repetitive, recurrent miscarriage due to APS is discussed on page 359.

**Inherited Thrombophilias**

Although thrombophilias were initially linked to various pregnancy outcomes, most putative
associations have been refuted. Currently, the American College of Obstetricians and Gynecologists (2013a) is of the opinion that there is not a definitive causal link between these thrombophilias and adverse pregnancy outcomes in general, and abortion in particular.

**Uterine Defects**

Various inherited and acquired uterine defects are known to cause both early and late recurrent miscarriages, and they are considered on page 358.

**Paternal Factors**

These factors in the genesis of miscarriage are not well studied. Chromosomal abnormalities in sperm reportedly had an increased abortion risk (Carrell, 2003). Increasing paternal age was significantly associated with increased risk for abortion in the Jerusalem Perinatal Study (Kleinhaus, 2006). This risk was lowest before age 25 years, after which it progressively increased at 5-year intervals.

**Clinical Classification of Spontaneous Abortion**

**Threatened Abortion**

The clinical diagnosis of threatened abortion is presumed when bloody vaginal discharge or bleeding appears through a closed cervical os during the first 20 weeks (Hasan, 2009). Bleeding in early pregnancy must be differentiated from implantation bleeding, which some women have at the time of the expected menses (Chap. 5, p. 90). Almost a fourth of women develop clinically significant bleeding during early gestation that may persist for days or weeks. With miscarriage, bleeding usually begins first, and cramping abdominal pain follows hours to days later. There may be low-midline clearly rhythmic cramps; persistent low backache with pelvic pressure; or dull and midline suprapubic discomfort. Bleeding is by far the most predictive risk factor for pregnancy loss (Eddleman, 2006). Overall, approximately half will abort, but this risk is substantially less if there is fetal cardiac activity (Tongsong, 1995).

Even if miscarriage does not follow early bleeding, the risk for later adverse pregnancy outcomes is increased as shown in Table 18-2. In the study of almost 1.8 million pregnancies from the Danish National Patient Registry, there was a threefold risk for many of these pregnancy complications.

| **TABLE 18-2.** Adverse Outcomes That are Increased in Women with Threatened Abortion |
Threatened Abortion versus Ectopic Pregnancy. Every woman with an early pregnancy, vaginal bleeding, and pain should be evaluated. The primary goal is prompt diagnosis of an ectopic pregnancy. As discussed in Chapter 19 (p. 381), serial quantitative serum β-hCG and progesterone levels and transvaginal sonography are used to ascertain if there is an intrauterine live fetus. Because these are not 100-percent accurate to confirm early fetal death or location, repeat evaluations are often necessary. Serum hCG levels in women with bleeding who went on to have an early miscarriage are shown in Figure 18-2 and in Table 19-1 (p. 381). Values for women with early pregnancy bleeding who went on to have a normal pregnancy are shown in Figure 18-3. Several predictive models have been described (Barnhart, 2010; Condous, 2007; Connolly, 2013). With a robust uterine pregnancy, serum β-hCG levels should increase at least 53 to 66 percent every 48 hours (Barnhart, 2004a; Kadar, 1982). Serum progesterone concentrations < 5 ng/mL suggest a dying pregnancy, whereas values > 20 ng/mL support the diagnosis of a healthy pregnancy.

FIGURE 18-2 Composite curve describing decline in serial human chorionic gonadotropin (hCG) values starting at a level of 2000 mIU/mL following early spontaneous miscarriage. The dashed line is the predicted curve based on the summary of data from all women. The colored area within
Transvaginal sonography is used to locate the pregnancy and determine if the fetus is alive. If this cannot be done, then pregnancy of unknown location is diagnosed (Chap. 19, p. 381). The gestational sac—an anechoic fluid collection that represents the exocoelomic cavity—may be seen by 4.5 weeks (Fig. 9-3, p. 170). At this same time, β-hCG levels are generally considered to be 1500 to 2000 mIU/mL (Barnhart, 1994; Timor-Tritsch, 1988). Connolly and colleagues (2013) observed that this value could be as low as 390 mIU/mL, but also noted that a threshold as high as 3500 mIU/mL may be needed to identify the gestational sac in 99 percent of cases.

Another caveat is that a gestational sac may appear similar to other intrauterine fluid accumulations—the so-called pseudogestational sac (Fig. 19-5, p. 382). This pseudosac may be seen with ectopic pregnancy and is easier to exclude once a yolk sac is seen. Typically, the yolk sac is visible by 5.5 weeks and with a mean gestational-sac diameter of 10 mm. Thus, the diagnosis of a uterine pregnancy should be made cautiously if the yolk sac is not yet seen (American College of Obstetricians and Gynecologists, 2011e).

At 5 to 6 weeks, a 1- to 2-mm embryo adjacent to the yolk sac can be seen (Daya, 1993). Absence of an embryo in a sac with a mean sac diameter of 16 to 20 mm suggests a dead fetus (Levi, 1988; Nyberg, 1987). Finally, fetal cardiac activity can be detected at 6 to 6.5 weeks with an embryonic length of 1 to 5 mm and a mean sac diameter of 13 to 18 mm. A 5-mm embryo without cardiac activity is likely dead (Goldstein, 1992; Levi, 1990).

There are various management schemes derived from these findings. At Parkland Hospital, to ensure that live intrauterine pregnancies are not interrupted, we define the threshold of embryo fetal death based on values two standard deviations from the mean. Thus, an anembryonic gestation is diagnosed when the mean gestational sac diameter measures ≥ 20 mm and no embryo is seen. Embryonic death is also diagnosed if an embryo measuring ≥ 10 mm has no cardiac activity.
Management. Acetaminophen-based analgesia will help relieve discomfort from cramping. If uterine evacuation is not indicated, bed rest is often recommended but does not improve outcomes. Neither has treatment with a host of medications that include chorionic gonadotropin (Devaseelan, 2010). With persistent or heavy bleeding, the hematocrit is determined. If there is significant anemia or hypovolemia, then pregnancy evacuation is generally indicated. In these cases in which there is a live fetus, some choose transfusion and further observation.

Anti-D Immunoglobulin. With spontaneous miscarriage, 2 percent of Rh D-negative women will become alloimmunized if not provided passive isoimmunization. With an induced abortion, this rate may reach 5 percent. The American College of Obstetricians and Gynecologists (2013c) recommends anti-Rh₀ (D) immunoglobulin given as 300 μg intramuscularly (IM) for all gestational ages, or 50 μg IM for pregnancies ≤ 12 weeks and 300 μg for ≥ 13 weeks.

With threatened abortion, immunoglobulin prophylaxis is controversial because of sparse evidence-based data (American College of Obstetricians and Gynecologists, 2013c; Hannafin, 2006; Weiss, 2002). That said, some choose to administer anti-D immunoglobulin up to 12 weeks’ gestation for a threatened abortion and a live fetus. At Parkland Hospital, we administer a 50-μg dose to all Rh D-negative women with first-trimester bleeding.

Inevitable Abortion
In the first trimester, gross rupture of the membranes along with cervical dilatation is nearly always followed by either uterine contractions or infection. A gush of vaginal fluid during the first half of pregnancy usually has serious consequences. In some cases not associated with pain, fever, or bleeding, fluid may have collected previously between the amnion and chorion. If this is documented, then diminished activity with observation is a reasonable course. After 48 hours, if no additional amnionic fluid has escaped and if there is no bleeding, cramping, or fever, then a woman may resume ambulation and pelvic rest. With bleeding, cramping, or fever, abortion is considered inevitable, and the uterus is evacuated.

Incomplete Abortion
Bleeding that follows partial or complete placental separation and dilation of the cervical os is termed incomplete abortion. The fetus and the placenta may remain entirely within the uterus or partially extrude through the dilated os. Before 10 weeks, they are frequently expelled together, but later, they deliver separately. Management options of incomplete abortion include curettage, medical abortion, or expectant management in clinically stable women as discussed on page 357. With surgical therapy, additional cervical dilatation may be necessary before suction curettage. In others, retained placental tissue simply lies loosely within the cervical canal and can be easily extracted with ring forceps.

Complete Abortion
At times, expulsion of the entire pregnancy may be completed before a woman presents to the hospital. A history of heavy bleeding, cramping, and passage of tissue or a fetus is common. Importantly, during examination, the cervical os is closed. Patients are encouraged to bring in passed tissue, which may be a complete gestation, blood clots, or a decidual cast. The last is a layer of endometrium in the shape of the uterine cavity that when sloughed can appear as a collapsed sac (Fig. 19-3, p. 379).

If an expelled complete gestational sac is not identified, sonography is performed to
differentiate a complete abortion from threatened abortion or ectopic pregnancy. Characteristic findings of a complete abortion include a minimally thickened endometrium without a gestational sac. However, this does not guarantee a recent uterine pregnancy. Condous and associates (2005) described 152 women with heavy bleeding, an empty uterus with endometrial thickness < 15 mm, and a diagnosis of completed miscarriage. Six percent were subsequently proven to have an ectopic pregnancy. Thus, unless products of conception are seen or unless sonography confidently documents, at first an intrauterine pregnancy, and then later an empty cavity, a complete abortion cannot be surely diagnosed. In unclear settings, serial serum hCG measurements aid clarification. With complete abortion, these levels drop quickly (Connolly, 2013).

**Missed Abortion**

Also termed early pregnancy failure or loss, missed abortion, as originally defined, is contemporaneously misused compared with its meaning many decades ago. Historically, the term was used to describe dead products of conception that were retained for days, weeks, or even months in the uterus with a closed cervical os. Early pregnancy appeared to be normal with amenorrhea, nausea and vomiting, breast changes, and uterine growth. Because suspected fetal death could not be confirmed, expectant management was the sole option, and spontaneous miscarriage would eventually ensue. And because the time of fetal death could not be determined clinically, pregnancy duration—and thus fetal age—was erroneously calculated from the last menses. To elucidate these disparities, Streeter (1930) studied aborted fetuses and reported that the mean death-to-abortion interval was approximately 6 weeks.

This historical description of missed abortion is in contrast to that defined currently based on results of serial serum β-hCG assays and transvaginal sonography (Fig. 18-4). With rapid confirmation of fetal or embryonic death, many women choose uterine evacuation. Although many classify these as a missed abortion, the term is used interchangeably with early pregnancy loss or wastage (Silver, 2011).
Transvaginal sonogram displays a large anechoic sac consistent with an anembryonic gestation. Calipers measure uterine length and anteroposterior thickness in a sagittal plane.

**Septic Abortion**

Horrific infections and maternal deaths associated with criminal septic abortions have become rare with legalized abortion. Still, perhaps 1 to 2 percent of women with threatened or incomplete miscarriage develop a pelvic infection and sepsis syndrome. Elective abortion, either surgical or medical, is also occasionally complicated by severe and even fatal infections (Barrett, 2002; Ho, 2009). Bacteria gain uterine entry and colonize dead conception products. Organisms may invade myometrial tissues and extend to cause parametritis, peritonitis, septicemia, and, rarely, endocarditis (Vartian, 1991). Particularly worrisome are severe necrotizing infections and toxic shock syndrome caused by group A streptococcus—\textit{S} pyogenes (Daif, 2009).

During the last few years, rare but severe infections with otherwise low-virulence organisms have complicated medical abortions. Deaths have been reported from toxic shock syndrome due to \textit{Clostridium perfringens} (Centers for Disease Control and Prevention, 2005). Similar infections are caused by \textit{Clostridium sordellii} and have clinical manifestations that begin within a few days after an abortion. Women may be afebrile when first seen with severe endothelial injury, capillary leakage, hemoconcentration, hypotension, and a profound leukocytosis (Cohen, 2007; Fischer, 2005; Ho, 2009). Maternal deaths from these clostridial species approximate 0.58 per 100,000 medical abortions (Meites, 2010).

Management of clinical infection includes prompt administration of broad-spectrum antibiotics as discussed in Chapter 37 (p. 685). If there are retained products or fragments, then suction curettage is also performed. Most women respond to this treatment within 1 to 2 days, and they are discharged when afebrile. Follow-up oral antibiotic treatment is likely unnecessary (Savaris, 2011). In a very few women, severe sepsis syndrome causes acute respiratory distress syndrome, acute kidney injury, or disseminated intravascular coagulopathy. In these cases, intensive supportive care is essential (Chap. 47, p. 940).

To prevent postabortal sepsis, prophylactic antibiotics are given at the time of induced abortion or spontaneous abortion that requires medical or surgical intervention. The American College of Obstetricians and Gynecologists (2011b) recommends doxycycline, 100 mg orally 1 hr before and then 200 mg orally after a surgical evacuation. At Planned Parenthood clinics, for medical abortion, doxycycline 100 mg is taken orally daily for 7 days and begins with abortifacient administration (Fjerstad, 2009b).

**Management of Spontaneous Abortion**

With embryofetal death now easy to verify with current sonographic technology, management can be more individualized. Unless there is serious bleeding or infection with an incomplete abortion, any of three options are reasonable—expectant, medical, or surgical management. Each has its own risks and benefits—for example, the first two are associated with unpredictable bleeding, and some women will undergo unscheduled curettage. Also, success of any method depends on whether the woman has an incomplete or missed abortion. Some of the risks and benefits are summarized as follows:

1. Expectant management of spontaneous incomplete abortion has failure rates as high as 50 percent.
2. Medical therapy with prostaglandin E$_1$ (PGE$_1$) has varying failure rates of 5 to 40 percent. In 1100 women with suspected first-trimester abortion, 81 percent had a spontaneous resolution (Luise, 2002).

3. Curettage usually results in a quick resolution that is 95- to 100-percent successful. It is invasive and not necessary for all women.

It is possible that patients and clinicians opt for surgical methods when there is not a strict protocol for medical treatment (Kollitz, 2011).

Several randomized studies that compared these management schemes were reviewed by Neilson (2010). A major drawback cited for between-study comparisons was varied inclusion criteria and techniques. For example, studies that included women with vaginal bleeding reported greater success for medical therapy than did studies that excluded such women (Creinin, 2006). With these caveats in mind, selected studies reported since 2005 are listed in Table 18-3. Importantly, Smith and coworkers (2009) reported that subsequent pregnancy rates did not differ among these management methods.

$^a$Includes anembryonic gestation, embryonic or fetal death, without signs of incomplete SAB.

$^b$Includes anembryonic gestation, embryonic or fetal death, or incomplete or inevitable SAB.

SAB = spontaneous abortion; PGE$_1$ = prostaglandin E$_1$; TVS = transvaginal sonography.
Other terms that have been used to describe repetitive early spontaneous pregnancy losses include *recurrent spontaneous abortion*, *recurrent pregnancy loss*, and *habitual abortion*. It is generally accepted that approximately 1 percent of fertile couples have recurrent miscarriages classically defined as three or more consecutive pregnancy losses at ≤ 20 weeks or with a fetal weight < 500 grams. Most of these are embryonic or early losses, and the remainder either are anembryonic or occur after 14 weeks. Studies are difficult to compare because of nonstandardized definitions. For example, some investigators include women with two instead of three consecutive losses, and yet others include women with three *nonconsecutive* losses. Documentation of pregnancy with β-hCG levels, sonography, and pathological examination also varies widely.

At minimum, recurrent miscarriage should be distinguished from sporadic pregnancy loss that implies intervening pregnancies that reached viability. Although women in the latter category were thought to have a much lower risk of yet another abortion, there are reports such as the one shown in Table 18-4 that question this assumption. In two studies, the risk for subsequent miscarriage is similar following either two or three pregnancy losses. Remarkably, the chances for a successful pregnancy are > 50 percent even after five losses (Brigham, 1999).

*Nonconsecutive miscarriages showed the same pattern of risk as consecutive miscarriages.*

Data from Bhattacharya, 2010.

The American Society for Reproductive Medicine (2008) proposed that recurrent pregnancy loss be defined as two or more failed clinical pregnancies confirmed by either sonographic or histopathological examination. A thorough evaluation certainly is warranted after three losses, and treatment is initiated earlier in couples with concordant subfertility (Jaslow, 2010; Reddy, 2007). Treatment considerations are beyond the scope of this book. The reader is referred to Chapters 6 and 20 in the 2nd edition of *Williams Gynecology* (Cunningham, 2012; Doody, 2012).

### Etiology

There are many putative causes of recurrent abortion, however, only three are widely accepted:
parental chromosomal abnormalities, antiphospholipid antibody syndrome, and a subset of uterine abnormalities. Other suspected but not proven causes are alloimmunity, endocrinopathies, environmental toxins, and various infections. Infections seldom cause even sporadic loss. Thus, most are unlikely to cause recurrent miscarriage, especially since maternal antibodies usually have developed. For years, various inherited thrombophilia mutations that include factor V Leiden, prothrombin G20210A, protein C and S deficiency, and antithrombin deficiency were suspected. But, as discussed in Chapter 52 (p. 1029), large studies have refuted an association between increased pregnancy wastage and these thrombophilias (American College of Obstetricians and Gynecologists, 2013a).

There is some evidence to support a role for various polymorphisms of gene expression in miscarriages. Just a few examples include polymorphisms that alter VEGF-A expression, those that exaggerate platelet aggregation, and those with a specific maternal type of Th1 and Th2 immune response (Calleja-Agius, 2011; Corardetti, 2013; Eller, 2011; Flood, 2010).

The timing of recurrent loss may offer clues, and in some women, each miscarriage may occur near the same gestational age (Heuser, 2010). Genetic factors usually result in early embryonic losses, whereas autoimmune or uterine anatomical abnormalities more likely cause second-trimester losses (Schust, 2002). As mentioned, first-trimester losses in recurrent miscarriage have a significantly lower incidence of genetic abnormalities than sporadic losses—25 versus 50 percent (Sullivan, 2004). That said, routine chromosomal evaluation of abortuses is costly and may not accurately reflect the fetal karyotype.

### Parental Chromosomal Abnormalities

Although these account for only 2 to 4 percent of recurrent losses, karyotypic evaluation of both parents is considered by many to be a critical part of evaluation. In an earlier study, balanced reciprocal translocations accounted for half of chromosomal abnormalities, robertsonian translocations for a fourth, and X chromosome mosaicism—47,XXY or Klinefelter syndrome—for 12 percent (Therapel, 1985). These chromosomal abnormalities are repetitive for consecutive losses (van den Boogaard, 2010). Inheritance of translocation syndromes and their sequelae are discussed in detail in Chapter 13 (p. 266).

After thorough genetic counseling, couples with an abnormal karyotype can usually be managed with IVF followed by preimplantation genetic diagnosis. These techniques are described in detail in Chapter 20 of Williams Gynecology (Doody, 2012).

### Anatomical Factors

Several genital tract abnormalities have been implicated in recurrent miscarriage and other adverse pregnancy outcomes, but not infertility (Reichman, 2010). According to Devi Wold and colleagues (2006), 15 percent of women with three or more consecutive miscarriages will be found to have a congenital or acquired uterine anomaly.

Of acquired abnormalities, uterine synechiae—Asherman syndrome—usually result from destruction of large areas of endometrium. This can follow uterine curettage or ablative procedures. Characteristic multiple filling defects are seen with hysterosalpingography or saline-infusion sonography. Treatment is done using directed hysteroscopic lysis of adhesions. In many women, this lowers miscarriage rates and improves the “take home” pregnancy rate (Al-Inany, 2001; Goldenberg, 1995).

Uterine leiomyomas are found in a large proportion of adult women and can cause miscarriage.
especially if located near the placental implantation site. That said, data indicating them to be a significant cause of recurrent pregnancy loss are not convincing (Saravelos, 2011). Uterine cavity distortion is apparently not requisite for bad outcomes (Sunkara, 2010). But in women undergoing IVF, pregnancy outcomes were adversely affected by submucous but not subserosal or intramural leiomyomas (Jun, 2001; Ramzy, 1998). As discussed in Chapter 63 (p. 1226), most agree that consideration be given to excision of submucosal and intracavitary leiomyomas in women with recurrent losses. Ironically, women undergoing uterine artery embolization of myomas had an increased risk for miscarriage in a subsequent pregnancy (Homer, 2010).

In contrast, congenital genital tract anomalies commonly originate from abnormal müllerian duct formation or abnormal fusion. These have an overall incidence of approximately 1 in 200 women (Nahum, 1998). The distribution of anomalies and associated loss rates are shown in Table 18-5. Depending on their anatomy, some may increase risks for early miscarriage, whereas others may cause midtrimester abortion or preterm delivery. Unicornuate, bicornuate, and septate uteri are associated with all three types of loss (Reichman, 2010). Looked at another way, developmental uterine anomalies were found in approximately 20 percent of women with recurrent pregnancy losses compared with about 7 percent of controls (Salim, 2003).

*Includes first- and second-trimester losses.

It has proven difficult to demonstrate that correction of uterine anomalies improves early pregnancy outcome. Additional discussion regarding the incidence, clinical impact, and treatment of anatomical abnormalities is found in Chapter 3 (p. 38), as well as in Chapter 18 of Williams Gynecology (Bradshaw, 2012).

### Immunological Factors

In their analysis of published studies, Yetman and Kutteh (1996) determined that 15 percent of more than 1000 women with recurrent miscarriage had recognized autoimmune factors. Two primary pathophysiological models are the autoimmune theory—immunity directed against self,
and the *alloimmune theory*—immunity against another person.

As discussed on page 352, miscarriages are more common in women with systemic lupus erythematosus, an autoimmune disease (Clowse, 2008; Warren, 2004). Many of these women were found to have *antiphospholipid antibodies*, a family of autoantibodies that bind to phospholipid-binding plasma proteins (Erkan, 2011). Women with recurrent spontaneous pregnancy loss have a higher frequency of these antibodies compared with normal controls—5 to 15 versus 2 to 5 percent, respectively (Branch, 2010). The *antiphospholipid antibody syndrome (APS)* is defined by these antibodies found together with various forms of reproductive losses along with substantively increased risks for venous thromboembolism (American College of Obstetricians and Gynecologists, 2011d, 2013a). Mechanisms that cause pregnancy loss are discussed along with treatment in Chapter 59 (p. 1173).

With regard to alloimmunity, a provocative theory suggests that normal pregnancy requires formation of blocking factors that prevent maternal rejection of foreign fetal antigens that are paternally derived (Chap. 5, p. 98). Factors said to prevent this include *human leukocyte antigen (HLA)* similarity with the father, altered natural killer cell activity, regulatory T cell stimulation, and HLA-G gene mutations (Berger, 2010; Williams, 2012). Various tests and treatment options proposed to address this have not withstood rigorous scrutiny, and they are currently investigational (Reddy, 2007). Proposed therapies using paternal or third-party leukocyte immunization or intravenous immunoglobulin (IVIG) have not proved beneficial in women with idiopathic miscarriage (American Society for Reproductive Medicine, 2006; Stephenson, 2010).

### Endocrine Factors

According to Arredondo and Noble (2006), 8 to 12 percent of recurrent miscarriages are caused by endocrine factors. Studies to evaluate these have been inconsistent and generally underpowered. Two examples, both controversial, are progesterone deficiency caused by a *luteal-phase defect* and *polycystic ovarian syndrome* (Bukulmez, 2004; Cocksedge, 2008; Nawaz, 2010).

In contrast, the well-known abortifacient effects of uncontrolled diabetes are detailed in Chapter 57. Optimal periconceptional glycemic control will mitigate much of this loss.

Likewise, the effects on early pregnancy loss of overt hypothyroidism and severe iodine deficiency are well known and discussed on page 353. Correction with supplementation reverses these effects. Also, the effects of subclinical hypothyroidism and antithyroid antibodies are sporadic, and thus any effects on recurrent miscarriage rates have been debated (Garber, 2012). That said, however, two recent metaanalyses reported convincingly positive associations between these antibodies and an increased risk for sporadic and recurrent miscarriages (Chen, 2011; Thangaratinam, 2011). Less convincing are preliminary data regarding thyroid hormone treatment for antibody-positive women.

### MIDTRIMESTER ABORTION

The timespan that defines a midtrimester fetal loss extends from the end of the first trimester until the fetus weighs ≥ 500 g or gestational age reaches 20 weeks. For reasons discussed on page 350, a gestational age of 22 to 23 weeks is more accurate. Importantly, in many of these losses, an etiology can be found if a careful evaluation is completed.
Incidence and Etiology

Abortion becomes much less common by the end of the first trimester, and its incidence decreases successively thereafter. Overall, spontaneous loss in the second trimester is estimated at 1.5 to 3 percent, and after 16 weeks, it is only 1 percent (Simpson, 2007; Wyatt, 2005). First-trimester bleeding doubles the incidence of second-trimester loss (Hasan, 2009; Velez Edwards, 2012). Unlike earlier miscarriages that frequently are caused by chromosomal aneuploidies, these later fetal losses are due to a multitude of causes and more closely reflect those discussed in the section under Recurrent Miscarriage (p. 358). There are no data to accurately estimate the incidences of these various causes, but some of the more common etiologies are listed in Table 18-6. One frequently overlooked factor is that many second-trimester abortions are medically induced because of fetal abnormalities detected by prenatal screening programs for chromosome trisomies and structural defects.

Risk factors for second-trimester abortion include race, ethnicity, prior poor obstetrical outcomes, and extremes of maternal age. First-trimester bleeding was cited previously as a potent risk factor (Hasan, 2009). Edlow and colleagues (2007) observed that 27 percent of women with such a loss in the index pregnancy had a recurrent second-trimester loss in their next pregnancy. Moreover, a third of these women had a subsequent preterm birth.

Data from Allanson, 2010; Dukhovny, 2009; Joo, 2009; Romero, 2011; Saravelos, 2011; Stout, 2010.

Fetal and Placental Evaluation

Because etiology is closely linked to recurrence risk, a thorough evaluation of obstetrical and perinatal findings is warranted. Pathological examination of the fetus and placenta is essential
Midtrimester abortions are classified similarly to first-trimester abortions. Management is also similar in many regards, and the schemes shown in **Table 18-3** are frequently successful with a dead fetus or an incomplete midtrimester abortion. An exception is that at these later gestational ages, oxytocin in concentrated doses is highly effective for labor induction or augmentation. As subsequently discussed on page **366**, surgical midtrimester abortion for fetal demise is technically more difficult. That said, there can be significant morbidity with either medical or surgical termination of these. Overall, however, for elective delivery, available data suggest that surgical termination by dilatation and evacuation has fewer complications than labor induction (Bryant, 2011; Edlow, 2011).

**Cervical Insufficiency**

Also known as incompetent cervix, this is a discrete obstetrical entity characterized classically by painless cervical dilatation in the second trimester. It can be followed by prolapse and ballooning of membranes into the vagina, and ultimately, expulsion of an immature fetus. Unless effectively treated, this sequence may repeat in future pregnancies. Many of these women have a history and clinical findings that make it difficult to verify *classic* cervical incompetence. For example, in a randomized trial of almost 1300 women with an atypical history, cerclage was found to be only marginally beneficial—13 versus 17 percent—to prolong pregnancy past 33 weeks (MacNaughton, 1993). It seems likely that many of these women with such a nonclassic history had preterm labor instead of classic cervical incompetence. In this study, for every 25 cerclage procedures, only one birth before 33 weeks was prevented. In a systematic review of similar women, however, indicated cerclages that were placed based on physical examination findings provided superior perinatal outcomes compared with expectant management (Ehsanipoor, 2013).

Because of these difficulties in identification of classic cervical insufficiency, interest has been focused on the predictive value of transvaginal sonography. Some findings assessed include cervical length as well as the presence of *funneling*, which is ballooning of the membranes into a dilated internal os, but with a closed external os (Owen, 2003). In women with these problems, early randomized trials were inconclusive in proving the clinical relevance of cerclage to prevent preterm birth (Rust, 2001; To, 2004). A multicenter randomized trial of 302 high-risk women with cervical length < 25 mm reported that cerclage prevented birth before viability but not birth before 34 weeks (Owen, 2009). Subsequently, however, Berghella and coworkers (2011) included five trials in a metaanalysis and showed that cerclage for these high-risk women significantly reduced preterm birth before 24, 28, 32, 35, and 37 weeks. One retrospective analysis found no improved outcomes with twin pregnancies in women with a cervical length ≤ 25 mm (Stoval, 2013).

**Risk Factors**

Although the cause of incompetence is obscure, previous cervical trauma such as dilatation and
curettage, conization, cauterization, or amputation has been implicated. A Norwegian cohort study of more than 15,000 women with prior cervical conization found a fourfold risk of pregnancy loss before 24 weeks (Albrechtsen, 2008). Even though prior dilatation and evacuation (D&E) has an incidence of cervical injury of 5 percent, neither it nor dilatation and extraction (D&X) after 20 weeks increased the likelihood of an incompetent cervix (Chasen, 2005). In other instances, abnormal cervical development, including that following in utero exposure to diethylstilbestrol (DES), may play a role (Hoover, 2011). This is discussed further in Chapter 3 (p. 42).

Evaluation and Treatment
Sonography is performed to confirm a living fetus with no major anomalies. Cervical secretions are tested for gonorrhea and chlamydia infection. These and other obvious cervical infections are treated. For at least a week before and after surgery, sexual intercourse is prohibited.

Classic cervical incompetence is treated surgically with cerclage, which reinforces a weak cervix by a purse-string suture. Contraindications to cerclage usually include bleeding, uterine contractions, or ruptured membranes. With ruptured membranes and bleeding or contractions or both, the likelihood of failure is substantially increased. Thus, prophylactic cerclage before dilatation is preferable. At times, this may not be possible, and a rescue cerclage is performed emergently after the cervix is found to be dilated, effaced, or both. In some or even many of these women, cerclage is unknowingly being used incorrectly to treat preterm labor with cervical dilatation rather than an incompetent cervix.

The timing of surgery depends on clinical circumstances. In women who are diagnosed with cervical insufficiency based on their previous obstetrical outcomes, elective cerclage is usually done between 12 and 14 weeks’ gestation. If the diagnosis is made in high-risk women using transvaginal sonography to document cervical shortening < 25 mm, then cerclage is done at that time. For the remainder who undergo emergent rescue cerclage, there is debate as to how late this should be performed. The conundrum is that the more advanced the pregnancy, the greater the risk that surgical intervention will stimulate preterm labor or membrane rupture. Although this practice is not evidence based, we usually do not perform cerclage after 23 weeks. Others, however, recommend placement later than this (Caruso, 2000; Terkildsen, 2003).

When outcomes of cerclage are evaluated, women with similar clinical presentations should be compared. For example, in the study of elective cerclage by Owen and associates (2009), approximately a third of women delivered before 35 weeks, and there were few complications with surgery. By contrast, in a 10-year review of 75 women undergoing emergency cerclage procedures, Chasen and Silverman (1998) reported that only half were delivered after 36 weeks. Importantly, only 44 percent of those with bulging membranes at the time of cerclage reached 28 weeks. Terkildsen and colleagues (2003) had similar experiences. Caruso and coworkers (2000) described emergency cerclage done in 23 women from 17 to 27 weeks who had a dilated cervix and protruding membranes. There were 11 liveborn infants, and these researchers concluded that success was unpredictable. Our experiences at Parkland Hospital are that rescue cerclages have a high failure rate, and women are counseled accordingly.

If the clinical indication for cerclage is questionable, these women may be advised to instead decrease physical activity and abstain from intercourse. Most undergo cervical examinations each week or every 2 weeks to assess effacement and dilatation. Unfortunately, rapid effacement and dilatation can develop despite such precautions (Witter, 1984).

Cerclage Procedures
Of the two vaginal cerclage operations, most use the simpler procedure developed by McDonald (1963) and shown in Figure 18-5. The more complicated operation is a modification of the procedure described by Shirodkar (1955) and shown in Figure 18-6. When either technique is performed prophylactically, women with a classic history of cervical incompetence have excellent outcomes (Caspi, 1990; Kuhn, 1977). As emphasized by Karl and Katz (2012), it is important to place the suture as high as possible and into the dense cervical stroma. There is some evidence that two cerclage sutures are not more effective than one (Giraldo-Isaza, 2013). For either vaginal or abdominal cerclage, there is insufficient evidence to recommend perioperative antibiotic prophylaxis (American College of Obstetricians and Gynecologist, 2011f, 2014).
FIGURE 18-5 McDonald cerclage procedure for incompetent cervix. A. Start of the cerclage procedure with a No. 2 monofilament suture being placed in the body of the cervix very near the level of the internal os. B. Continuation of suture placement in the body of the cervix so as to encircle the os. C. Encirclement completed. D. The suture is tightened around the cervical canal sufficiently to reduce the diameter of the canal to 5 to 10 mm, and then the suture is tied. The effect of the suture placement on the cervical canal is apparent. A second suture placed somewhat higher
may be of value if the first is not in close proximity to the internal os.

FIGURE 18-6 Modified Shirodkar cerclage for incompetent cervix. A. A transverse incision is made in the mucosa overlying the anterior cervix, and the bladder is pushed cephalad. B. A 5-mm Mersilene tape on a swaged-on or Mayo needle is passed anteriorly to posteriorly. C. The tape is then directed posteriorly to anteriorly on the other side of the cervix. Allis clamps are placed so as to bunch the cervical tissue. This diminishes the distance that the needle must travel submucosally and aids tape placement. D. The tape is snugly tied anteriorly, after ensuring that all slack has been taken up. The cervical mucosa is then closed with continuous stitches of chromic suture to bury the anterior knot.

Emergency or rescue cerclage is, of course, more difficult to perform. Replacement of the prolapsed amnionic sac back into the uterus will usually aid suture placement (Locatelli, 1999).
This is sometimes made easier by tilting the operating table in the head-down position along with filling the bladder with 600 mL of saline through an indwelling Foley catheter. Although this may reduce the prolapsing membranes, it also may carry the cervix cephalad and away from the operating field. Some advocate placing a Foley catheter through the cervix and inflating the 30-mL balloon to deflect the amnionic sac cephalad. The balloon is deflated gradually as the cerclage suture is tightened around the catheter. In some women with bulging membranes, transabdominal amnionic fluid aspiration may be helpful. If this is done, bacterial cultures of the fluid should be obtained.

**Transabdominal cerclage** with the suture placed at the uterine isthmus can be used if there are severe cervical anatomical defects or if there have been prior transvaginal cerclage failures (Cammarano, 1995; Gibb, 1995). Zaveri and associates (2002) reviewed 14 observational studies in which a prior transvaginal cerclage had failed to prevent preterm delivery. The risk of perinatal death or delivery before 24 weeks was only slightly lower following transabdominal cerclage compared with the risk following repeat transvaginal cerclage—6 versus 13 percent, respectively. Importantly, 3 percent of women who underwent transabdominal cerclage had serious operative complications, whereas there were none in women in the transvaginal group. Whittle and coworkers (2009) described 31 women in whom transabdominal cervicoisthmic cerclage was done laparoscopically between 10 and 16 weeks. The procedure was converted to laparotomy in 25 percent, and there were four failures due to chorioamnionitis. Overall, fetal survival rate approximated 80 percent.

**Complications.** Principal complications of cerclage are membrane rupture, preterm labor, hemorrhage, infection, or combinations thereof. All are uncommon with prophylactic cerclage. In the multicenter study by Owen and colleagues (2009), of 138 procedures, there was one instance each of ruptured membranes and bleeding. In the trial by MacNaughton and associates (1993), membrane rupture complicated only 1 of more than 600 procedures done before 19 weeks. Thomason and coworkers (1982) found that perioperative antimicrobial prophylaxis failed to prevent most infection, and tocolytics failed to arrest most labor. In our view, clinical infection mandates immediate removal of the suture with labor induced or augmented. Similarly, with imminent abortion or delivery, the suture should be removed at once because uterine contractions can tear through the uterus or cervix.

Membrane rupture during suture placement or within the first 48 hours following surgery is considered by some to be an indication for cerclage removal because of the likelihood of serious fetal or maternal infection (Kuhn, 1977). That said, the range of management options includes observation, removal of the cerclage and observation, or removal of the cerclage and labor induction (Barth, 1995; O’Connor, 1999).

If subsequent cervical thinning is detected by sonographic assessment, then some consider a **reinforcement cerclage**. In one retrospective study, reinforcing cerclage sutures placed later did not significantly prolong pregnancy (Woo, 2013).

**INDUCED ABORTION**

The term induced abortion is defined as the medical or surgical termination of pregnancy before the time of fetal viability. Definitions to describe its frequency include: (1) **abortion ratio**—the number of abortions per 1000 live births, and (2) **abortion rate**—the number of abortions per 1000 women aged 15 to 44 years.
In the United States, abortion statistics most likely are underreported. This probably is because clinics inconsistently give statistics for medically induced abortions. For example, the Guttmacher Institute (2011) found that 1.2 million procedures were performed annually from 2005 through 2008. But for 2010, there were only about 765,650 elective abortions reported to the Centers for Disease Control and Prevention (Pazol, 2013). The abortion ratio was 227 per 1000 live births and the abortion rate was 15.1 per 1000 women aged 15 to 44 years. For the same year, women aged 20 to 29 years accounted for 58 percent of abortions and had the highest abortion rate. Black women had an abortion ratio of 477 per 1000 live births, white women had 140 per 1000, and Hispanic women had 195 per 1000. In 2009, 64 percent of abortions were done ≤ 8 weeks; 92 percent ≤ 13 weeks; 7 percent at 14 to 20 weeks; and only 1.3 percent were performed at ≥ 21 weeks. Global statistics for abortion rates are reported by the World Health Organization. According to its latest report, approximately 1 in 5 pregnancies were aborted worldwide in 2008 (Sedgh, 2012). Sadly, almost half of these abortions were considered unsafe.

### Classification

**Therapeutic Abortion**

There are several diverse medical and surgical disorders that are indications for termination of pregnancy. Examples include persistent cardiac decompensation, especially with fixed pulmonary hypertension; advanced hypertensive vascular disease or diabetes; and malignancy. In cases of rape or incest, most consider termination reasonable. The most common indication currently is to prevent birth of a fetus with a significant anatomical, metabolic, or mental deformity. The seriousness of fetal deformities is wide ranging and usually defies social, legal, or political classification.

**Elective or Voluntary Abortion**

The interruption of pregnancy before viability at the request of the woman, but not for medical reasons, is usually termed **elective** or **voluntary abortion**. Regardless of terminology, these are stigmatized in this country (Harris, 2012). Most abortions done today are elective, and thus, it is one of the most commonly performed medical procedures. The pregnancy-associated mortality rate is 14-fold greater than the abortion-related mortality rate—8 versus 0.6 deaths per 100,000 (Raymond, 2012). From the Guttmacher Institute, Jones and Kavanaugh (2011) estimate that a third of American women will have at least one elective abortion by age 45. The Executive Board of the American College of Obstetricians and Gynecologists (2013d) supports the legal right of women to obtain an abortion prior to fetal viability and considers this a medical matter between a woman and her physician.

### Abortion in the United States

The legality of elective abortion was established by the United States Supreme Court in the case of **Roe v. Wade**. The Court defined the extent to which states might regulate abortion and ruled that first-trimester procedures must be left to the medical judgment of the physician. After this, the State could regulate abortion procedures in ways reasonably related to maternal health. Finally, subsequent to viability, the State could promote its interest in the potential of human life and regulate and even proscribe abortion, except for the preservation of the life or health of the mother.

Other legislation soon followed. The 1976 Hyde Amendment forbids use of federal funds to
provide abortion services except in case of rape, incest, or life-threatening circumstances. The Supreme Court in 1992 reviewed *Planned Parenthood v. Casey* and upheld the fundamental right to abortion, but established that regulations before viability are constitutional as long as they do not impose an “undue burden” on the woman. Subsequently, many states passed legislation that imposes counseling requirements, waiting periods, parental consent or notification for minors, facility requirements, and funding restrictions. One major choice-limiting decision was the 2007 Supreme Court decision that reviewed *Gonzales v. Carhart* and upheld the 2003 Partial-Birth Abortion Ban Act. This was problematic because there is no medically approved definition of partial-birth abortion according to the American College of Obstetricians and Gynecologists (2011a). According to the Guttmacher Institute, 41 states set new limits on abortion during 2011 and 2012 (Tanner, 2012).

**Residency Training in Abortion Techniques**

Because of its inherent controversial aspects, abortion training for residents has been both championed and assailed. The American College of Obstetricians and Gynecologists (2009a) supports abortion training, and the Accreditation Council for Graduate Medical Education mandated in 1996 that Obstetrics and Gynecology residency education must include access to experience with induced abortion. The Kenneth J. Ryan Residency Training Program was established in 1999 at the University of California at San Francisco to work with residency programs to improve training in abortion and family planning. By 2013, 59 Ryan programs had been started in the United States and in Canada (Heartwell, 2013). These programs provide comprehensive didactics and evidence-based, opt-out clinical training in all pregnancy-termination methods and contraceptive methodology.

Other programs are less codified, but teach residents technical aspects through their management of early incomplete and missed abortions as well as pregnancy interruption for fetal death, severe fetal anomalies, and life-threatening medical or surgical disorders. Freedman and colleagues (2010) rightly emphasize that considerations for abortion training should include social, moral, and ethical aspects.

Programs have been designed for postresidency training in abortion and contraceptive techniques. Formal fellowships in Family Planning are 2-year postgraduate programs that, by 2010, were located in 22 departments of obstetrics and gynecology at academic centers across the country. Training includes experience with high-level research and with all methods of pregnancy prevention and termination.

**Abortion Providers**

The American College of Obstetricians and Gynecologists (2013d) respects the need and responsibility of health-care providers to determine their individual positions on induced abortion. It also emphasizes the need to provide standard-of-care counseling and timely referral if providers have individual beliefs that preclude pregnancy termination. From a mail survey of 1800 obstetrician-gynecologists, 97 percent had encountered women seeking an abortion, but only 14 percent performed them (Stulberg, 2011). Still, most practitioners help women find an abortion provider (Harris, 2011). And at least for midtrimester procedures, maternal-fetal medicine specialists provide some services (Kerns, 2012). In any event, it is imperative that any physician who cares for women must be familiar with various abortion techniques so that complications can be managed or referrals made for suitable care (Steinauer, 2005a,b).
Counseling before Elective Abortion

There are three basic choices available to a woman considering an abortion: (1) continued pregnancy with its risks and parental responsibilities; (2) continued pregnancy with arranged adoption; or (3) termination of pregnancy with its risks. Knowledgeable and compassionate counselors should objectively describe and provide information regarding these choices so that a woman or couple can make an informed decision (Baker, 2009; Templeton, 2011).

TECHNIQUES FOR ABORTION

In the absence of serious maternal medical disorders, abortion procedures do not require hospitalization. With outpatient abortion, capabilities for cardiopulmonary resuscitation and for immediate transfer to a hospital must be available.

First-trimester abortions can be performed either medically or surgically by several methods that are listed in Table 18-7. Results are comparable with methods for spontaneous miscarriages discussed previously on page 357 and shown in Table 18-3. They have a high success rate—95 percent with medical and 99 percent with surgical techniques. Further comparison of medical and surgical methods is shown in Table 18-8. Medical therapy has more drawbacks in that it is more time consuming; it has an unpredictable outcome—extending for days up to a few weeks; and bleeding is usually heavier and unpredictable (Niinimäki, 2009; Robson, 2009). Likely for these reasons, only 10 percent of abortions in the United States are managed using medical methods (Templeton, 2011).

aAll procedures are aided by pretreatment using hygroscopic cervical dilators.
Cervical Preparation

There are several methods that will soften and slowly dilate the cervix to minimize trauma from mechanical dilatation (Newmann, 2014). A Cochrane review confirmed that hygroscopic dilators and cervical ripening medications had similar efficacy in decreasing the length of first-trimester procedures (Kapp, 2010).

Of these, hygroscopic dilators are devices that draw water from cervical tissues and expand to gradually dilate the cervix. One type is derived from various species of Laminaria algae that are harvested from the ocean floor (Figs. 18-7 and 18-8). Another is Dilapan-S, which is composed of an acrylic-based gel.

FIGURE 18-7 Insertion of laminaria before dilatation and curettage. A. Laminaria immediately after being appropriately placed with its upper end just through the internal os. B. Several hours later the laminaria is now swollen, and the cervix is dilated and softened. C. Laminaria inserted too far through the internal os; the laminaria may rupture the membranes.
FIGURE 18-8 Hygroscopic dilators. With each type, the dry unit (left) expands exponentially when exposed to water (right) as in the endocervical canal. A. Laminaria. B. Dilapan-S.

Schneider and associates (1991) described 21 cases in which women who had a hygroscopic
Dilatation placed changed their minds. Of 17 women who chose to continue their pregnancy, there were 14 term deliveries, two preterm deliveries, and one miscarriage 2 weeks later. None suffered infection-related morbidity, including three untreated women with cervical cultures positive for *Chlamydia trachomatis*.

In contrast to these devices, there are medications used for cervical preparations. The most common is misoprostol (Cytotec), which is used off-label, and patients are counseled accordingly (Tang, 2013). The dose is 400 to 600 μg administered orally, sublingually, or placed into the posterior vaginal fornix. In a multicenter randomized trial, Meirik and coworkers (2012) enrolled nearly 4900 women undergoing an elective first-trimester abortion. Half were given two 200-μg tablets orally 3 hours preprocedure, and the other group was given placebo. Marginal benefits ascribed to misoprostol included easier cervical dilatation and a lower composite complication rate. Another effective cervical-ripening agent is the progesterone antagonist mifepristone (Mifeprex). With this, 200 to 600 μg is given orally. Other options include formulations of prostaglandins $E_2$ and $F_2\alpha$, which have unpleasant side effects and are usually reserved as second-line drugs (Kapp, 2010).

### Surgical Abortion

Surgical pregnancy termination includes a transvaginal approach through an appropriately dilated cervix or, rarely, laparotomy with either hysterotomy or hysterectomy. With transvaginal evacuation, preoperative cervical ripening is favored and is typically associated with less pain, a technically easier procedure, and shorter operating times (Kapp, 2010). Curettage usually requires intravenously or orally administered sedatives or analgesics, and some also use paracervical blockade with lidocaine (Allen, 2009; Cansino, 2009; Renner, 2012). Perioperative antibiotic prophylaxis is described on page 357. No recommendations specifically address venous thromboembolism (VTE) prophylaxis for curettage in low-risk pregnant patients. The American College of Chest Physicians (Bates, 2012) recommends only early ambulation for cesarean delivery in those without risk factors, and at our hospital, we apply this also to less invasive curettage.

### Dilatation and Curettage (D&C)

Transcervical approaches to surgical abortion require first dilating the cervix and then evacuating the pregnancy by mechanically scraping out the contents—sharp curettage, by suctioning out the contents—suction curettage, or both. Vacuum aspiration, the most common form of suction curettage, requires a rigid cannula attached to an electric-powered vacuum source or to a handheld syringe for its vacuum source (Goldberg, 2004; MacIsaac, 2000; Masch, 2005).

Curettage—either sharp or suction—is recommended for gestations ≤ 15 weeks. Complication rates increase after the first trimester. Perforation, cervical laceration, hemorrhage, incomplete removal of the fetus or placenta, and postoperative infections are among these. Niinimäki and associates (2009) reported results from more than 20,000 Finnish women undergoing surgical termination before 63 days. The 5.6-percent complication rate was made up equally of hemorrhage, incomplete abortion, and infection. A second curettage procedure was necessary in 2 percent. As further discussed on page 368, there was a 20-percent complication rate in the more than 22,000 women undergoing a medical termination.

**Technique.** After bimanual examination is performed to determine uterine size and orientation, a
speculum is inserted, and the cervix is swabbed with a toothed tenaculum. The cervix, vagina, and uterus are richly supplied by nerves of Frankenhäuser plexus, which lies within connective tissue lateral to the uterosacral and cardinal ligaments. Thus, a paracervical block is effective to relieve pain (Renner, 2012). A local anesthetic, such as 5 mL of 1- or 2-percent lidocaine, is most effective if placed immediately lateral to the insertion of the uterosacral ligaments into the uterus at 4 and 8 o’clock. An intracervical block with 5-mL aliquots of 1-percent lidocaine injected at 12, 3, 6, and 9 o’clock was reported to be equally effective (Mankowski, 2009). Dilute vasopressin may be added to the local anesthetic to decrease blood loss (Keder, 2003).

Uterine sounding measures the depth and inclination of the cavity before other instrument insertion. If required, the cervix is further diluted with Hegar, Hank, or Pratt dilators until a suction cannula of the appropriate diameter can be inserted. Small cannulas carry the risk of leaving retained intrauterine tissue postoperatively, whereas large cannulas risk cervical injury and more discomfort. The fourth and fifth fingers of the hand introducing the dilator should rest on the perineum and buttocks as the dilator is pushed through the internal os (Fig. 18-9). This technique minimizes forceful dilatation and provides a safeguard against uterine perforation. The suction cannula is moved toward the fundus and then back toward the os and is turned circumferentially to cover the entire surface of the uterine cavity (Fig. 18-10). When no more tissue is aspirated, a gentle sharp curettage should follow to remove any remaining placental or fetal fragments (Fig. 18-11).

**FIGURE 18-9** Dilatation of cervix with a Hegar dilator. Note that the fourth and fifth fingers rest against the perineum and buttocks, lateral to the vagina. This maneuver is an important safety measure because if the cervix relaxes abruptly, these fingers prevent a sudden and uncontrolled
thrust of the dilator, a common cause of uterine perforation.

**FIGURE 18-10** A suction curette has been placed through the cervix into the uterus. The figure shows the rotary motion used to aspirate the contents. (From Word, 2012, with permission.)
Because uterine perforation usually occurs with insertion of any of these instruments, manipulations should be carried out with the thumb and forefinger only (see Fig. 18-9). For pregnancies beyond 16 weeks, the fetus is extracted, usually in parts, using Sopher forceps and other destructive instruments. Inherent risks include uterine perforation, cervical laceration, and uterine bleeding due to the larger fetus and placenta and to the thinner uterine walls. Morbidity can be minimized if careful attention is paid to performing the steps outlined above.

Complications. The incidence of uterine perforation with elective abortion is variable, and determinants include clinician skill and uterine position. Perforation is more common with a retroverted uterus and is usually recognized when the instrument passes without resistance deep into the pelvis. Observation is usually sufficient if the uterine perforation is small, as when produced by a uterine sound or narrow dilator. Although perforations through old cesarean incision or myomectomy scars are potentially possible, Chen and colleagues (2008) reported no perforations through such scars in 78 women undergoing medical or surgical abortion.

If some instruments—especially suction and sharp curettes—pass through a uterine defect and into the peritoneal cavity, considerable intraabdominal damage can ensue (Keegan, 1982). In these women, laparotomy or laparoscopy to examine the abdominal contents is often the safest course of action. Bowel injury can cause severe peritonitis and sepsis (Kambiss, 2000).
of curettage with more advanced pregnancies is sudden, severe consumptive coagulopathy.

If prophylactic antimicrobials are given, pelvic sepsis is decreased by 40 to 90 percent and depends on whether the procedure is surgical or medical. Most infections that do develop respond readily to appropriate antimicrobial treatment (Chap. 37, p. 685). Rarely, infections such as bacterial endocarditis will develop, but they can be fatal (Jeppson, 2008). Uncommon long-term complications of curettage include cervical insufficiency or uterine synechiae.

**Dilatation and Evacuation (D&E)**

Beginning at 16 weeks, fetal size and structure dictate use of this technique. Wide mechanical cervical dilatation, achieved with metal or hygroscopic dilators, precedes mechanical destruction and evacuation of fetal parts. With complete removal of the fetus, a large-bore vacuum curette is used to remove the placenta and remaining tissue. This is better accomplished using intraoperative sonographic imaging.

**Dilatation and Extraction (D&X)**

This is similar to dilatation and evacuation except that a suction cannula is used to evacuate the intracranial contents after delivery of the fetal body through the dilated cervix. This aids extraction and minimizes uterine or cervical injury from instruments or fetal bones. In political parlance, this procedure has been termed *partial birth abortion*.

**Menstrual Aspiration**

This is done within 1 to 3 weeks after a missed menstrual period and with a positive serum or urine pregnancy test result. It is performed with a flexible 5- or 6-mm Karman cannula that is attached to a syringe. This procedure has been referred to as *menstrual extraction, menstrual induction, instant period, traumatic abortion, and mini-abortion*. A distinct drawback is that because the pregnancy is so small, an implanted zygote can be missed by the curette, or an ectopic pregnancy can be unrecognized. To identify placenta in the aspirate, MacIsaac and Darney (2000) recommend that the syringe contents be rinsed in a strainer to remove blood, then placed in a clear plastic container with saline and examined with back lighting. Placental tissue macroscopically appears soft, fluffy, and feathery. A magnifying lens, colposcope, or microscope also can improve visualization. Despite the possibility of missing the products, Paul and coworkers (2002) reported a 98-percent success rate with more than 1000 such procedures.

**Manual Vacuum Aspiration**

This procedure is similar to menstrual aspiration but is used for early pregnancy failures or elective termination up to 12 weeks. Some recommend that pregnancy terminations done in the office with this method be limited to ≤ 10 weeks because blood loss rises sharply between 10 and 12 weeks (Masch, 2005; Westfall, 1998). For pregnancies ≤ 8 weeks, preprocedure cervical ripening is usually not necessary. After this time, some recommend that osmotic dilators be placed the day prior or misoprostol given 2 to 4 hours before the procedure. Paracervical blockade with or without sedation is used. The technique employs a hand-operated 60-mL syringe and cannula. A vacuum is created in the syringe attached to the cannula, which is inserted transcervically into the uterus. The vacuum produces up to 60 mm Hg suction. Complications are similar to other surgical methods (Goldberg, 2004).

**Hysterotomy or Hysterectomy**
In some women with second-trimester pregnancies who desire sterilization, hysterotomy with tubal ligation is reasonable. If there is significant uterine disease, then hysterectomy may provide ideal treatment. In some cases of a failed second-trimester medical induction, either of these may be considered.

### Medical Abortion

According to the American College of Obstetricians and Gynecologists (2011c), outpatient medical abortion is an acceptable alternative to surgical pregnancy termination in appropriately selected pregnant women less than 49 days’ menstrual age. After this time, available data—albeit less robust—support surgical abortion as preferable. Throughout history, many natural substances have been given for alleged abortifacient effects. In many of these, serious illness and even death have resulted. Currently, there are only three medications for early medical abortion that have been widely studied. These are used either alone or in combination and include: (1) the antiprogestin mifepristone, (2) the antimetabolite methotrexate, and (3) the prostaglandin misoprostol. Mifepristone and methotrexate increase uterine contractility by reversing progesterone-induced inhibition, whereas misoprostol directly stimulates the myometrium. Clark and associates (2006) have reported that mifepristone causes cervical collagen degradation, possibly from increased expression of matrix metalloprotease-2 (MMP-2). *Methotrexate and misoprostol are both teratogens. Thus there must be a commitment to completing the abortion once these drugs have been given.*

With these three agents, a number of dosing schemes have been proven effective, and some are shown in Table 18-9. *For all three, misoprostol is given initially.* This is either used alone or given with methotrexate or mifepristone. In each instance, it is followed by further but variable misoprostol doses. As shown in Table 18-3, any regimen used for “early pregnancy loss” is likely to be successful for elective pregnancy interruption. For elective termination at ≤ 63 days’ gestation, randomized trials by von Hertzen (2009, 2010) and Winikoff (2008) and their colleagues showed 92- to 96-percent efficacy when one of the mifepristone/misoprostol regimens was used. Similar results were reported from 10 large urban Planned Parenthood clinics (Fjerstad 2009a). In this latter study, buccal misoprostol-oral mifepristone regimens were 87-to 98-percent successful for abortion induction with pregnancies < 10 weeks’ gestation, and this rate diminished with advancing gestations. In another study of 122 women at 9 to 12 weeks’ gestation, the success rate was approximately 80 percent (Dalenda, 2010).

</tbody>
</table>
800 μg vaginally or sublingually, repeated for up to three doses

Doses of 200 versus 600 mg similarly effective.

Oral route may be less effective and have more nausea and diarrhea. Sublingual route has more side effects than vaginal route. Shorter intervals (6 hours) with misoprostol may be less effective when given > 36 hours.

Efficacy similar for routes of administration.

Similar efficacy when given on day 3 versus day 5.

Intervals 3–12 hours given vaginally; 3–4 hours given sublingually.

BSA = body surface area.

**Contraindications**

In many cases, contraindications to medical abortion evolved from exclusion criteria that were used in initial clinical trials. Thus, some are relative contraindications: in situ intrauterine device; severe anemia, coagulopathy, or anticoagulant use; and significant medical conditions such as active liver disease, cardiovascular disease, or uncontrolled seizure disorders. Because misoprostol diminishes glucocorticoid activity, women with disorders requiring glucocorticoid therapy are usually excluded (American College of Obstetricians and Gynecologists, 2009b). In women with renal insufficiency, the methotrexate dose should be modified and given with caution, or preferably, another regimen should be chosen (Kelly, 2006).

**Administration**

With the mifepristone/misoprostol regimen, mifepristone treatment is followed by misoprostol given at that same time or up to 72 hours later as shown in Table 18-9. Some prefer that misoprostol be administered on site, after which the woman typically remains for 4 hours. Symptoms are common within 3 hours and include lower abdominal pain, vomiting, diarrhea, fever, and chills or shivering. In the first few hours after misoprostol is given, if the pregnancy appears to have been expelled, a pelvic examination is done to confirm this. If not and if the pregnancy is still intact, the woman is discharged and appointed to return in 1 to 2 weeks. Some choose to repeat a prostaglandin dose (Dickinson, 2014). Conversely, if there is an incomplete abortion on clinical or sonographic evaluation, then suction curettage usually is recommended. Other complications are hemorrhage and infection (Niinimäki, 2009; von Hertzen, 2010).

With the methotrexate regimens, misoprostol is given 3 to 7 days later, and women are seen again at least 24 hours after misoprostol administration. They are next seen approximately 7 days after methotrexate is given, and sonographic examination is performed. If an intact pregnancy is seen, then another dose of misoprostol is given. Afterward, the woman is seen again in 1 week if fetal cardiac activity is present or in 4 weeks if there is no heart motion. If abortion has not occurred by the second visit, it is usually completed by suction curettage.

**Complications**

In a 2-year review of more than 233,000 medical abortions performed at Planned Parenthood affiliates, there were 1530 (0.65 percent) significant adverse events. Most of these were ongoing
pregnancy (Cleland, 2013). Bleeding and cramping with medical termination can be significantly worse than menstrual cramps. Thus adequate analgesia, usually including a narcotic, is provided. The American College of Obstetricians and Gynecologists (2011c) recommends that if there is enough blood to soak two or more pads per hour for at least 2 hours, the woman is instructed to contact her provider to determine whether she needs to be seen.

Unnecessary surgical intervention in women undergoing medical abortion can be avoided if properly indicated follow-up sonographic results are interpreted appropriately. Specifically, if no gestational sac is seen and there is no heavy bleeding, then intervention is unnecessary. This is true even when, as is common, the uterus contains sonographically evident debris. Another study reported that a multilayered sonographic pattern indicated a successful abortion (Tzeng, 2013). Clark and coworkers (2010) provided data that routine postabortal sonographic examination is unnecessary. They instead recommend assessment of the clinical course along with bimanual pelvic examination. Follow-up serum $\beta$-hCG levels have shown promise in preliminary investigations (Dayananda, 2013).

### Midtrimester Abortion

There have long been invasive means of midtrimester surgical abortion as shown in Table 18-10 and discussed on page 367. In the past 25 years, medical methods that safely and effectively accomplish midtrimester abortion have also evolved considerably. Risks versus benefits of medical versus surgical midtrimester termination are similar to those shown in Table 18-8 (Bryant, 2011; Edlow, 2011; Kelly, 2010; Mentula, 2011). Principal among noninvasive methods is high-dose intravenous oxytocin. Others include a number of prostaglandin analogues that can be given orally, vaginally, or parenterally. Regardless of method, hygroscopic dilators as shown in Figure 18-7 and 18-8 shorten the duration (Goldberg, 2005).

a
All procedures are aided by pretreatment using hygroscopic cervical dilators.

Oxytocin

Given alone in high doses, oxytocin will result in second-trimester abortion in 80 to 90 percent of cases. Oxytocin is delivered in an isotonic solution. Thus, by avoiding excessive administration of dilute intravenous solutions, hyponatremia or water intoxication is rare. One regimen is shown in Table 18-11.

Modified from Ramsey, 2000.

Prostaglandins E₂ (PGE₂) and E₁ (PGE₁)

A 20-mg prostaglandin E₂ suppository placed in the posterior vaginal fornix is an effective means of inducing a second-trimester abortion. It is not more effective than high-dose oxytocin, and it causes more frequent side effects such as nausea, vomiting, fever, and diarrhea (Owen, 1992). If PGE₂ is used, simultaneous administration of an antiemetic such as metoclopramide, an antipyretic such as acetaminophen, and an antidiarrheal such as diphenoxylate/atropine will help prevent or treat symptoms.

Misoprostol (Cytotec) used alone is also a simple and effective method for second-trimester pregnancy termination. In one randomized trial, a 600-μg misoprostol dose given vaginally was followed by 400 μg every 4 hours (Ramsey, 2004). This regimen effected abortion significantly faster than concentrated oxytocin plus PGE₂—median time to abortion 12 versus 17 hours, respectively. By 24 hours, 95 percent of women given misoprostol had aborted compared with 85 percent in the oxytocin-PGE₂ cohort. Two percent of women in the misoprostol group required curettage for retained placenta compared with 15 percent in the oxytocin-PGE₂ group. In another study, 200 mg mifepristone given orally 1 day before misoprostol reduced the median time-to-expulsion from 10.6 to 8.1 hours (Ngoc, 2011).

Outcomes of medically induced second-trimester abortion in women with a prior cesarean delivery were at first discouraging, but recent evidence is less pessimistic. In two systematic reviews, the risk of uterine rupture in such women given misoprostol was reported to be 0.3 to 0.4 percent (Berghella, 2009; Goyal, 2009).
CONSEQUENCES OF ELECTIVE ABORTION

Maternal Mortality

Because they are common, regulated, and reportable, most abortion statistics are for elective procedures. Even so, abortion-related deaths are likely underreported (Horon, 2005). With this caveat in mind, legally induced abortion, performed by trained gynecologists during the first 2 months of pregnancy, has a mortality rate of less than 1 per 100,000 procedures (Pazol, 2011). In a report from Finland comprising nearly 43,000 abortions performed before 63 days, only one procedure-related death was documented (Niinimaki, 2009). Early abortions are even safer, and the relative mortality risk of abortion approximately doubles for each 2 weeks after 8 weeks’ gestation. The Centers for Disease Control and Prevention identified 12 abortion-related deaths in the United States in 2008 (Pazol, 2012). As emphasized by Raymond and Grimes (2012), mortality rates are 14-fold greater for pregnancies that are continued.

Health and Future Pregnancies

Data relating abortion to overall maternal health and to subsequent pregnancy outcome are limited. From studies, there is no evidence for excessive mental disorders (Munk-Olsen, 2011; Steinberg, 2014). There are few data regarding subsequent reproductive health, although the rates of infertility or ectopic pregnancy are not increased. There may be exceptions if there are postabortal infections, especially those caused by chlamydiae. Also, other data suggest that some adverse pregnancy outcomes are more common in women who have had an induced abortion (Maconochie, 2007). Specifically, several studies note an approximate 1.5-fold increased incidence of preterm delivery—22 to 32 weeks (Hardy, 2013; Moreau, 2005; Swingle, 2009). Multiple sharp curettage procedures may increase the subsequent risk of placenta previa, whereas vacuum aspiration procedures likely do not (Johnson, 2003).

It appears that subsequent pregnancy outcomes are similar regardless of whether a prior induced abortion was completed medically or surgically. In a report of 30,349 procedures from the Danish Abortion Registry, there were 16,883 women who had a subsequent pregnancy (Virk, 2007). Rates of ectopic pregnancy, miscarriage, and preterm delivery were not significantly different in those with prior surgical abortion or previous medical termination.

CONTRACEPTION FOLLOWING MISCARRIAGE OR ABORTION

Ovulation may resume as early as 2 weeks after an early pregnancy termination. Lahteenmaki and Luukkainen (1978) detected surges of luteinizing hormone (LH) 16 to 22 days after abortion in 15 of 18 women studied. Plasma progesterone levels, which had plummeted after the abortion, increased soon after LH surges. These hormonal events agree with histological changes observed in endometrial biopsies by Boyd and Holmstrom (1972).

Thus, it is important that unless another pregnancy is desired right away, effective contraception should be initiated very soon after abortion. There is no reason to delay this, and an intrauterine device can be inserted after the procedure is completed (Bednarek, 2011; Shimoni, 2011).
Alternatively, any of the various forms of hormonal contraception can be initiated at this time (Madden, 2009; Reeves, 2007). For women who desire another pregnancy, sooner may be preferable to later. Specifically, Love and colleagues (2010) analyzed the next pregnancy outcomes in nearly 31,000 women following miscarriage and found that conceptions within 6 months after miscarriage had better pregnancy outcomes compared with pregnancies conceived after 6 months.

ABDOMINAL PREGNANCY

OVARIAN PREGNANCY

CERVICAL PREGNANCY

CESAREAN SCAR PREGNANCY

Following fertilization and fallopian tube transit, the blastocyst normally implants in the endometrial lining of the uterine cavity. Implantation elsewhere is considered ectopic and comprises 1 to 2 percent of all first-trimester pregnancies in the United States. This small proportion disparately accounts for 6 percent of all pregnancy-related deaths (Berg, 2010; Stulberg, 2013). In addition, the chance for a subsequent successful pregnancy is reduced after an ectopic pregnancy. Fortunately, urine and serum beta-human chorionic gonadotropin (β-hCG) assays and transvaginal sonography have made earlier diagnosis possible. And as a result, both maternal survival rates and conservation of reproductive capacity are improved.

TUBAL PREGNANCY

Classification

Nearly 95 percent of ectopic pregnancies are implanted in the various segments of the fallopian tube and give rise to fimbrial, ampullary, isthmic, or interstitial tubal pregnancies (Fig. 19-1). As
shown, the ampulla is the most frequent site, followed by the isthmus. The remaining 5 percent of nontubal ectopic pregnancies implant in the ovary, peritoneal cavity, cervix, or prior cesarean scar. Occasionally, a multifetal pregnancy is composed of one conceptus with normal uterine implantation coexisting with one implanted ectopically. The natural incidence of these heterotopic pregnancies approximates 1 per 30,000 pregnancies. However, because of assisted reproductive technologies (ART), their incidence has increased to 1 in 7000 overall, and following ovulation induction, it may be as high as 0.5 to 1 percent (Mukul, 2007). Rarely, twin tubal pregnancy with both embryos in the same tube or with one in each tube has been reported (Eze, 2012; Svirsky, 2010).}

**FIGURE 19-1** Sites of implantation of 1800 ectopic pregnancies from a 10-year population-based study. (Data from Callen, 2000; Bouyer, 2003.)

Regardless of location, D-negative women with an ectopic pregnancy who are not sensitized to D-antigen should be given IgG anti-D immunoglobulin (American College of Obstetricians and Gynecologists, 2013). In first-trimester pregnancies, a 50-μg or a 300-μg dose is appropriate, whereas a standard 300-μg dose is used for later gestations.

**Risks**

Abnormal fallopian tube anatomy underlies many cases of tubal ectopic pregnancy. Surgeries for a
prior tubal pregnancy, for fertility restoration, or for sterilization confer the highest risk of tubal implantation. After one previous ectopic pregnancy, the chance of another approximates 10 percent (Ankum, 1996; Skjeldestad, 1998). Prior sexually transmitted disease or other tubal infection, which can distort normal tubal anatomy, is another common risk factor. Specifically, one episode of salpingitis can be followed by a subsequent ectopic pregnancy in up to 9 percent of women (Westrom, 1992). Similarly, peritubal adhesions subsequent to salpingitis, appendicitis, or endometriosis may increase the risk for tubal pregnancy. Salpingitis isthmica nodosa, which is a condition in which epithelium-lined diverticula extend into a hypertrophied muscularis layer, also poses an increased risk (Schippert, 2012). Congenital fallopian tube anomalies, especially those secondary to in utero diethylstilbestrol exposure, can also lead to malformed tubes and higher ectopic rates (Hoover, 2011).

Infertility, per se, as well as the use of ART to overcome it, is linked to substantively increased risks for ectopic pregnancy (Clayton, 2006). And “atypical” implantations—cornual, abdominal, cervical, ovarian, and heterotopic pregnancy—are more common following ART procedures. Smoking is also a known association, although the underlying mechanism is unclear (Waylen, 2009). Last, with any form of contraception, the absolute number of ectopic pregnancies is decreased because pregnancy occurs less often. However, with some contraceptive method failures, the relative number of ectopic pregnancies is increased. Examples include tubal sterilization, copper and progestin-releasing intrauterine devices (IUDs), and progestin-only contraceptives (Furlong, 2002).

Evolution and Potential Outcomes

With tubal pregnancy, because the fallopian tube lacks a submucosal layer, the fertilized ovum promptly burrows through the epithelium. The zygote comes to lie near or within the muscularis, which is invaded in most cases by rapidly proliferating trophoblast. The embryo or fetus in an ectopic pregnancy is often absent or stunted.

Outcomes of ectopic pregnancy include tubal rupture, tubal abortion, or pregnancy failure with resolution. With rupture, the invading expanding products of conception and associated hemorrhage may tear rents in the fallopian tube at any of several sites. As a rule, if the tube ruptures in the first few weeks, the pregnancy is most likely located in the isthmic portion, whereas the ampulla is slightly more distensible (Fig. 19-2). However, if the fertilized ovum implants within the interstitial portion, rupture usually occurs later. Tubal ectopic pregnancies usually burst spontaneously but may occasionally rupture following coitus or bimanual examination.
Alternatively, the pregnancy may abort out the distal fallopian tube, and the frequency of this depends in part on the initial implantation site. Abortion is common in fimbrial and ampullary pregnancies, whereas rupture is the usual outcome with those in the tubal isthmus. With tubal abortion, hemorrhage disrupts the connection between the placenta and membranes and the tubal wall. If placental separation is complete, the entire conceptus may be extruded through the fimbriated end into the peritoneal cavity. At this point, hemorrhage may cease and symptoms eventually disappear. Some bleeding usually persists as long as products remain in the tube. Blood slowly trickles from the tubal fimbria into the peritoneal cavity and typically pools in the rectouterine cul-de-sac. If the fimbriated extremity is occluded, the fallopian tube may gradually become distended by blood, forming a hematosalpinx.

Last, an unknown number of ectopic pregnancies spontaneously fail and are reabsorbed. This may be documented now more regularly with the advent of sensitive β-hCG assays.

There are differences between “acute” ectopic pregnancy just described and “chronic” ectopic pregnancy. The more common acute ectopic pregnancies are those with a high serum β-hCG level and rapid growth, leading to an immediate diagnosis. These carry a higher risk of tubal rupture (Barnhart, 2003c). With chronic ectopic pregnancy, abnormal trophoblast die early, and thus negative or lower, static serum β-hCG levels are found (Brennan, 2000). Chronic ectopic pregnancies typically rupture late, if at all, but commonly form a complex pelvic mass, which often is the reason prompting diagnostic surgery (Cole, 1982; Grynberg, 2009; Uğur, 1996).

Clinical Manifestations

Earlier patient presentation and more precise diagnostic technology typically allow identification before rupture. In these cases, symptoms and signs of ectopic pregnancy are often subtle or even absent. The woman does not suspect tubal pregnancy and assumes that she has a normal early
prenancy or is having a miscarriage.

With later diagnosis, a “classic” presentation is characterized by the triad of delayed menstruation, pain, and vaginal bleeding or spotting. With tubal rupture, there is usually severe lower abdominal and pelvic pain that is frequently described as sharp, stabbing, or tearing. There is tenderness during abdominal palpation. Bimanual pelvic examination, especially cervical motion, causes exquisite pain. The posterior vaginal fornix may bulge from blood in the rectouterine cul-de-sac, or a tender, boggy mass may be felt to one side of the uterus. Although minimal early, later the uterus may be pushed to one side by an ectopic mass. The uterus may also be slightly enlarged due to hormonal stimulation. Symptoms of diaphragmatic irritation, characterized by pain in the neck or shoulder, especially on inspiration, develop in perhaps half of women with sizable hemoperitoneum.

Some degree of vaginal spotting or bleeding is reported by 60 to 80 percent of women with tubal pregnancy. Although profuse vaginal bleeding is suggestive of an incomplete abortion, such bleeding occasionally is seen with tubal gestations. Moreover, tubal pregnancy can lead to significant intraabdominal hemorrhage. Responses to moderate bleeding include no change in vital signs, a slight rise in blood pressure, or a vasovagal response with bradycardia and hypotension. Birkhahn and colleagues (2003) noted that in 25 women with ruptured ectopic pregnancy, most at presentation had a heart rate < 100 beats per minute and a systolic blood pressure > 100 mm Hg. Blood pressure will fall and pulse will rise only if bleeding continues and hypovolemia becomes significant. Vasomotor disturbances develop, ranging from vertigo to syncope.

Even after substantive hemorrhage, hemoglobin or hematocrit readings may at first show only a slight reduction. Hence, after an acute hemorrhage, a decline in hemoglobin or hematocrit level over several hours is a more valuable index of blood loss than is the initial level. In approximately half of women with a ruptured ectopic pregnancy, varying degrees of leukocytosis up to 30,000/μL may be documented.

Decidua is endometrium that is hormonally prepared for pregnancy, and the degree to which the endometrium is converted with ectopic pregnancy is variable. Thus, in addition to bleeding, women with ectopic tubal pregnancy may pass a **decidual cast**, which is the entire sloughed endometrium that takes the form of the endometrial cavity (Fig. 19-3). Importantly, decidual sloughing may also occur with uterine abortion. Thus, tissue should be carefully evaluated visually and then histologically for evidence of a conceptus. If no clear gestational sac is visually seen or if no villi are identified histologically within the cast, then the possibility of ectopic pregnancy must still be considered.
FIGURE 19-3 This decidual cast was passed by a patient with a tubal ectopic pregnancy. The cast mirrors the shape of the endometrial cavity, and each arrow marks the portion of decidua that lined the cornua.

Multimodality Diagnosis

The differential diagnosis for abdominal pain coexistent with pregnancy is extensive. Pain may derive from uterine conditions such as miscarriage, infection, degenerating or enlarging leiomyomas, molar pregnancy, or round-ligament pain. Adnexal disease may include ectopic pregnancy; hemorrhagic, ruptured, or torsed ovarian masses; salpingitis; or tuboovarian abscess. Last, appendicitis, cystitis, renal stone, or gastroenteritis may be nongynecological sources of lower abdominal pain in early pregnancy.

A number of algorithms have been proposed to identify ectopic pregnancy. Most include these key components: physical findings, transvaginal sonography (TVS), serum β-hCG level measurement—both the initial and the subsequent pattern of rise or decline, and diagnostic surgery, which includes uterine curettage, laparoscopy, and occasionally, laparotomy (Fig. 19-4). Algorithm use applies only to hemodynamically stable women—those with presumed rupture should undergo prompt surgical therapy. For a suspected unruptured ectopic pregnancy, all diagnostic strategies involve trade-offs. Strategies that maximize detection of ectopic pregnancy may result in termination of a normal pregnancy. Conversely, those that reduce the potential for normal pregnancy interruption will delay ectopic pregnancy diagnosis. Patient desires for the index pregnancy are also discussed and may influence these trade-offs.

(Modified from Gala, 2012.)

Beta Human Chorionic Gonadotropin

Rapid and accurate determination of pregnancy is essential to identify an ectopic pregnancy. Current serum and urine pregnancy tests that use enzyme-linked immunosorbent assays (ELISAs) for β-hCG are sensitive to levels of 10 to 20 mIU/mL and are positive in > 99 percent of ectopic pregnancies (Kalinski, 2002). Rare cases of chronic ectopic pregnancy, described earlier, with negative serum β-hCG assay results have been reported.

With bleeding or pain and a positive pregnancy test result, an initial TVS is typically performed to identify gestation location. If a yolk sac, embryo, or fetus is identified within the uterus or the adnexa, then a diagnosis can be made. In many cases however, TVS is nondiagnostic, and tubal pregnancy is still a possibility. In these cases in which neither intrauterine nor extrauterine pregnancy is identified, the term pregnancy of unknown location (PUL) is used until additional clinical information allows determination of pregnancy location.

Levels above the Discriminatory Zone. A number of investigators have described discriminatory β-hCG levels above which failure to visualize an intrauterine pregnancy (IUP) indicates that the pregnancy either is not alive or is ectopic. Barnhart and colleagues (1994) reported that an empty uterus with a serum β-hCG concentration ≥ 1500 mIU/mL was 100-percent accurate in excluding a live uterine pregnancy. Some institutions set their discriminatory threshold higher at ≥ 2000 mIU/mL. Moreover, Connolly and associates (2013) reported evidence to suggest an even higher threshold. They noted that with live uterine pregnancies, a gestational sac was seen 99 percent of the time with a discriminatory level of 3510 mIU/mL.

If the initial β-hCG level exceeds the set discriminatory level and no evidence for a uterine pregnancy is seen with TVS, then the diagnosis is narrowed in most cases to a failed uterine pregnancy, completed abortion, or an ectopic pregnancy. Early multifetal gestation also remains a possibility. If there is a suspicion in a stable patient that a PUL could be a normal pregnancy, it is prudent to continue expectant management with serial β-hCG level assessment to avoid harming an early normal pregnancy. If patient history or extruded uterine tissue suggests a completed abortion, then serial β-hCG levels will drop rapidly. Otherwise, curettage will distinguish an ectopic from a nonliving uterine pregnancy. Some do not recommend diagnostic curettage because it results in unnecessary surgical therapy (Barnhart, 2002). This is countered by concern for methotrexate toxicity if this drug is given erroneously to women with a presumed ectopic pregnancy.

Levels below the Discriminatory Zone. If the initial β-hCG level is below the set discriminatory value, pregnancy location is often not technically discernible with TVS. With these PULs, serial β-hCG level assays are done to identify patterns that indicate either a growing or failing uterine pregnancy. Levels that rise or fall outside these expected parameters increase the concern for ectopic pregnancy. Thus, appropriately selected women with a possible ectopic pregnancy, but whose initial β-hCG level is below the discriminatory threshold, are seen 2 days later for further evaluation. First, with early normal progressing uterine pregnancies, Kadar and Romero (1987) reported that mean doubling time for serum β-hCG levels was approximately 48 hours. The lowest normal value for this increase was 66 percent. Barnhart and coworkers (2004) reported a 53-
percent 48-hour minimum rise with a 24-hour minimum rise of 24 percent. Seeber and associates (2006) used an even more conservative 35-percent 48-hour rise. Importantly, Silva and colleagues (2006) caution that a third of women with an ectopic pregnancy will have a 53-percent rise at 48 hours. They further reported that no single pattern characterizes ectopic pregnancy and that approximately half of ectopic pregnancies will show decreasing β-hCG levels, whereas the other half will have increasing levels.

With a failing intrauterine pregnancy, patterned rates of β-hCG level decline can also be anticipated. Rates of decline ranging between 21 and 35 percent are commonly used. As seen in Table 19-1, the percentage drop is greater if the initial β-hCG level is higher.

Data from Barnhart, 2004; Chung, 2006.

In pregnancies without these expected rises or falls in β-hCG levels, distinction between a nonliving intrauterine and an ectopic pregnancy may be aided by repeat β-hCG level evaluation (Zee, 2013). Also, uterine curettage is an option. Barnhart and associates (2003b) reported that endometrial biopsy was less sensitive than curettage. Before curettage, a second TVS examination may be indicated and may display new informative findings.

**Serum Progesterone**

A single serum progesterone measurement may clarify the diagnosis in a few cases (Stovall, 1989, 1992b). A value exceeding 25 ng/mL excludes ectopic pregnancy with 92.5-percent sensitivity (Lipscomb, 1999a; Pisarska, 1998). Conversely, values below 5 ng/mL are found in only 0.3 percent of normal pregnancies (Mol, 1998). Thus, values < 5 ng/mL suggest either a nonliving uterine pregnancy or an ectopic pregnancy. Because in most ectopic pregnancies, progesterone levels range between 10 and 25 ng/mL, the clinical utility is limited (American College of Obstetricians and Gynecologists, 2012). One caveat is that pregnancy achieved with ART may be associated with higher than usual progesterone levels (Perkins, 2000).

A number of preliminary studies have been done to evaluate novel markers to detect ectopic pregnancy (Rausch, 2012; Senapati, 2013). However, none of these are in current clinical use.
Transvaginal Sonography

Endometrial Findings. In a woman in whom ectopic pregnancy is suspected, TVS is performed to look for findings indicative of intrauterine or ectopic pregnancy. During endometrial cavity evaluation, an intrauterine gestational sac is usually visible between 4½ and 5 weeks. The yolk sac appears between 5 and 6 weeks, and a fetal pole with cardiac activity is first detected at 5½ to 6 weeks (Fig. 9-3, p. 170). With transabdominal sonography, these structures are visualized slightly later.

In contrast, with ectopic pregnancy, a trilaminar endometrial pattern can be diagnostic (Fig. 19-5). Its specificity is 94 percent, but with a sensitivity of only 38 percent (Hammoud, 2005). In addition, Moschos and Twickler (2008b) determined that in women with PUL at presentation, no normal pregnancies had a stripe thickness < 8 mm.

Anechoic fluid collections, which might normally suggest an early intrauterine gestational sac, may also be seen with ectopic pregnancy. These include pseudogestational sac and decidual cyst. First, a pseudosac is a fluid collection between the endometrial layers and conforms to the cavity shape (see Fig. 19-5). If a pseudosac is noted, the risk of ectopic pregnancy is increased (Hill, 1990; Nyberg, 1987). Second, a decidual cyst is identified as an anechoic area lying within the endometrium but remote from the canal and often at the endometrial-myometrial border. Ackerman and colleagues (1993b) suggested that this finding represents early decidual breakdown and precedes decidual cast formation.

These two findings contrast with the intradecidual sign seen with intrauterine pregnancy. This is an early gestational sac and is eccentrically located within one of the endometrial stripe layers (Dashefsky, 1988). The American College of Obstetricians and Gynecologists (2011) advises caution in diagnosing a uterine pregnancy in the absence of a definite yolk sac or embryo.
Adnexal Findings. The sonographic diagnosis of ectopic pregnancy rests on visualization of an adnexal mass separate from the ovary (Fig. 19-6). If fallopian tubes and ovaries are visualized and an extrauterine yolk sac, embryo, or fetus is identified, then an ectopic pregnancy is clearly confirmed. In other cases, a hyperechoic halo or tubal ring surrounding an anechoic sac can be seen. Alternatively, an inhomogeneous complex adnexal mass is usually caused by hemorrhage within the ectopic sac or by an ectopic pregnancy that has ruptured into the tube. Overall, approximately 60 percent of ectopic pregnancies are seen as an inhomogeneous mass adjacent to the ovary; 20 percent appear as a hyperechoic ring; and 13 percent have an obvious gestational sac with a fetal pole (Condous, 2005). Importantly, not all adnexal masses represent an ectopic pregnancy, and integration of sonographic findings with other clinical information is necessary.
Various transvaginal sonographic findings with ectopic tubal pregnancies. For sonographic diagnosis, an ectopic mass should be seen in the adnexa separate from the ovary and may be seen as: (A) a yolk sac (shown here) and/or fetal pole with or without cardiac activity within an extrauterine sac, (B) an empty extrauterine sac with a hyperechoic ring, or (C) an inhomogeneous adnexal mass. In this last image, color Doppler shows a classic “ring of fire,” which reflects increased vascularity typical of ectopic pregnancies. LT OV = left ovary; SAG LT AD = sagittal left adnexal; UT = uterus.

Placental blood flow within the periphery of the complex adnexal mass—the ring of fire—can be seen with transvaginal color Doppler imaging. Although this can aid in the diagnosis, this finding can also be seen with a corpus luteum of pregnancy, and differentiation can be challenging.

Hemoperitoneum. In women with suspected ectopic pregnancy, evaluation for hemoperitoneum can add valuable clinical information. More commonly, this is completed using sonography, but assessment can also be made by culdocentesis. Sonographically, hemoperitoneum is anechoic or hypoechoic fluid. Blood initially collects in the dependent retouterine cul-de-sac, and then additionally surrounds the uterus as it fills the pelvis (Fig. 19-7). As little as 50 mL can be seen in the cul-de-sac using TVS, and transabdominal imaging helps to assess the hemoperitoneum extent. For example, with significant intraabdominal hemorrhage, blood will track up the pericolic gutters to fill Morison pouch near the liver. Free fluid in this pouch typically is not seen until accumulated blood reaches 400 to 700 mL (Branney, 1995; Rodgerson, 2001; Rose, 2004). Diagnostically, peritoneal fluid in conjunction with an adnexal mass is highly predictive of ectopic pregnancy (Nyberg, 1991). Importantly, however, a small amount of peritoneal fluid is physiologically normal.
18-gauge spinal needle attached to a syringe, the cul-de-sac is entered through the posterior vaginal fornix as upward traction is applied to the cervix with a tenaculum.

Culdocentesis is a simple technique used commonly in the past to identify hemoperitoneum. The cervix is pulled outward and upward toward the symphysis with a tenaculum, and a long 18-gauge needle is inserted through the posterior vaginal fornix into the retrouterine cul-de-sac. If present, fluid can be aspirated. However, a failure to do so is interpreted only as unsatisfactory entry into the cul-de-sac and does not exclude ectopic pregnancy. Fluid containing fragments of old clots or bloody fluid that does not clot is compatible with the diagnosis of hemoperitoneum. In contrast, if the blood sample clots, it may have been obtained from an adjacent blood vessel or from a briskly bleeding ectopic pregnancy. A number of studies have challenged its usefulness, and culdocentesis has been largely replaced by TVS (Glezerman, 1992; Vermesh, 1990).

Laparoscopy
Direct visualization of the fallopian tubes and pelvis by laparoscopy offers a reliable diagnosis in most cases of suspected ectopic pregnancy. There is also a ready transition to definitive operative therapy, which is discussed subsequently.

Treatment Options
Options for ectopic tubal pregnancy treatment include medical and surgical approaches, and their comparison is discussed on page 387. Medical therapy traditionally involves the antimetabolite methotrexate. Surgical choices include mainly salpingostomy or salpingectomy.

Medical Management
Regimen Options
Methotrexate is a folic acid antagonist. It tightly binds to dihydrofolate reductase, blocking the reduction of dihydrofolate to tetrahydrofolate, which is the active form of folic acid. As a result, de novo purine and pyrimidine synthesis is halted, which leads to arrested DNA, RNA, and protein synthesis. Thus, methotrexate is highly effective against rapidly proliferating tissue such as trophoblast, and overall ectopic tubal pregnancy resolution rates approximate 90 percent with its use. However, bone marrow, gastrointestinal mucosa, and respiratory epithelium can also be harmed. It is directly toxic to hepatocytes and is renally excreted. Importantly, methotrexate is a potent teratogen, and methotrexate embryopathy is notable for craniofacial and skeletal abnormalities and fetal-growth restriction (Chap. 12, p. 248) (Nurmohamed, 2011). In addition, methotrexate is excreted into breast milk and may accumulate in neonatal tissues and interfere with neonatal cellular metabolism (American Academy of Pediatrics, 2001; Briggs, 2011). Based on all these findings, a list of contraindications and pretherapy laboratory testing is found in Table 19-2. Methotrexate is bound primarily to albumin, and its displacement by other medications such as phenytoin, tetracyclines, salicylates, and sulfonamides can increase methotrexate serum drug levels. Moreover, renal clearance of methotrexate may be impaired by nonsteroidal antiinflammatory drugs, probenecid, aspirin, or penicillins (Stika, 2012). Last, vitamins containing folic acid may lower methotrexate efficacy.
For ease and efficacy, intramuscular methotrexate administration is used most frequently for ectopic pregnancy resolution, and single-dose and multidose methotrexate protocols are available (see Table 19-2). As noted, methotrexate can lead to bone marrow depression. This toxicity can be blunted by early administration of leucovorin, which is folinic acid and has activity equivalent to folic acid. Thus, leucovorin, which is given within the multidose protocol, allows for some purine and pyrimidine synthesis to buffer side effects.

In comparing these two protocols, trade-offs are recognized. For example, single-dose therapy offers simplicity, less expense, and less intensive posttherapy monitoring and does not require leucovorin rescue. However, some but not all studies report a higher success rate for the multidose regimen (Alleyassin, 2006; Barnhart, 2003a; Lipscomb, 2005). At our institution, we use single-dose methotrexate.

A third hybrid “two dose” protocol has been proposed in an effort to balance the efficacy and convenience of the two most commonly used protocols (Barnhart, 2007). The regimen involves administering 50 mg/m² of methotrexate on days 0 and 4 without leucovorin rescue. Data are limited on its comparative efficacy with the two standard regimens, but one study showed single-dose to be as effective as the two-dose regimen (Gungorduk, 2011).

BSA = body surface area; β-hCG = β-human chorionic gonadotropin; MTX = methotrexate; NA = not applicable.

From American College of Obstetricians and Gynecologists, 2012; Practice Committee of American Society for Reproductive Medicine, 2013.
Patient Selection
The best candidate for medical therapy is the woman who is asymptomatic, motivated, and compliant. With medical therapy, some classic predictors of success include a low initial serum β-hCG level, small ectopic pregnancy size, and absent fetal cardiac activity. Of these, initial serum β-hCG level is the single best prognostic indicator of successful treatment with single-dose methotrexate. Specifically, reported failure rates are 1.5 percent if the initial serum β-hCG concentration is < 1000 mIU/mL; 5.6 percent with 1000 to 2000 mIU/mL; 3.8 percent with 2000 to 5000 mIU/mL; and 14.3 percent when levels are between 5000 and 10,000 mIU/mL (Menon, 2007). Interestingly, the initial serum β-hCG value is not a valid indicator of the number of doses needed for successful resolution (Nowak-Markwitz, 2009).

Many early trials also used “large size” as an exclusion criterion, although these data are less precise. Lipscomb and colleagues (1998) reported a 93-percent success rate with single-dose methotrexate when the ectopic mass was < 3.5 cm. This compared with success rates between 87 and 90 percent when the mass was > 3.5 cm. Last, most studies report increased failure rates if there is cardiac activity. Lipscomb and colleagues (1998) reported an 87-percent success rate in such cases.

Treatment Side Effects
These regimens are associated with minimal laboratory changes and symptoms, although occasional toxicity may be severe. Kooi and Kock (1992) reviewed 16 studies and reported that adverse effects were resolved by 3 to 4 days after methotrexate was discontinued. The most common were liver involvement—12 percent, stomatitis—6 percent, and gastroenteritis—1 percent. One woman had bone marrow depression. Regarding long-term effects, Oriol and coworkers (2008), using antimüllerian hormone assays, concluded that ovarian reserve was not compromised by single-dose methotrexate therapy.

Importantly, 65 to 75 percent of women initially given methotrexate will have increasing pain beginning several days after therapy. This separation pain generally is mild and relieved by analgesics. In a series of 258 methotrexate-treated women by Lipscomb and colleagues (1999b), 20 percent had pain severe enough to require evaluation in the clinic or emergency room. Ultimately, 10 of these 53 underwent surgical exploration. Said another way, 20 percent of women given single-dose methotrexate will have significant pain, and 20 percent of these will require laparoscopy.

Overall, the failure rate is similar for either medical or surgical management. In three randomized trials, 5 to 14 percent of women treated initially with methotrexate ultimately required surgery, whereas 4 to 20 percent of those undergoing laparoscopic resection eventually received methotrexate for persistent trophoblast (Fernandez, 1998; Hajenius, 1997, 2007; Saraj, 1998). Rupture of persistent ectopic pregnancy is the worst form of primary therapy failure and occurs in 5 to 10 percent of women treated medically. Lipscomb and associates (1998) described a 14-day mean time to rupture, but one woman had tubal rupture 32 days after single-dose methotrexate.

Monitoring Therapy Efficacy
Serum β-hCG levels are used to monitor response to both medical and surgical therapy. After linear salpingostomy, serum β-hCG levels decline rapidly over days and then more gradually, with a mean resolution time of approximately 20 days. In contrast, after single-dose methotrexate, mean serum β-hCG levels increase for the first 4 days, and then gradually decline, with a mean resolution time of 27 days. Lipscomb and colleagues (1998) used single-dose methotrexate to
successfully treat 287 women and reported that the average time to resolution—defined as a serum β-hCG level < 15 mIU/mL, was 34 days. Importantly, the longest time was 109 days.

As shown in Table 19-2, monitoring single-dose therapy calls for serum β-hCG determinations at days 4 and 7 following initial injection on day 1. If the level fails to drop more than 15 percent between days 4 and 7, then a second dose of methotrexate is required. This is necessary in 15 to 20 percent of women treated with single-dose therapy. With multidose methotrexate, levels are measured at 48-hour intervals until they fall more than 15 percent. Once appropriately dropping levels are achieved in either regimen, serum β-hCG determinations are then measured weekly until undetectable. Outpatient surveillance is preferred, but if there is any question of safety or compliance, the woman is hospitalized. Failure is judged when the β-hCG level plateaus or rises or tubal rupture occurs. Importantly, tubal rupture can occur in the face of declining β-hCG levels.

Surgical Management

Laparoscopy is the preferred surgical treatment for ectopic pregnancy unless a woman is hemodynamically unstable. There have been only a few prospective studies that compare laparotomy with laparoscopic surgery. Hajenius and associates (2007) performed a Cochrane Database review and found that subsequent uterine pregnancy rates and tubal patency rates in those treated with salpingostomy were comparable with either abdominal entry route. Subsequent ectopic pregnancies were fewer in women treated laparoscopically, although this was not statistically significant. As experience has accrued, cases previously managed by laparotomy—for example, ruptured tubal pregnancies or interstitial pregnancies—can safely be managed laparoscopically by those with suitable expertise. Before surgery, future fertility desires of the patient should be discussed. In those desiring permanent sterilization, the unaffected tube can be ligated concurrently with salpingectomy for the affected fallopian tube.

Tubal surgery is considered conservative when there is tubal salvage, such as with salpingostomy. Radical surgery is defined by salpingectomy. Some have shown conservative surgery may increase the rate of subsequent uterine pregnancy but is associated with higher rates of persistently functioning trophoblast (Bangsgaard, 2003; de Bennetot, 2012). This may not be the case, however. In a randomized controlled trial, Fernandez and associates (2013) evaluated 2-year rates of attaining an intrauterine pregnancy following either salpingostomy or salpingectomy. Although pregnancy rates with salpingectomy were 64 percent compared with 71 percent following salpingostomy, these differences were not statistically significant.

Salpingostomy

This procedure is typically used to remove a small unruptured pregnancy that is usually < 2 cm in length and located in the distal third of the fallopian tube (Fig. 19-8). Natale and associates (2003) reported that serum β-hCG levels > 6000 mIU/mL are associated with a higher risk of implantation into the muscularis and thus with more tubal damage.
With surgery, a 10- to 15-mm linear incision is made on the antimesenteric border over the pregnancy. The products usually will extrude from the incision. These can be carefully removed or flushed out using high-pressure irrigation that more thoroughly removes the trophoblastic tissue (Al-Sunaidi, 2007). Small bleeding sites are controlled with needlepoint electrocoagulation, and the incision is left unsutured to heal by secondary intention.

Seldom performed today, salpingotomy is essentially the same procedure as salpingostomy except that the incision is closed with delayed-absorbable suture. According to Tulandi and Guralnick (1991), there is no difference in prognosis with or without suturing.

**Salpingectomy**

Tubal resection may be used for both ruptured and unruptured ectopic pregnancies. To minimize the rare recurrence of pregnancy in the tubal stump, complete excision of the fallopian tube is advised. With one laparoscopic technique, the affected fallopian tube is lifted and held with atraumatic grasping forceps (Thompson, 2012). One of several suitable bipolar grasping devices is placed across the fallopian tube at the uterotubal junction. Once desiccated, the tube is cut. The bipolar device is then advanced across the most proximal portion of mesosalpinx. Similarly, current is applied, and the desiccated tissue cut. This process moves serially from the proximal mesosalpinx to its distal extent under the tubal ampulla. Alternatively, an endoscopic suture loop can be used to encircle and ligate the knuckle of fallopian tube that contains the ectopic pregnancy.
and its underlying vascular supply within the mesosalpinx. Two consecutive suture loops are placed, and the tube distal to these ligatures is then cut free with scissors.

Most tubal ectopic pregnancies are small and pliant. Accordingly, they can be held firmly by grasping forceps and drawn up into one of the accessory site cannulas. Larger tubal ectopic pregnancies may be placed in an endoscopic sac to prevent fragmentation as they are removed through the laparoscopic port site. Importantly, to remove all trophoblastic tissue, the pelvis and abdomen should be irrigated and suctioned free of blood and tissue debris. Slow and systematic movement of the patient from Trendelenburg to reverse Trendelenburg positioning during irrigation can also assist in dislodging stray tissue and fluid. These should be suctioned and removed from the peritoneal cavity.

**Persistent Trophoblast**

Incomplete removal of trophoblast may result in persistent trophoblastic tissue. This complicates 5 to 20 percent of salpingostomies and can be identified by stable or rising \( \beta \)-hCG levels. Usually, \( \beta \)-hCG levels fall quickly and are at approximately 10 percent of preoperative values by day 12 (Hajenius, 1995; Vermesh, 1988). Also, if the postoperative day 1 serum \( \beta \)-hCG value is less than 50 percent of the preoperative value, then persistent trophoblast rarely is a problem (Spandorfer, 1997). According to Seifer (1997), factors that increase the risk of persisting trophoblast include: pregnancies less than 2 cm, early pregnancy less than 42 menstrual days, serum \( \beta \)-hCG level > 3000 mIU/mL, or implantation medial to the salpingostomy site. With stable or increasing \( \beta \)-hCG levels, additional surgical or medical therapy is necessary. Currently, standard therapy for this is single-dose methotrexate, 50 mg/m\(^2\) × body surface area (BSA). To prevent persistent trophoblastic tissue, some advocate postoperative administration of “prophylactic” methotrexate with a dose of 1 mg/m\(^2\) BSA (Akira, 2008; Graczykowski, 1997).

### Medical versus Surgical Therapy

Several randomized trials have compared methotrexate treatment with laparoscopic surgery. One multicenter trial compared a multidose methotrexate protocol with laparoscopic salpingostomy and found no differences for tubal preservation and primary treatment success (Hajenius, 1997). However, in this same study group, health-related quality of life factors such as pain, posttherapy depression, and decreased perception of health were significantly impaired after systemic methotrexate compared with laparoscopic salpingostomy (Nieuwkerk, 1998). In their randomized controlled trial, Fernandez and coworkers (2013) compared multidose medical therapy against salpingostomy and found that medical and conservative surgery provided similar 2-year rates of attaining an intrauterine pregnancy.

There is conflicting evidence when single-dose methotrexate is compared with surgical intervention. In two separate studies, single-dose methotrexate was overall less successful in resolving pregnancy than laparoscopic salpingostomy, although tubal patency and subsequent uterine pregnancy rates were similar between both groups (Fernandez, 1998; Sowter, 2001). Women treated with methotrexate had significantly better physical functioning immediately following therapy, but there were no differences in psychological functioning. Krag Moeller and associates (2009) reported the results from their randomized trial that had a median surveillance period of 8.6 years during which future pregnancy rates were evaluated. Ectopic-resolution success rates were not significantly different between those managed surgically and those treated with methotrexate. Moreover, cumulative spontaneous intrauterine pregnancy rates were not
different between the methotrexate group (73 percent) and the surgical group (62 percent). Based on these studies, we conclude that women who are hemodynamically stable and in whom there is a small tubal diameter, no fetal cardiac activity, and serum β-hCG concentrations < 5000 mIU/mL have similar outcomes with medical or surgical management. Despite lower success rates with medical therapy for women with larger tubal size, higher serum β-hCG levels, and fetal cardiac activity, medical management can be offered to the motivated woman who understands the risks.

**Expectant Management**

In select cases, it is reasonable to observe very early tubal pregnancies that are associated with stable or falling serum β-hCG levels. As many as a third of such women will present with declining β-hCG levels (Shalev, 1995). Stovall and Ling (1992a) restrict expectant management to women with tubal ectopic pregnancies only, decreasing serial β-hCG levels, diameter of the ectopic mass ≤ 3.5 cm, and no evidence of intraabdominal bleeding or rupture by transvaginal sonography. Mavrelos and coworkers (2013) noted that almost one third of 333 tubal ectopic pregnancies measuring < 3 cm and with β-hCG levels < 1500 mIU/mL resolved without intervention. Noted by the American College of Obstetricians and Gynecologists (2012), 88 percent of ectopic pregnancies will resolve if the β-hCG is < 200 mIU/mL.

With expectant management, subsequent rates of tubal patency and intrauterine pregnancy are comparable with surgery and medical management. The potentially grave consequences of tubal rupture, coupled with the established safety of medical and surgical therapy, require that expectant therapy be undertaken only in appropriately selected and counseled women.

**INTERSTITIAL PREGNANCY**

**Diagnosis**

These pregnancies implant within the proximal tubal segment that lies within the muscular uterine wall (Fig. 19-9). Incorrectly, they may be called cornual pregnancies, but this term describes a conception that develops in the rudimentary horn of a uterus with a müllerian anomaly. Risk factors are similar to others discussed for tubal ectopic pregnancy, although previous ipsilateral salpingectomy is a specific risk factor for interstitial pregnancy (Lau, 1999). Undiagnosed interstitial pregnancies usually rupture following 8 to 16 weeks of amenorrhea, which is later than for more distal tubal ectopic pregnancies. This is due to greater distensibility of the myometrium covering the interstitial fallopian tube segment. Because of the proximity of these pregnancies to the uterine and ovarian arteries, there is a risk of severe hemorrhage, which is associated with mortality rates as high as 2.5 percent (Tulandi, 2004).
FIGURE 19-9 Interstitial ectopic pregnancy. **A.** This parasagittal view using transvaginal sonography shows an empty uterine cavity and a mass that is cephalad and lateral to the uterine fundus (calipers). **B.** Intraoperative photograph during laparotomy and before cornual resection of the same ectopic pregnancy. In this frontal view, the bulging right-sided interstitial ectopic pregnancy is lateral to the round ligament insertion and medial to the isthmic portion of the fallopian tube. (Photograph contributed by Drs. David Rogers and Elaine Duryea.)

With TVS and serum β-hCG assays, interstitial pregnancy can now be diagnosed early in many cases, but diagnosis can be challenging. These pregnancies sonographically can appear similar to an eccentrically implanted intrauterine pregnancy, especially in a uterus with a müllerian anomaly. Criteria that may aid differentiation include: an empty uterus, a gestational sac seen separate from the endometrium and >1 cm away from the most lateral edge of the uterine cavity, and a thin, <5-mm myometrial mantle surrounding the sac (Timor-Tritsch, 1992). Moreover, an echogenic line, known as the “interstitial line sign,” extending from the gestational sac to the endometrial cavity most likely represents the interstitial portion of the fallopian tube and is highly sensitive and specific (Ackerman, 1993a). In unclear cases, three-dimensional sonography, magnetic resonance (MR) imaging, or diagnostic laparoscopy may also provide clarification (Izquierdo, 2003; Parker, 2012). Laparoscopically, an enlarged protuberance lying outside the round ligament coexistent with normal distal fallopian tubes and ovaries is found.

### Management

Surgical management with either cornual resection or cornuostomy may be performed via laparotomy or laparoscopy, depending on patient hemodynamic stability and surgeon expertise (Word, 2012; Zuo, 2012). With either approach, intraoperative intramyometrial vasopressin injection may limit surgical blood loss, and β-hCG levels should be monitored postoperatively to exclude remnant trophoblast. Cornual resection removes the gestational sac and surrounding...
cornual myometrium by means of a wedge excision (Fig. 19-10). Alternatively, cornuostomy involves incision of the cornua and suction or instrument extraction of the pregnancy.

**FIGURE 19-10** During cornual resection, the pregnancy, surrounding myometrium, and ipsilateral fallopian tube are excised en bloc. The incision is angled inward as it is deepened. This creates a characteristic wedge shape into the myometrium, which is then closed in layers with delayed-absorbable suture. The serosa is closed with subcuticular style suturing. (From Word, 2012, with permission.)

With early diagnosis, conservative medical management may be considered. However, because of the low incidence, consensus regarding methotrexate route or regimen is lacking. In their small series, Jermy and associates (2004) reported a 94-percent success with systemic methotrexate using a dose of 50 mg/m² BSA. Others have described direct methotrexate injection into the gestational sac (Timor-Tritsch, 1996). Importantly, because these women typically have higher initial serum β-hCG levels at diagnosis, longer surveillance is usually needed.

The risk of uterine rupture with subsequent pregnancies following either medical or conservative surgical management is unclear. Thus, careful observation of these women during pregnancy, along with strong consideration of elective cesarean delivery, is warranted.

Distinct from interstitial pregnancy, the term *angular pregnancy* describes intrauterine implantation in one of the lateral angles of the uterus and medial to the uterotubal junction and round ligament. This distinction is important because angular pregnancies can sometimes be carried to term but with increased risk of abnormal placentation and its consequences (Jansen, 1981).
Diagnosis

Strictly defined, abdominal pregnancy is an implantation in the peritoneal cavity exclusive of tubal, ovarian, or intraligamentous implantations. These are rare ectopic pregnancies with an estimated incidence of 1 in 10,000 to 25,000 live births (Atrash, 1987; Worley, 2008). Although a zygote can traverse the tube and implant primarily in the peritoneal cavity, most abdominal pregnancies are thought to follow early tubal rupture or abortion with reimplantation. In cases of advanced extrauterine pregnancy, it is not unusual that the placenta is still at least partially attached to the uterus or adnexa (Fig. 19-11).

FIGURE 19-11 Sagittal view of an abdominal pregnancy at term. The placenta is implanted on the posterior surface of the uterus and broad ligament. The enlarged, flattened uterus is located just beneath the anterior abdominal wall and to the level of the umbilicus. The cervix and vagina are pulled up and are dislodged anteriorly and superiorly by the large fetal head in the cul-de-sac.
Diagnosis may be difficult. First, symptoms may be absent or vague. Laboratory tests are typically uninformative, although maternal serum alpha-fetoprotein levels may be elevated. Clinically, abnormal fetal positions may be palpated, or the cervix is displaced (Zeck, 2007). Sonographically, findings with an abdominal pregnancy may not be recognized, and the diagnosis is often missed (Costa, 1991). Oligohydramnios is common but nonspecific. Other clues include a fetus seen separate from the uterus or eccentrically positioned within the pelvis; lack of myometrium between the fetus and the maternal anterior abdominal wall or bladder; and extrauterine placental tissue (Sherer, 2007). If additional anatomical information is needed, MR imaging can be used to confirm the diagnosis and provide maximal information concerning placental implantation (Bertrand, 2009; Mittal, 2012).

Management

An abdominal pregnancy can be life-threatening, and management depends on the gestational age at diagnosis. Some describe waiting until fetal viability with close surveillance (Gomez, 2008; Varma, 2003). Of note, Stevens (1993) reported fetal malformations and deformations in 20 percent. The most common malformations were limb deficiency and central nervous system anomalies. The most common deformations were facial and/or cranial asymmetry and various joint abnormalities. Conservative management also carries a maternal risk for sudden and dangerous hemorrhage. We are of the opinion that termination generally is indicated when the diagnosis is made. Certainly, before 24 weeks, conservative treatment rarely is justified.

Once placental implantation has been assessed, several options are available. Preoperative angiographic embolization has been used successfully in some women with advanced abdominal pregnancy. Alternatively, catheters placed in the uterine arteries may be inflated to decrease intraoperative blood loss. In either case, vascularization of ectopic placental implantation may be difficult to occlude. Other preoperative considerations include insertion of ureteral catheters, bowel preparation, assurance of sufficient blood products, and availability of a multidisciplinary surgical team or elective transfer to a tertiary care facility. In many ways, surgical management is similar to that for placenta percreta, which is detailed in Chapter 41 (p. 807).

The principal surgical objectives involve delivery of the fetus and careful assessment of placental implantation without provoking hemorrhage. Unnecessary exploration is avoided because the anatomy is commonly distorted and surrounding areas will be extremely vascular. Importantly, placental removal may precipitate torrential hemorrhage because the normal hemostatic mechanism of myometrial contraction to constrict hypertrophied blood vessels is lacking. If it is obvious that the placenta can be safely removed or if there is already hemorrhage from its implantation site, then removal begins immediately. When possible, blood vessels supplying the placenta should be ligated first.

Some advocate leaving the placenta in place as the lesser of two evils. It decreases the chance of immediate life-threatening hemorrhage, but at the expense of long-term sequelae. If left in the abdominal cavity, the placenta commonly becomes infected, with subsequent formation of abscesses, adhesions, intestinal or ureteral obstruction, and wound dehiscence (Bergstrom, 1998; Martin, 1988). In many of these cases, surgical removal becomes inevitable. If the placenta is left, its involution may be monitored using sonography and serum β-hCG levels (France, 1980; Martin 1990). Color Doppler sonography can be used to assess changes in blood flow. In some cases, and usually depending on its size, placental function rapidly declines, and the placenta is resorbed. However, placental resorption may take years (Roberts, 2005; Valenzano, 2003).

If the placenta is left in place, postoperative methotrexate use is controversial. It has been
recommended to hasten involution but has been reported to cause accelerated placental destruction with accumulation of necrotic tissue and infection with abscess formation (Rahman, 1982). It is difficult to envision a supporting role for the use of an antimetabolite for a senescent organ (Worley, 2008).

**INTRALIGAMENTOUS PREGNANCY**

In zygotes implanted toward the mesosalpinx, rupture may occur at the portion of the tube not immediately covered by peritoneum. The gestational contents may then be extruded into a space formed between the broad ligament leaves and become an intraligamentous or broad ligament pregnancy. These are rare, and information accrues from case reports (Seckin, 2011). Clinical findings and management mirror those for abdominal pregnancy. Although laparotomy is required in most instances, a few case reports describe laparoscopic excision of early small pregnancies (Apantaku, 2006; Cormio, 2006).

**OVARIAN PREGNANCY**

Ectopic implantation of the fertilized egg in the ovary is rare and is diagnosed if four clinical criteria are met. These were outlined by Spiegelberg (1878): (1) the ipsilateral tube is intact and distinct from the ovary; (2) the ectopic pregnancy occupies the ovary; (3) the ectopic pregnancy is connected by the uteroovarian ligament to the uterus; and (4) ovarian tissue can be demonstrated histologically amid the placental tissue (Fig. 19-12). Risk factors are similar to those for tubal pregnancies, but ART or IUD failure seems to be disproportionately associated (Ko, 2012). Presenting complaints and findings mirror tubal ectopic pregnancy. Although the ovary can accommodate the expanding pregnancy more easily than the fallopian tube, rupture at an early stage is the usual consequence.
FIGURE 19-12 Ovarian pregnancy. A. Transvaginal sonogram shows a gestational sac containing fetal parts of a 16-week gestation. The placenta is marked by a red asterisk. B. Due to concern for extensive parasitic blood supply to the pregnancy, exploratory laparotomy was performed. Here, the right ovary is lifted by the surgeon, and the fallopian tube is the cordlike structure stretched across the top of the mass. Due to mass size and vascularity and scant normal ovarian stroma, this patient was treated by right salpingo-oophorectomy. (Photograph contributed by Dr. Kyler Elwell.)

TVS use has resulted in a more frequent diagnosis of unruptured ovarian pregnancies. Sonographically, an internal anechoic area is surrounded by a wide echogenic ring, which in turn is surrounded by ovarian cortex (Comstock, 2005). In their review of 49 cases, Choi and associates (2011) noted that the diagnosis may not be made until surgery as many cases are presumed tubal ectopic pregnancy. Moreover, at surgery, an early ovarian pregnancy may be considered to be a hemorrhagic corpus luteum cyst or a bleeding corpus luteum.

Evidence-based management accrues mainly from case reports (Hassan, 2012; Scutiero, 2012). Classically, management for ovarian pregnancies has been surgical. Small lesions have been managed by ovarian wedge resection or cystectomy, whereas larger lesions require oophorectomy. Finally, systemic or locally injected methotrexate has been used successfully to treat small unruptured ovarian pregnancies (Pagidas, 2013). With conservative surgery or medical management, β-hCG levels should be monitored to exclude remnant trophoblast.

CERVICAL PREGNANCY

Diagnosis
This ectopic pregnancy is defined by cervical glands noted histologically opposite the placental attachment site and by part or all of the placenta found below the entrance of the uterine vessels or below the peritoneal reflection on the anterior uterus. In a typical case, the endocervix is eroded by trophoblast, and the pregnancy develops in the fibrous cervical wall. The more cephalad that the trophoblast is implanted along the cervical canal, the greater is its capacity to grow and hemorrhage. The incidence of cervical pregnancy lies between 1 in 8,600 and 1 in 12,400 pregnancies, but the incidence is increasing as a result of ART (Ginsburg, 1994). Another risk according to Jeng and colleagues (2007) is previous dilation and curettage.

Painless vaginal bleeding is reported by 90 percent of women with a cervical pregnancy—a third of these have massive hemorrhage (Ushakov, 1997). As pregnancy progresses, a distended, thin-walled cervix with a partially dilated external os may be evident. Above the cervical mass, a slightly enlarged uterine fundus can be felt. Identification of cervical pregnancy is based on speculum examination, palpation, and TVS. Sonographic findings typical of cervical pregnancy are shown and described in Figure 19-13. MR imaging and 3-D sonography have also been used to confirm the diagnosis (Jung, 2001; Sherer, 2008).

![Image of cervical pregnancy with sonographic findings](image)

**Figure 19-13** Cervical pregnancy. Transvaginal sonographic findings may include: (1) an hourglass uterine shape and ballooned cervical canal; (2) gestational tissue at the level of the cervix (*black arrow*); (3) absent intrauterine gestational tissue (*white arrows*); and (4) a portion of the endocervical canal seen interposed between the gestation and the endometrial canal. (Image contributed by Dr. Elysia Moschos.)

**Management**

Cervical pregnancy may be treated medically or surgically. In many centers, including ours, methotrexate has become the first-line therapy in stable women, and administration follows protocols listed in Table 19-2 (Verma, 2011; Zakaria, 2011). The drug has also been injected...
directly into the gestational sac, alone or with systemic doses (Jeng, 2007; Kirk, 2006). Others describe methotrexate infusion combined with uterine artery embolization (Xiaolin, 2010). With methotrexate regimens, resolution and uterine preservation are achieved for gestations < 12 weeks in 91 percent of cases (Kung, 1997). In selecting appropriate candidates, Hung and colleagues (1996) noted higher risks of systemic methotrexate treatment failure in those with a gestational age > 9 weeks, β-hCG levels > 10,000 mIU/mL, crown-rump length > 10 mm, and fetal cardiac activity. For this reason, many induce fetal death with intracardiac or intrathoracic injection of potassium chloride. With a single-dose intramuscular methotrexate protocol, a dose between 50 and 75 mg/m² BSA is typical. For women in whom fetal cardiac activity is detectable, a sonographically guided fetal intracardiac injection of 2 mL (2 mEq/mL) potassium chloride solution can be given (Verma, 2009). If β-hCG levels do not decline more than 15 percent after 1 week, a second dose of methotrexate can be given. Song and associates (2009) described management of 50 cases and observed that sonographic resolution lagged far behind serum β-hCG regression.

As an adjunct to medical or surgical therapy, uterine artery embolization has been described either as a response to bleeding or as a preprocedural preventive tool (Hirakawa, 2009; Nakao, 2008; Zakaria, 2011). The specifics of this interventional radiological technique are detailed in Chapter 41 (p. 820). Also in the event of hemorrhage, a 26F Foley catheter with a 30-mL balloon can be placed intracervically and inflated to effect hemostasis by vessel tamponade and to monitor uterine drainage. The balloon remains inflated for 24 to 48 hours and is gradually decompressed over a few days (Ushakov, 1997).

Although conservative management is feasible for many women with cervical pregnancies, suction curettage or hysterectomy may be selected. Moreover, hysterectomy may be required with bleeding uncontrolled by conservative methods. Unfortunately, due to the close proximity of the ureters to the ballooned cervix, urinary tract injury rates are of concern with hysterectomy.

Suction curettage may be especially favored in rare cases of a heterotopic pregnancy composed of a cervical and a desired uterine pregnancy (Moragianni, 2012). If cervical curettage is planned, intraoperative bleeding may be lessened by preoperative uterine artery embolization, by ligation of the descending branches of the uterine arteries, by vasopressin injection, or by a cerclage placed at the internal cervical os to compress feeding vessels (Davis, 2008; De La Vega, 2007; Trojano, 2009; Wang, 2011). Of these, cervical branches of the uterine artery can effectively be ligated with placement of hemostatic cervical sutures on the lateral aspects of the cervix at 3 and 9 o’clock. Cerclage placement is described in Chapter 18 (p. 361). Following curettage, a Foley balloon is placed to tamponade bleeding and is managed as described earlier.

**CESAREAN SCAR PREGNANCY**

This term describes implantation within the myometrium of a prior cesarean delivery scar. Its incidence approximates 1 in 2000 normal pregnancies and has increased alongside the cesarean delivery rate (Ash, 2007; Rotas, 2006). The pathogenesis of cesarean scar pregnancy (CSP) has been likened to that for placenta accreta and carries similar risk for serious hemorrhage (Timor-Tritsch, 2012a). It is unknown if the incidence increases with multiple cesarean deliveries or if it is affected by either one- or two-layer uterine incision closure.

Women with CSP usually present early, and pain and bleeding are common. However, up to 40 percent of women are asymptomatic, and the diagnosis is made during routine sonographic
examination (Rotas, 2006). Rarely, early rupture can lead to an abdominal pregnancy (Teng, 2007).

Sonographically, differentiating between a cervicoisthmic intrauterine pregnancy and CSP can be difficult, and several investigators have described sonographic findings (Jurkovic, 2003; Moschos, 2008a). According to Godin (1997), there are four sonographic criteria that should be satisfied for the diagnosis, which are shown and described in Figure 19-14. Although TVS is the typical first-line imaging tool, MR imaging is useful when sonography is equivocal or inconclusive before intervention (Osborn, 2012).
FIGURE 19-14 Cesarean scar pregnancy. **A.** Transvaginal sonogram of a uterus with a cesarean scar pregnancy (CSP) in a sagittal plane. An empty uterine cavity is identified by a bright hyperechoic endometrial stripe (*long, white arrow*). An empty cervical canal is similarly identified (*short, white arrow*). Last, an intrauterine mass is seen in the anterior part of the uterine isthmus (*red arrows*). Healthy myometrium between the bladder and gestational sac is absent. (Image contributed by Dr. Elysia Moschos.) **B.** Hysterectomy specimen containing a cesarean scar pregnancy. **C.** This same hysterectomy specimen is transversely sectioned at the level of the uterine isthmus and through the gestational sac. The uterine body lies to the left, and the cervix is on the right. A metal probe is placed through the endocervical canal to show the eccentric development of this gestation. Only a thin layer of myometrium overlies this pregnancy, which pushes anteriorly through the uterine wall. (Photographs contributed by Drs. Sunil Balgobin, Manisha Sharma, Rebecca Stone.)

Treatment standards are lacking, and several options are available. Hysterectomy is an acceptable initial choice in those desiring sterilization. It is sometimes a necessary option with heavy uncontrolled bleeding. Fertility-preserving options include systemic or locally injected methotrexate, either alone or combined with conservative surgery (Shen, 2012; Timor-Tritsch, 2012b; Yang, 2010). Surgeries include visually guided suction curettage or transvaginal aspiration, hysteroscopic removal, or isthmic excision. These are completed solely or more typically with adjunctive methotrexate (Michener, 2009; Seow, 2004, 2013; Timor-Tritsch, 2012a; Wang, 2009, 2012; Yang, 2009). Often uterine artery embolization is used preoperatively to minimize hemorrhage risk (Zhang, 2012; Zhuang, 2009).

OTHER SITES OF ECTOPIC PREGNANCY

Ectopic placental implantations in less expected sites have been described in case reports and include the omentum, spleen, liver, and retroperitoneum, among others (Chin, 2010; Chopra, 2009; Gang, 2010; Martínez-Varea, 2011). Also, intramural uterine implantations at sites other than a cesarean scar have been noted in women with prior uterine surgeries, ART, or adenomyosis (Memtsa, 2013; Wu, 2013). Although laparotomy is preferred by many for these ectopic sites, laparoscopic excision in hemodynamically stable patients by those with suitable skills is gaining acceptance.

spontaneous abortions are low. Fertil Steril 85:508, 2006

Gestational trophoblastic disease (GTD) is the term used to encompass a group of tumors typified by abnormal trophoblast proliferation. Trophoblast produce human chorionic gonadotropin (hCG), thus the measurement of this peptide hormone in serum is essential for GTD diagnosis, management, and surveillance. GTD histologically is divided into hydatidiform moles, which are characterized by the presence of villi, and nonmolar trophoblastic neoplasms, which lack villi. Hydatidiform moles are excessively edematous immature placentas (Benirschke, 2012). These include the benign complete hydatidiform mole and partial hydatidiform mole and the malignant invasive mole. Invasive mole is deemed malignant due to its marked penetration into and destruction of the myometrium as well as its ability to metastasize. Nonmolar trophoblastic neoplasms include choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. These three are differentiated by the type of trophoblast they contain.

The malignant forms of gestational trophoblastic disease are termed gestational trophoblastic neoplasia (GTN). These include invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. Other terms applied to GTN are malignant gestational trophoblastic disease and persistent gestational trophoblastic disease. These malignancies develop weeks or years following any type of pregnancy, but frequently occur after a hydatidiform mole. Each of the GTN tumor types is histologically distinct and varies in its propensity to invade and...
metastasize. However, histological confirmation is typically not available. Instead, measurement of serum hCG levels combined with clinical findings—rather than a histological specimen—is used to diagnose and treat this malignancy. Accordingly, GTN is often identified and effectively treated as a group.

In the past, these metastatic tumors had a prohibitively high mortality rate. However, with chemotherapy, currently most tumors are highly curable (Goldstein, 2010). Early-stage GTN is typically cured with single-agent chemotherapy, whereas later-stage disease usually responds to combination chemotherapy.

HYDATIDIFORM MOLE—MOLAR PREGNANCY

The classic histological findings of molar pregnancy include villous stromal edema and trophoblast proliferation (Fig. 20-1). The degree of histological changes, karyotypic differences, and the absence or presence of embryonic elements are used to classify them as either complete or partial moles. These two also vary in associated risks for developing medical comorbidities and postevacuation GTN. Of the two, GTN more frequently follows complete hydatidiform mole.

![Complete hydatidiform mole. A. Gross specimen with characteristic vesicles of variable size. (Image contributed by Dr. Brian Levenson.) B. A complete mole has abnormal chorionic villi that grossly appear as a mass of clear vesicles. These vary in size and often hang in clusters from thin pedicles. In contrast, a partial molar...
pregnancy has focal and less advanced hydatidiform changes and contains some fetal tissue. Although both forms of moles usually fill the uterine cavity, they rarely may be tubal or other forms of ectopic pregnancy (Sebire, 2005).

**Epidemiology and Risk Factors**

There is an ethnic predisposition to hydatidiform mole, which has increased prevalence in Asians, Hispanics, and American Indians (Drake, 2006; Lee, 2011; Smith, 2006). The incidence in the United States and Europe has been relatively constant at 1 to 2 per 1000 deliveries (Lee, 2011; Lybol, 2011; Salehi, 2011).

The strongest risk factors are age and a history of prior hydatidiform mole. Women at both extremes of reproductive age are most vulnerable. Specifically, adolescents and women aged 36 to 40 years have a twofold risk, but those older than 40 have an almost tenfold risk (Altman, 2008; Sebire, 2002a). For those with a prior complete mole, the risk of another mole is 1.5 percent. With a previous partial mole, the rate is 2.7 percent (Garrett, 2008). After two prior molar pregnancies, Berkowitz and associates (1998) reported that 23 percent of women had a third mole.

**Pathogenesis**

With rare exceptions, molar pregnancies arise from chromosomally abnormal fertilizations. Complete moles most often have a diploid chromosomal composition (Table 20-1). These usually are 46,XX and result from androgenesis, meaning both sets of chromosomes are paternal in origin. As shown in Figure 20-2A, an ovum is fertilized by a haploid sperm, which then duplicates its own chromosomes after meiosis. The chromosomes of the ovum are either absent or inactivated. Less commonly, the chromosomal pattern may be 46,XY or 46,XX and due to fertilization by twc sperm, that is, dispermic fertilization or dispermy (Lawler, 1991; Lipata, 2010).

<sup>a</sup>Typical karyotypes.

<sup>b</sup>These include anemia, hyperthyroidism, hyperemesis gravidarum, preeclampsia, and infection.

GTN = gestational trophoblastic neoplasia; hCG = human chorionic gonadotropin.
FIGURE 20-2 Typical pathogenesis of complete and partial moles. A. A 46,XX complete mole may be formed if a 23,X-bearing haploid sperm penetrates a 23,X-containing haploid egg whose genes have been “inactivated.” Paternal chromosomes then duplicate to create a 46,XX diploid complement solely of paternal origin. 

B. A partial mole may be formed if two sperm—either 23,X- or 23,Y-bearing—both fertilize (dispermy) a 23,X-containing haploid egg whose genes have not been inactivated. The resulting fertilized egg is triploid with two chromosome sets being donated by the father (diandry).

Partial moles usually have a triploid karyotype—69,XXX, 69,XXY—or much less commonly 69,XYY. These are each composed of two paternal haploid sets of chromosomes contributed by dispermy and one maternal haploid set (see Fig. 20-2B). Less frequently, a similar haploid egg may be fertilized by an unreduced diploid 46,XY sperm. These triploid zygotes result in some embryonic development, however, it ultimately is a lethal fetal condition. Fetuses that reach advanced ages have severe growth restriction, multiple congenital anomalies, or both.

Twin Pregnancy Comprised of a Normal Fetus and Coexistent Complete Mole

Rarely, in some twin pregnancies, one chromosomally normal fetus is paired with a complete diploid molar pregnancy. These are recognized in only 1 in 22,000 to 100,000 pregnancies (Steller, 1994). It is important that these cases be distinguished from a single partial molar pregnancy with its abnormal associated fetus. Amniocentesis done for fetal karyotyping is used to confirm the diagnosis.

There are a number of unique pregnancy complications with this twin pregnancy. And, many
women may choose to terminate the pregnancy, if diagnosed early. In those with continuing pregnancy, survival of the normal fetus is variable and dependent on complications that commonly develop from the molar component. The most worrisome are preeclampsia or hemorrhage, which frequently necessitate preterm delivery. Wee and Jauniaux (2005) reviewed outcomes in 174 women of whom 82 chose termination. Of the remaining 92 pregnancies, 42 percent either miscarried or had a perinatal death; approximately 60 percent delivered preterm; and only 40 percent delivered at term.

Another concern for those continuing their pregnancy is the possible risk for developing subsequent GTN. Sebire and colleagues (2002b) reviewed such twin pregnancies and reported that in those not terminated, 21 percent of mothers subsequently required chemotherapy. But, this was not significantly different from a rate of 16 percent among women who chose termination. Others have reported rates up to 50 percent following continuation (Massardier, 2009). At this time, most data indicate that women with these twin pregnancies are not at greater risk for subsequent neoplasia than those with a singleton complete mole (Niemann, 2007b). Postdelivery surveillance is conducted as for any molar pregnancy and is discussed on page 401.

### Clinical Findings

The clinical presentation of women with a molar pregnancy has changed remarkably over the past several decades because prenatal care is sought much earlier and because sonography is virtually universal. As a result, most molar pregnancies are detected when they are small and before complications ensue (Kerkmeijer, 2009; Mangili, 2008).

Typically, there are usually 1 to 2 months of amenorrhea before discovery. In 41 women with a complete mole diagnosed at a mean of 10 weeks, Gemer and colleagues (2000) reported that 41 percent were asymptomatic and 58 percent had vaginal bleeding. Moreover, only 2 percent had anemia or hyperemesis, and none had other manifestations that in the past were common in these women.

As gestation advances, symptoms generally tend to be more pronounced with complete compared with partial moles (Niemann, 2007a). Untreated molar pregnancies will almost always cause uterine bleeding that varies from spotting to profuse hemorrhage. Bleeding may presage spontaneous molar abortion, but more often, it follows an intermittent course for weeks to months. In more advanced moles with considerable concealed uterine hemorrhage, moderate iron-deficiency anemia develops. Many women have uterine growth that is more rapid than expected. The enlarged uterus has a soft consistency, but typically no fetal heart motion is detected. Nausea and vomiting may become significant. The ovaries contain multiple theca-lutein cysts in 25 to 60 percent of women with a complete mole (Fig. 20-3). These likely result from overstimulation of lutein elements by sometimes massive amounts of hCG. Because theca-lutein cysts regress following pregnancy evacuation, expectant management is preferred. Occasionally a larger cyst may undergo torsion, infarction, and hemorrhage. However, oophorectomy is not performed unless there is extensive infarction that persists after untwisting.
The thyrotropin-like effects of hCG frequently cause serum free thyroxine (fT₄) levels to be elevated and thyroid-stimulating hormone (TSH) levels to be decreased. Despite this, clinically apparent thyrotoxicosis is unusual and, in our experience, can be mimicked by bleeding and sepsis from infected products. Moreover, the serum free T₄ levels rapidly normalize after uterine evacuation. Despite this, a case of presumed “thyroid storm” has been reported (Moskovitz, 2010).

Severe preeclampsia and eclampsia are relatively common with large molar pregnancies. However, these are seldom seen today because of early diagnosis and evacuation. An exception is in the case of a normal fetus coexisting with a complete mole, described earlier. In those cases in which pregnancy is not terminated, severe preeclampsia frequently mandates preterm delivery. The predilection for preeclampsia is explained by the hypoxic trophoblastic mass, which releases antiangiogenic factors that activate endothelial damage (Chap. 40, p. 733).

**Diagnosis**

Most women initially have amenorrhea that is followed by irregular bleeding that almost always prompts pregnancy testing and sonography. Some women will present with spontaneous passage of molar tissue.

**Serum β-HCG Measurements**

With a complete molar pregnancy, serum β-hCG levels are commonly elevated above those expected for gestational age. With more advanced moles, values in the millions are not unusual. Importantly, these high values can lead to erroneous false-negative urine pregnancy test results because of oversaturation of the test assay by excessive β-hCG hormone (Chap. 9, p. 169). In these
cases, serum β-hCG determinations with or without sample dilution will clarify the conundrum. With a partial mole, β-hCG levels may also be significantly elevated, but more commonly concentrations fall into ranges expected for gestational age.

**Sonography**

Although sonographic imaging is the mainstay of trophoblastic disease diagnosis, not all cases are confirmed initially. Sonographically, a complete mole appears as an echogenic uterine mass with numerous anechoic cystic spaces but without a fetus or amnionic sac. The appearance is often described as a “snowstorm” (Figure 20-4). A partial mole has features that include a thickened, multicystic placenta along with a fetus or at least fetal tissue. In early pregnancy, however, these sonographic characteristics are seen in fewer than half of hydatidiform moles (Fowler, 2006). The most common misdiagnosis is incomplete or missed abortion. Occasionally, molar pregnancy may be confused for a multifetal pregnancy or a uterine leiomyoma with cystic degeneration.

![Sonograms of hydatidiform moles. A. Sagittal view of a uterus with a complete hydatidiform mole. In this image of a partial hydatidiform mole, the fetus is seen above a multicystic placenta. (Image contributed by Dr. Elysia Moschos.)](image)

**Pathological Diagnosis**

Surveillance for subsequent neoplasia following molar pregnancy is crucial. Thus, moles must be histologically distinguished from other types of pregnancy failure that have hydropic placental degeneration, which can mimic molar villous changes. Some distinguishing histological characteristics are shown in Table 20-1.

In pregnancies before 10 weeks, classic molar changes may not be apparent because villi may not be enlarged and molar stroma may not yet be edematous and avascular (Paradinas, 1996).
such situations, other techniques are used to differentiate. One takes advantage of the differing ploidy to distinguish partial (triploid) moles from diploid entities. Complete moles and nonmolar pregnancies with hydropic placental degeneration are both diploid.

Another technique involves histological immunostaining to identify the p57<sup>KIP2</sup> nuclear protein. Because the gene that expresses p57<sup>KIP2</sup> is paternally imprinted, only maternally donated genes are expressed. Because complete moles contain only paternal genetic material, they cannot express this gene; do not produce p57<sup>KIP2</sup>; and thus, do not pick up this immunostain. In contrast, this nuclear protein is strongly expressed in partial moles and in nonmolar pregnancies with hydropic change (Castrillon, 2001). As a result, the combined use of ploidy analysis and p57<sup>KIP2</sup> immunostaining can be used to differentiate: (1) a complete mole (diploid/p57<sup>KIP2</sup>-negative), (2) a partial mole (triploid/p57<sup>KIP2</sup>-positive), and spontaneous abortion with hydropic placental degeneration (diploid/p57<sup>KIP2</sup>-positive) (Merchant, 2005).

### Management

Maternal deaths from molar pregnancies are rare because of early diagnosis, timely evacuation, and vigilant postevacuation surveillance for GTN. Preoperative evaluation attempts to identify known potential complications such as preeclampsia, hyperthyroidism, anemia, electrolyte depletions from hyperemesis, and metastatic disease (Table 20-2) (Lurain, 2010). Most recommend chest x-ray, whereas computed tomography (CT) and magnetic resonance (MR) imaging are not routinely done unless the chest radiograph shows lung lesions or unless there is evidence of other extraterine disease such as in the brain or liver.

**Termination of Molar Pregnancy**

Regardless of uterine size, molar evacuation by suction curettage is usually the preferred treatment. Preoperative cervical dilatation with an osmotic agent is recommended if the cervix is minimally dilated. Intraoperative bleeding can be greater with molar pregnancy than with a comparably sized uterus containing nonmolar products. Thus with large moles, adequate anesthesia, sufficient intravenous access, and blood-banking support is imperative. The cervix is mechanically dilated to allow insertion of a 10- to 14-mm suction curette. As evacuation is begun, oxytocin is infused to limit bleeding. Intraoperative sonography is recommended to help ensure that the uterine cavity has been emptied. When the myometrium has contracted, thorough but gentle curettage with a sharp large-loop Sims curette is performed. If bleeding continues despite uterine evacuation and oxytocin infusion, other uterotonic agents shown in Table 20-2 are given. In some cases, pelvic arterial embolization or hysterectomy may be necessary (Tse, 2007). Profuse hemorrhage and surgical methods that may be useful for its management are discussed in Chapter 41 (p. 818).

It is invariable that some degree of trophoblastic deportation into the pelvic venous system takes place during molar evacuation (Hankins, 1987). With large molar pregnancies, the volume of tissue may be sufficient to produce clinically apparent respiratory insufficiency, pulmonary edema, or even embolism. In our earlier experiences with very large moles, these and their chest x-ray manifestations clear rapidly without specific treatment. However, fatalities have been described (Delmis, 2000). Because of deportation, there is concern that trophoblastic tissue will thrive within the lung parenchyma to cause persistent disease or even overt malignancy. Fortunately, there is no evidence that this is a major problem.

Following curettage, anti-D immunoglobulin (Rhogam) is given to Rh D-negative women because fetal tissues with a partial mole may include red cells with D-antigen (Chap. 15, p. 311). Those with suspected complete mole are similarly treated because a definitive diagnosis of complete versus partial mole may not be confirmed until pathological evaluation of the evacuated products.

Following evacuation, the long-term prognosis for women with a hydatidiform mole is not improved with prophylactic chemotherapy (Goldstein, 1995). Moreover, chemotherapy toxicity—including death—may be significant, and thus it is not recommended routinely by the American College of Obstetricians and Gynecologists (2012).

Methods other than suction curettage may be considered for select cases. Hysterectomy with ovarian preservation may be preferable for women who have completed childbearing. Of women
Aged 40 and older, approximately a third will subsequently develop GTN, and hysterectomy markedly reduces this likelihood (Hanna, 2010). Theca-lutein cysts seen at the time of hysterectomy do not require removal, and they spontaneously regress following molar termination. Some recommend aspiration of larger cysts to minimize pain and torsion risk. In contrast, labor induction or hysterotomy is seldom used for molar evacuation in the United States. Both will likely increase blood loss and theoretically may increase the incidence of persistent trophoblastic disease (American College of Obstetricians and Gynecologists, 2012).

Postevacuation Surveillance

Close biochemical surveillance for persistent gestational neoplasia should follow hydatidiform mole evacuation. Concurrently, reliable contraception is imperative to avoid confusion caused by rising β-hCG levels from a new pregnancy. Most recommend either combination hormonal contraception or injectable medroxyprogesterone acetate. The latter is particularly useful if there is poor compliance. Intrauterine devices are not used until β-hCG levels are undetectable because of the risk of uterine perforation if there is an invasive mole. Finally, barrier and other methods are not recommended because of their relatively high failure rates.

Biochemical surveillance is by serial measurements of serum β-hCG to detect persistent or renewed trophoblastic proliferation. The initial β-hCG level is obtained within 48 hours after evacuation. This serves as the baseline, which is compared with β-hCG quantification done thereafter every 1 to 2 weeks until levels progressively decline to become undetectable.

The median time for such resolution is 7 weeks for partial moles and 9 weeks for complete moles. Once β-hCG is undetectable, this is confirmed with monthly determinations for another 6 months. After this, surveillance is discontinued and pregnancy allowed. Because such intensive monitoring has a high noncompliance rate, a truncated approach has been studied, and it may be unnecessary to verify undetectable β-hCG levels for 6 months. Specifically, it was shown that no woman with a partial or complete mole whose serum β-hCG level became undetectable subsequently developed neoplasia (Lavie, 2005; Wolfberg, 2004). Importantly, during the time during which β-hCG levels are monitored, either increasing or persistently plateaued levels mandate evaluation for trophoblastic neoplasia. If the woman has not become pregnant, then these levels signify increasing trophoblastic proliferation that is most likely malignant.

There are a number of risk factors for developing trophoblastic neoplasia following molar evacuation. Most important, complete moles have a 15 to 20 percent incidence of malignant sequelae, compared with 1 to 5 percent following partial moles. Surprisingly, with much earlier recognition and evacuation of molar pregnancies, the risk for neoplasia has not been lowered (Schorge, 2000). Other risk factors are older age, β-hCG levels > 100,000 mIU/mL, uterine size that is large-for-gestational age, theca-lutein cysts > 6 cm, and slow decline in β-hCG levels (Berkowitz, 2009; Kang, 2012; Wolfberg, 2005). Although not routine, postevacuation uterine sonographic surveillance showing myometrial nodules or hypervascularity may be a predictor of subsequent neoplasia (Garavaglia, 2009).

GESTATIONAL TROPHOBLASTIC NEOPLASIA

This group includes invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. These tumors almost always develop with or follow some form of recognized pregnancy. Half follow hydatidiform mole, a fourth follow miscarriage or tubal
pregnancy, and another fourth develop after a preterm or term pregnancy (Goldstein, 2012). Although these four tumor types are histologically distinct, they are usually diagnosed solely by persistently elevated serum β-hCG levels because tissue is frequently not available for pathological study. Criteria for the diagnosis of postmolar gestational trophoblastic neoplasia are shown in Table 20-3.

Clinical Findings

These placental tumors are characterized clinically by their aggressive invasion into the myometrium and propensity to metastasize. The most common finding with gestational trophoblastic neoplasms is irregular bleeding associated with uterine subinvolution. The bleeding may be continuous or intermittent, with sudden and sometimes massive hemorrhage. Myometrial perforation from trophoblastic growth may cause intraperitoneal hemorrhage. In some women, lower genital tract metastases are evident, whereas in others there are only distant metastases with no trace of a uterine tumor.

Diagnosis, Staging, and Prognostic Scoring

Consideration for the possibility of gestational trophoblastic neoplasia is the most important factor in its recognition. Unusually persistent bleeding after any type of pregnancy should prompt measurement of serum β-hCG levels and consideration for diagnostic curettage. Uterine size is assessed along with careful examination for lower genital tract metastases, which usually appear as bluish vascular masses (Cagayan, 2010). Tissue diagnosis is unnecessary, thus biopsy is not required and may cause significant bleeding.

Once the diagnosis is verified, in addition to a baseline serum β-hCG level and hemogram, a search for local disease and metastases includes tests of liver and renal function, transvaginal sonography, chest CT scan or radiograph, and brain and abdominopelvic CT scan or MR imaging. Less commonly, positron-emission tomographic (PET) scanning and cerebrospinal fluid β-hCG level determination are used to identify metastases (Lurain, 2011).

Gestational trophoblastic neoplasia is staged clinically using the system of the International Federation of Gynecology and Obstetrics (FIGO) (2009). This includes a modification of the World Health Organization (1983) prognostic index score, with which scores of 0 to 4 are given for each of the categories shown in Table 20-4. Women with WHO scores of 0 to 6 are considered to have low-risk disease, whereas those with a score ≥ 7 are considered in the high-risk group.

<table>
<thead>
<tr>
<th>TABLE 20-4. International Federation of Gynecology and Obstetrics (FIGO) Staging and Diagnostic Scoring System for Gestational Trophoblastic Neoplasia</th>
</tr>
</thead>
</table>
# Histological Classification

Again, it is stressed that the diagnosis of trophoblastic neoplasias is usually made by persistently elevated serum β-hCG levels without confirmation by pathological tissue study. Clinical staging is arrived at without regard for histological findings, even if available. Still, there are distinct histological types that are described next.

## Invasive Mole

These are the most common trophoblastic neoplasms that follow hydatidiform moles, and almost all invasive moles arise from partial or complete moles (Sebire, 2005). Previously known as *chorioadenoma destruens*, invasive mole is characterized by extensive tissue invasion by trophoblast and whole villi. There is penetration deep into the myometrium, sometimes with involvement of the peritoneum, adjacent parametrium, or vaginal vault. Although locally aggressive, invasive moles are less prone to metastasize such as with choriocarcinoma.

<sup>a</sup>Adapted by FIGO.

<sup>b</sup>Low risk = WHO score of 0 to 6; high risk = WHO score of ≥ 7.

β-hCG = beta human chorionic gonadotropin; GI = gastrointestinal; GTN = gestational trophoblastic neoplasia.

Adapted from FIGO Committee on Gynecologic Oncology, 2009.
This is the most common type of trophoblastic neoplasm to follow a term pregnancy or a miscarriage, and only a third of cases follow a molar gestation (Soper, 2006). Choriocarcinoma is composed of cells reminiscent of early cytotrophoblast and syncytiotrophoblast, however, it contains no villi. This rapidly growing tumor invades both myometrium and blood vessels to create hemorrhage and necrosis. Myometrial tumor may spread outward and become visible on the uterine surface as dark, irregular nodules. Metastases often develop early and are generally blood-borne (Fig. 20-5). The most common sites are the lungs and vagina, but tumor may be metastatic to the vulva, kidneys, liver, ovaries, brain, and bowel. Choriocarcinomas are commonly accompanied by ovarian theca-lutein cysts.
FIGURE 20-5 Metastatic choriocarcinoma. A. Chest radiograph demonstrates widespread metastatic lesions. B. Autopsy specimen with multiple hemorrhagic hepatic metastases. (Images contributed by Dr. Michael Conner.)

Placental Site Trophoblastic Tumor (PSST)
This uncommon tumor arises from implantation site-intermediate trophoblast. These tumors have associated serum β-hCG levels that may be only modestly elevated, but they produce variant forms
of hCG, and identification of a high proportion of free β-hCG (> 30 percent) is considered diagnostic. Treatment of placental site trophoblastic tumor by hysterectomy is preferred because these locally invasive tumors are usually resistant to chemotherapy (Baergen, 2006). For higher-risk stage I and for later stages, adjuvant multidrug chemotherapy is also given (Schmid, 2009).

**Epithelioid Trophoblastic Tumor**

This rare tumor develops from chorionic-type intermediate trophoblast. Grossly, the tumor grows in a nodular fashion. Primary treatment is hysterectomy because this tumor is relatively resistant to chemotherapy. Approximately a fourth of women with this neoplasm will have metastatic disease, and they are given combination chemotherapy (Morgan, 2008).

**Treatment**

Women with gestational trophoblastic neoplasia are best managed by oncologists. Chemotherapy is usually the primary treatment, and repeat evacuation is not recommended by most because of risks for uterine perforation, bleeding, infection, or intrauterine adhesion formation. In a few, suction curettage may be necessary if there is bleeding or a substantial amount of retained molar tissue. Although controversial, some also consider a second uterine evacuation to be an initial therapeutic option in some cases of GTN following molar evacuation in an effort to avoid or minimize chemotherapy (Pezeshki, 2004; van Trommel, 2005). Moreover, in specific cases, hysterectomy may be primary or adjuvant treatment (Clark, 2010).

Single-agent chemotherapy protocols are usually sufficient for nonmetastatic or low-risk metastatic neoplasia (Horowitz, 2009). In their review of 108 women with low-risk disease, Abrão and colleagues (2008) reported that monotherapy protocols with either methotrexate or actinomycin D were equally effective compared with a regimen containing both. In general, methotrexate is less toxic than actinomycin D (Chan, 2006; Seckl, 2010). Regimens are repeated until serum β-hCG levels are undetectable.

Combination chemotherapy is given for high-risk disease, and reported cure rates approximate 90 percent (Lurain, 2010). A number of regimens have been used with success. One is *EMA-CO*, which includes etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincovin (vincristine). Adjuvant surgical and radiotherapy may also be employed (Hanna, 2010).

With either low- or high-risk disease, once serum β-hCG levels are undetectable, serosurveillance is continued for 1 year. During this time, effective contraception is crucial to avoid any teratogenic effects of chemotherapy to the fetus as well as to mitigate confusion from rising β-hCG levels caused by superimposed pregnancy.

A small number of women during surveillance, despite no evidence of metastases, will be found to have very low β-hCG levels that plateau. This phenomenon is referred to as quiescent hCG and presumably is caused by dormant trophoblast. Close observation without therapy is recommended, and 20 percent will eventually have recurrent active and progressive trophoblastic neoplasia (Khanlian, 2003).

**SUBSEQUENT PREGNANCY**

Women with prior gestational trophoblastic disease or successfully treated neoplasia usually do not have impaired fertility, and their pregnancy outcomes are usually normal (Tse, 2012). The
primary concern in these women is their 2-percent risk for developing trophoblastic disease in a subsequent pregnancy (Garrett, 2008). Sonographic evaluation is recommended in early pregnancy, and subsequently if indicated. At delivery, the placenta or products of conception are sent for pathological evaluation, and a serum β-hCG level is measured 6 weeks postpartum.

LABOR
CHAPTER 21

Physiology of Labor

PHASES OF PARTURITION
PHASE 1 OF PARTURITION: UTERINE QUIESENCE AND CERVICAL SOFTENING
PHASE 2 OF PARTURITION: PREPARATION FOR LABOR
PHASE 3 OF PARTURITION: LABOR
PHASE 4 OF PARTURITION: THE Puerperium

PHYSIOLOGICAL AND BIOCHEMICAL PROCESSES REGULATING PARTURITION

PHASE 1: UTERINE QUIESCEENCE AND CERVICAL COMPETENCE
PHASE 2: UTERINE ACTIVATION AND CERVICAL RIPENING
PHASE 3: UTERINE STIMULATION

The last few hours of human pregnancy are characterized by forceful and painful uterine contractions that effect cervical dilatation and cause the fetus to descend through the birth canal. There are extensive preparations in both the uterus and cervix long before this. During the first 36 to 38 weeks of normal gestation, the myometrium is in a preparatory yet unresponsive state. Concurrently, the cervix begins an early stage of remodeling—termed softening—yet maintains structural integrity. Following this prolonged uterine quiescence, there is a transitional phase during which myometrial unresponsiveness is suspended, and the cervix undergoes ripening, effacement, and loss of structural integrity.

The physiological processes that regulate parturition and the onset of labor continue to be defined. It is clear, however, that labor onset represents the culmination of a series of biochemical changes in the uterus and cervix. These result from endocrine and paracrine signals emanating from both mother and fetus. Their relative contributions vary between species, and it is these differences that complicate elucidation of the exact factors that regulate human parturition. When parturition is abnormal, then preterm labor, dystocia, or postterm pregnancy may result. Of these, preterm labor remains the major contributor to neonatal mortality and morbidity in developed countries.
The bringing forth of young—parturition—requires well-orchestrated transformations in both uterine and cervical function. As shown in Figure 21-1, parturition can be arbitrarily divided into four overlapping phases that correspond to the major physiological transitions of the myometrium and cervix during pregnancy (Casey, 1993, 1997; Challis, 2000; Word, 2007). These phases of parturition include: (1) a prelude to it, (2) the preparation for it, (3) the process itself, and (4) recovery. Importantly, the phases of parturition should not be confused with the clinical stages of labor, that is, the first, second, and third stages—which comprise the third phase of parturition (Fig. 21-2).

**FIGURE 21-1** The phases of parturition.
FIGURE 21-2 Composite of the average dilatation curve for labor in nulliparous women. The curve is based on analysis of data derived from a large, nearly consecutive series of women. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts: an acceleration phase, a linear phase of maximum slope, and a deceleration phase. (Redrawn from Friedman, 1978.)

Phase 1 of Parturition: Uterine Quiescence and Cervical Softening

Uterine Quiescence
Beginning even before implantation, a remarkably effective period of myometrial quiescence is imposed. This phase normally comprises 95 percent of pregnancy and is characterized by uterine
smooth muscle tranquility with maintenance of cervical structural integrity. The inherent propensity of the myometrium to contract is held in abeyance, and uterine muscle is rendered unresponsive to natural stimuli. Concurrently, the uterus must initiate extensive changes in its size and vascularity to accommodate the pregnancy and prepare for uterine contractions. The myometrial unresponsiveness of phase 1 continues until near the end of pregnancy. Some low-intensity myometrial contractions are felt during the quiescent phase, but they do not normally cause cervical dilatation. Contractions of this type become more common toward the end of pregnancy, especially in multiparous women, and are referred to as Braxton Hicks contractions or false labor (Chap. 4, p. 47).

Cervical Softening
The cervix has multiple functions during pregnancy that include: (1) maintenance of barrier function to protect the reproductive tract from infection, (2) maintenance of cervical competence despite increasing gravitational forces, and (3) orchestration of extracellular matrix changes that allow progressive increases in tissue compliance.

In nonpregnant women, the cervix is closed and firm, and its consistency is similar to nasal cartilage. By the end of pregnancy, the cervix is easily distensible, and its consistency is similar to the lips of the oral cavity. Thus, the first stage of this remodeling—termed softening—is characterized by an increase in tissue compliance, yet the cervix remains firm and unyielding. Hegar (1895) first described palpable softening of the lower uterine segment at 4 to 6 weeks’ gestation, and this sign was once used to diagnose pregnancy.

Clinically, the maintenance of cervical anatomical and structural integrity is essential for continuation of pregnancy to term. Preterm cervical dilatation, structural incompetence, or both may forecast delivery (Iams, 1996).

Structural Changes with Softening. Cervical softening results from increased vascularity, stromal hypertrophy, glandular hypertrophy and hyperplasia, and slow, progressive compositional or structural changes of the extracellular matrix (House, 2009; Leppert, 1995; Mahendroo, 2012; Word, 2007). During matrix changes, collagen, the main structural protein in the cervix, undergoes conformational changes that alter tissue strength and flexibility. Specifically, collagen processing and the number or type of covalent cross-links between collagen triple helices are altered. These cross-links are normally required for stable collagen fibril formation (Canty, 2005). A reduction in cross-links between newly synthesized collagen monomers results from reduced expression and activity of the cross-link forming enzymes, lysyl hydroxylase and lysyl oxidase, beginning in early pregnancy (Akins, 2011; Drewes, 2007; Ozasa, 1981). Concurrently there is reduced expression of the matricellular proteins thrombospondin 2 and tenascin C. These proteins also influence collagen fibril structure and strength. Together, these early pregnancy changes contribute to the gradual increase in tissue compliance during pregnancy.

The clinical importance of these matrix changes is supported by the greater prevalence of cervical insufficiency in those with inherited defects in collagen and elastin synthesis or assembly (Anum, 2009; Hermanns-Lê, 2005; Paternoster, 1998; Rahman, 2003; Wang, 2006). Examples are Ehlers-Danlos and Marfan syndromes, discussed in Chapter 59 (p. 1181). Additionally, human cervical stromal cells express a transcription factor, microphthalmia-associated transcription factor (MiTF-Cx). During pregnancy, this factor maintains cervical competency by repressing the expression of genes involved in cervical dilation and parturition (Hari Kishore, 2012).
Phase 2 of Parturition: Preparation for Labor

To prepare for labor, the myometrial tranquility of phase 1 of parturition must be suspended—so-called *uterine awakening* or *activation*. This phase 2 is a progression of uterine changes during the last 6 to 8 weeks of pregnancy. Importantly, shifting events associated with phase 2 can cause either preterm or delayed labor.

**Myometrial Changes**

Phase 2 myometrial changes prepare it for labor contractions. This shift probably results from alterations in the expression of key proteins that control contractility. These *contraction-associated proteins (CAPs)* include the oxytocin receptor, prostaglandin F receptor, and connexin 43 (Smith, 2007). Thus, myometrial oxytocin receptors markedly increase along with increased numbers and surface areas of gap junction proteins such as connexin 43. Together, these lead to increased uterine irritability and responsiveness to *uterotonins*—agents that stimulate contractions.

Another critical change in phase 2 is formation of the lower uterine segment from the isthmus. With this development, the fetal head often descends to or even through the pelvic inlet—so-called *lightening*. The abdomen commonly undergoes a shape change, sometimes described by women as “the baby dropped.” It is also likely that the lower segment myometrium is unique from that in the upper uterine segment, resulting in distinct roles for each during labor. This is supported by baboon studies that demonstrate differential expression of prostaglandin receptors within myometrial regions. There are also human studies that report an expression gradient of oxytocin receptors, with greater expression in fundal myometrial cells (Fuchs, 1984; Havelock, 2005; Smith, 2001).

**Cervical Ripening During Phase 2**

Before contractions begin, the cervix must undergo more extensive remodeling. This eventually results in cervical yielding and dilatation upon initiation of forceful uterine contractions. Cervical modifications during this second phase principally involve connective tissue changes—so-called *cervical ripening*. The transition from the softening to the ripening phase begins weeks or days before onset of contractions. During this transformation, the total amount and composition of proteoglycans and glycosaminoglycans within the matrix are altered. Many of the processes that aid cervical remodeling are controlled by the same hormones regulating uterine function. That said, the molecular events of each are varied because of differences in cellular composition and physiological requirements. The uterine corpus is predominantly smooth muscle, whereas the cervix is primarily connective tissue. Cellular components of the cervix include fibroblasts, epithelia, and few smooth muscle cells.

**Endocervical Epithelia**

During pregnancy, endocervical epithelial cells proliferate such that endocervical glands occupy a significant percentage of cervical mass. The endocervical canal is lined with mucus-secreting columnar and stratified squamous epithelia, which protect against microbial invasion. Mucosal epithelia function as sentinels for antigens by expressing Toll-like receptors that recognize pathogens. In addition, epithelia respond in ways that lead to bacterial and viral killing. For this, the epithelia express antimicrobial peptides and protease inhibitors and signal to underlying immune cells when a pathogenic challenge exceeds their protective capacity (Wira, 2005).

In mice, studies suggest that cervical epithelia may also aid cervical remodeling by regulating
tissue hydration and maintenance of barrier function. Hydration may be regulated by expression of aquaporins—water channel proteins. Maintenance of barrier function and paracellular transport of ion and solutes is regulated by tight junction proteins, such as claudins 1 and 2 (Anderson, 2006; Timmons, 2007). In the human cervical and vaginal mucosal epithelia, junctional proteins are also reported to be expressed (Blaskewicz, 2011).

Cervical Connective Tissue

Collagen. The cervix is an extracellular matrix-rich tissue. Constituents of the matrix include type I, III, and IV collagen, glycosaminoglycans, matricellular proteins, proteoglycans, and elastin. Of these, collagen is largely responsible for structural disposition of the cervix. Collagen is the most abundant mammalian protein and has a complex biosynthesis pathway that includes at least six enzymes and chaperones to accomplish maturation. Each collagen molecule is composed of three alpha chains, which wind around each other to form procollagen. Multiple collagen triple-helical molecules are cross-linked to one another by the actions of lysyl oxidase to form fibrils. Collagen fibrils interact with small proteoglycans such as decorin or biglycan, as well as matricellular proteins such as thrombospondin 2. These interactions determine fibril size, packing, and organization (Fig. 21-3). This ensures that collagen fibrils are of uniform diameter and are packed together in a regular and highly organized pattern (Canty, 2005).

FIGURE 21-3 Fibrillar collagen synthesis and organization. Collagen fibrils are assembled into collagen fibers. Fibril size and packing are regulated in part by small proteoglycans such as decorin that bind collagen. Before cervical ripening, fibril size is uniform, and fibrils are well packed and organized. During cervical ripening, fibril size is less uniform, and spacing between
collagen fibrils and fibers is increased and disorganized.

During cervical ripening, collagen fibril diameter is increased, and there is increased spacing between fibrils. These changes may result in part from accumulation of poorly cross-linked collagen and reduced expression of matricellular proteins. Dispersion of collagen fibrils leads to a loss of tissue integrity and increased tissue compliance. Matrix metalloproteases (MMPs) are proteases capable of degrading extracellular matrix proteins. Of these, collagenase members of the MMP family degrade collagen. Some studies support a role of MMPs in cervical ripening. But others suggest that the biomechanical changes are not consistent solely with collagenase activation and loss of collagen. For example, Buhrnschi and colleagues (2004) performed tissue biomechanical studies in the rat and suggest that ripening correlates with changes in the three-dimensional structure of collagen rather than its degradation by collagenases. Moreover, mouse and human studies document no changes in collagen content between nonpregnancy and term pregnancy (Akins, 2011; Myers, 2008; Read, 2007).

Thus, it is likely that dynamic changes in collagen structure rather than collagen content may regulate remodeling. This point is well illustrated in specialized microscopy images of mouse and human cervical collagen (Zhang, 2012). In further support, polymorphisms or mutations in genes required for collagen assembly are associated with an increased incidence of cervical insufficiency (Anum, 2009; Paternoster, 1998; Rahman, 2003; Warren, 2007).

Glycosaminoglycans (GAGs). These are high-molecular-weight polysaccharides that complex with proteins to form proteoglycans. One glycosaminoglycan is hyaluronan (HA), a carbohydrate polymer whose synthesis is carried out by hyaluronan synthase isoenzymes. Expression of these enzymes is increased in the cervix during ripening (Akgul, 2012; Osmers, 1993; Straach, 2005). The functions of hyaluronans are dependent on size, and the breakdown of large- to small-molecular-weight molecules is carried out by a family of hyaluronidase enzymes. Hyaluronidase genes are expressed in both the mouse and human cervix, and increased hyaluronidase activity is reported in the mouse cervix at term (Akgul, 2012). Large-molecular-weight HA predominates in the mouse cervix during ripening and has a dynamic role to increase viscoelasticity and matrix disorganization. Low-molecular-weight HA has proinflammatory properties, and studies in mice and women reveal increased concentrations during labor and in the puerperium (Akgul, 2012; Ruscheinsky, 2008). The importance of regulated changes in HA size during cervical ripening and dilatation is supported by a study reporting hyaluronidase administration to the cervix for ripening in term pregnant women (Spallacci, 2007). Activation of intracellular signaling cascades and other biological functions requires interactions with cell-associated HA-binding proteins such as versican (Ruscheinsky, 2008).

Proteoglycans. These glycoproteins are composed of a protein core and GAG chains. Changes in the amount of core protein or in the number, length, or degree of sulfation of GAG chains can influence proteoglycan function. Although not well-defined, changes in proteoglycan composition are thought to accompany cervical ripening. At least three small leucine-rich proteoglycans are expressed in the cervix—decorin, biglycan, and fibromodulin (Westergren-Thorsson, 1998). In other connective tissues, decorin and other family members interact with collagen and influence the packing and order of collagen fibrils (Ameye, 2002). Collagen fibrils are rearranged in the skin of decorin-deficient mice and result in collagen fibers that are weakened, shortened, and disorganized (see Fig. 21-3). In addition to the cervix, these proteoglycans are expressed in the fetal membranes and uterus. Changes in expression levels may regulate fetal membrane tensile strength and uterine function (Meiner, 2007; Wu, 2012).
Inflammatory Changes. The marked changes within the extracellular matrix during cervical ripening in phase 2 are accompanied by stromal invasion with inflammatory cells. This has led to a model in which cervical ripening is considered an inflammatory process. As such, cervical chemoattractants attract inflammatory cells, which in turn release proteases that may aid degradation of collagen and other matrix components. In phase 3 or 4 of parturition, there is increased cervical expression of chemokines and collagenase/protease activity. It was assumed that processes regulating phases 3 and 4 of dilation and postpartum recovery of the cervix were similar to those in phase 2 of cervical ripening (Bokström, 1997; Osman, 2003; Sennström, 2000; Young, 2002). This has been challenged by observations from both human and animal studies. Sakamoto and associates (2004, 2005) found no correlation between the degree of clinical cervical ripening and the tissue concentrations of cervical neutrophil-chemoattractant interleukin 8 (IL-8). Microarray studies comparing gene expression patterns at term before and after cervical ripening report little increase in expression of proinflammatory genes. In contrast, there is a robust increase in proinflammatory and immunosuppressive genes in the cervix after delivery compared with during cervical ripening (Bollapragada, 2009; Hassan, 2006, 2009).

In mouse models, monocyte migration, but not activation, takes place before labor (Timmons, 2006, 2007, 2009). Mice deficient in the chemokine receptor CCR2, important in monocyte homing to tissues, have normally timed labor. This further supports the suggestion that labor is not initiated by an inflammatory response (Menzies, 2012). Furthermore, tissue depletion of neutrophils before birth has no effect on the timing or success of parturition. Finally, activation of neutrophils, proinflammatory M1 macrophages, and alternatively of activated M2 macrophages is increased within 2 hours after birth. This suggests a role for inflammatory cells in postpartum cervical remodeling and repair.

Induction and Prevention of Cervical Ripening

There are no therapies to prevent premature cervical ripening. Cervical cerclage is used to circumvent cervical insufficiency, although success appears limited (Owen, 2012). In contrast, treatment to promote cervical ripening for labor induction includes direct application of prostaglandins $E_2$ ($PGE_2$) and $F_2\alpha$ ($PGF_2\alpha$). Prostaglandins likely modify extracellular matrix structure to aid ripening. Although the role of prostaglandins in the normal physiology of cervical ripening remains unclear, this property is useful clinically to assist labor induction (Chap. 26, p. 526). In some nonhuman species, the cascades of events that allow cervical ripening are induced by decreasing serum progesterone concentrations. And in humans, administration of progesterone antagonists causes cervical ripening. As discussed later, humans may have developed unique mechanisms to localize decreases in progesterone action in the cervix and myometrium.

Phase 3 of Parturition: Labor

This phase is synonymous with active labor, which is customarily divided into three stages. These compose the commonly used labor graph shown in Figure 21-2. The clinical stages of labor may be summarized as follows. The first stage begins when spaced uterine contractions of sufficient frequency, intensity, and duration are attained to bring about cervical thinning, or effacement. This labor stage ends when the cervix is fully dilated—about 10 cm—to allow passage of the term-sized fetus. The first stage of labor, therefore, is the stage of cervical effacement and dilatation.

The second stage begins when cervical dilatation is complete and ends with delivery. Thus, the second stage of labor is the stage of fetal expulsion. Last, the third stage begins immediately after delivery of the fetus and ends with the delivery of the placenta. Thus, the third stage of labor is the
stage of placental separation and expulsion.

First Stage of Labor: Clinical Onset of Labor

In some women, forceful uterine contractions that effect delivery begin suddenly. In others, labor initiation is heralded by spontaneous release of a small amount of blood-tinged mucus from the vagina. This extrusion of the mucus plug that had previously filled the cervical canal during pregnancy is referred to as “show” or “bloody show.” There is very little blood with the mucous plug, and its passage indicates that labor is already in progress or likely will ensue in hours to days.

Uterine Labor Contractions

Unique among physiological muscular contractions, those of uterine smooth muscle during labor are painful. The cause of this is not known definitely, but several possibilities have been suggested: (1) hypoxia of the contracted myometrium—such as that with angina pectoris; (2) compression of nerve ganglia in the cervix and lower uterus by contracted interlocking muscle bundles; (3) cervical stretching during dilatation; and (4) stretching of the peritoneum overlying the fundus.

Of these, compression of nerve ganglia in the cervix and lower uterine segment by the contracting myometrium is an especially attractive hypothesis. Paracervical infiltration with local anesthetic usually produces appreciable pain relief with contractions (Chap. 25, p. 509). Uterine contractions are involuntary and, for the most part, independent of extrauterine control. Neural blockade from epidural analgesia does not diminish their frequency or intensity. In other examples, myometrial contractions in paraplegic women and in women after bilateral lumbar sympathectomy are normal but painless.

Mechanical stretching of the cervix enhances uterine activity in several species, including humans. This phenomenon has been referred to as the Ferguson reflex (Ferguson, 1941). Its exact mechanism is not clear, and release of oxytocin has been suggested but not proven. Manipulation of the cervix and “stripping” the fetal membranes is associated with an increase in blood levels of prostaglandin F$_{2\alpha}$ metabolite (PGFM).

The interval between contractions diminishes gradually from approximately 10 minutes at the onset of first-stage labor to as little as 1 minute or less in the second stage. Periods of relaxation between contractions, however, are essential for fetal welfare. Unremitting contractions compromise uteroplacental blood flow sufficiently to cause fetal hypoxemia. In active-phase labor, the duration of each contraction ranges from 30 to 90 seconds, averaging about 1 minute. There is appreciable variability in contraction intensity during normal labor. Specifically, amnionic fluid pressures generated by contractions during spontaneous labor average 40 mm Hg, but vary from 20 to 60 mm Hg (Chap. 24, p. 498).

Distinct Lower and Upper Uterine Segments. During active labor, the anatomical uterine divisions that were initiated in phase 2 of parturition become increasingly evident (Figs. 21-4 and 21-5). By abdominal palpation, even before membrane rupture, the two segments can sometimes be differentiated. The upper segment is firm during contractions, whereas the lower segment is softer, distended, and more passive. This mechanism is imperative because if the entire myometrium, including the lower uterine segment and cervix, were to contract simultaneously and with equal intensity, the net expulsive force would be markedly decreased. Thus, the upper segment contracts, retracts, and expels the fetus. In response to these contractions, the softened
lower uterine segment and cervix dilate and thereby form a greatly expanded, thinned-out tube through which the fetus can pass.

**FIGURE 21-4** Sequence of development of the segments and rings in the uterus at term and in labor. Note comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower uterine segment is derived from the isthmus, and the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. Anat. I.O. = anatomical internal os; E.O. = external os; Hist. I.O. = histological internal os; Ph. R.R. = physiological retraction ring.
FIGURE 21-5 The uterus at the time of vaginal delivery. The active upper segment retracts around the presenting part as the fetus descends through the birth canal. In the passive lower segment, there is considerably less myometrial tone.

The myometrium of the upper segment does not relax to its original length after contractions. Instead, it becomes relatively fixed at a shorter length. The upper active uterine segment contracts down on its diminishing contents, but myometrial tension remains constant. The net effect is to take up slack, thus maintaining the advantage gained in expulsion of the fetus. Concurrently, the uterine musculature is kept in firm contact with the uterine contents. As the consequence of retraction, each successive contraction commences where its predecessor left off. Thus, the upper part of the uterine cavity becomes slightly smaller with each successive contraction. Because of the successive shortening of the muscular fibers, the upper active segment becomes progressively thickened throughout first- and second-stage labor (see Fig. 21-4). This process continues and results in a tremendously thickened upper uterine segment immediately after delivery.

Clinically, it is important to understand that the phenomenon of upper segment retraction is contingent on a decrease in the volume of its contents. For this to happen, particularly early in labor when the entire uterus is virtually a closed sac with only minimal cervical dilatation, the musculature of the lower segment must stretch. This permits an increasing portion of the uterine contents to occupy the lower segment. The upper segment retracts only to the extent that the lower segment distends and the cervix dilates.

Relaxation of the lower uterine segment mirrors the same gradual progression of retraction. Recall that after each contraction of the upper segment, the muscles do not return to their previous
Changes in Uterine Shape During Labor. Each contraction produces an elongation of the ovoid uterine shape with a concomitant decrease in horizontal diameter. This change in shape has important effects on the labor process. First, there is increased fetal axis pressure, that is, the decreased horizontal diameter serves to straighten the fetal vertebral column. This presses the upper pole of the fetus firmly against the fundus, whereas the lower pole is thrust downward. The lengthening of the ovoid shape has been estimated at 5 and 10 cm. Second, with lengthening of the uterus, the longitudinal muscle fibers are drawn taut. As a result, the lower segment and cervix are the only parts of the uterus that are flexible, and these are pulled upward and around the lower pole of the fetus.

Ancillary Forces in Labor
After the cervix is dilated fully, the most important force in fetal expulsion is that produced by maternal intraabdominal pressure. Contraction of the abdominal muscles simultaneously with forced respiratory efforts with the glottis closed is referred to as pushing. The force is similar to that with defecation, but the intensity usually is much greater. The importance of intraabdominal pressure is shown by the prolonged descent during labor in paraplegic women and in those with a dense epidural block. And, although increased intraabdominal pressure is necessary to complete second-stage labor, pushing accomplishes little in the first stage. It exhausts the mother, and its associated increased intrauterine pressures may be harmful to the fetus.

Cervical Changes
As the result of contraction forces, two fundamental changes—effacement and dilatation—occur in the already-ripened cervix. For an average-sized fetal head to pass through the cervix, its canal must dilate to a diameter of approximately 10 cm. At this time, the cervix is said to be completely or fully dilated. Although there may be no fetal descent during cervical effacement, most commonly the presenting fetal part descends somewhat as the cervix dilates. During second-stage labor in nulliparas, the presenting part typically descends slowly and steadily. In multiparas, however, particularly those of high parity, descent may be rapid.

Cervical effacement is “obliteration” or “taking up” of the cervix. It is manifest clinically by shortening of the cervical canal from a length of approximately 2 cm to a mere circular orifice with almost paper-thin edges. The muscular fibers at the level of the internal cervical os are pulled upward, or “taken up,” into the lower uterine segment. The condition of the external os remains temporarily unchanged (Fig. 21-6).
FIGURE 21-6 Schematic showing effacement and dilatation. **A.** Before labor, the primigravid cervix is long and undilated in contrast to that of the multipara, which has dilatation of the internal and external os. **B.** As effacement begins, the multiparous cervix shows dilatation and funneling of the internal os. This is less apparent in the primigravid cervix. **C.** As complete effacement is achieved in the primigravid cervix, dilation is minimal. The reverse is true in the multipara.

Effacement may be compared to a funneling process in which the whole length of a narrow cylinder is converted into a very obtuse, flaring funnel with a small circular opening. Because of increased myometrial activity during uterine preparedness for labor, appreciable effacement of a softened cervix sometimes is accomplished before active labor begins. Effacement causes expulsion of the mucous plug as the cervical canal is shortened.

Because the lower segment and cervix have lesser resistance during a contraction, a centrifugal pull is exerted on the cervix and creates *cervical dilatation* (Fig. 21-7). As uterine contractions cause pressure on the membranes, the hydrostatic action of the amnionic sac in turn dilates the cervical canal like a wedge. In the absence of intact membranes, the pressure of the presenting fetal part against the cervix and lower uterine segment is similarly effective. Early rupture of the membranes does not retard cervical dilatation so long as the presenting fetal part is positioned to exert pressure against the cervix and lower segment. The process of cervical effacement and
dilatation causes formation of the *forebag* of amnionic fluid. This is the leading portion of fluid and amnionic sac located in front of the presenting part.
FIGURE 21-7 Hydrostatic action of membranes in effecting cervical effacement and dilatation. With labor progression, note the changing relations of the internal and external os in (A), (B), and (C). Although not shown in this diagram, with membrane rupture, the presenting part, applied to the cervix and the forming lower uterine segment, acts similarly.

Referring back to Figure 21-2, recall that cervical dilatation is divided into latent and active phases. The active phase is subdivided further into the acceleration phase, the phase of maximum slope, and the deceleration phase (Friedman, 1978). The duration of the latent phase is more variable and sensitive to changes by extraneous factors. For example, sedation may prolong the latent phase, and myometrial stimulation shortens it. The latent phase duration has little bearing on the subsequent course of labor, whereas the characteristics of the accelerated phase are usually predictive of labor outcome. Completion of cervical dilatation during the active phase is accomplished by cervical retraction about the presenting part. The first stage ends when cervical dilatation is complete. Once the second stage commences, only progressive descent of the presenting part will foretell further progress.

Second Stage of Labor: Fetal Descent

In many nulliparas, engagement of the head is accomplished before labor begins. That said, the head may not descend further until late in labor. In the descent pattern of normal labor, a typical hyperbolic curve is formed when the station of the fetal head is plotted as a function of labor duration. Station describes descent of the fetal biparietal diameter in relation to a line drawn between maternal ischial spines (Chap. 22, p. 449). Active descent usually takes place after dilatation has progressed for some time (Fig. 21-8). In nulliparas, increased rates of descent are observed ordinarily during cervical dilatation phase of maximum slope. At this time, the speed of descent is also maximal and is maintained until the presenting part reaches the perineal floor (Friedman, 1978).
FIGURE 21-8 Labor course divided on the basis of expected evolution of the dilatation and descent curves into three functional divisions. The preparatory division includes the latent and acceleration phases. The dilatational division is the phase of maximum slope of dilatation. The pelvic division encompasses both the deceleration phase and the second stage, which is concurrent with the phase of maximum slope of fetal descent. (Redrawn from Friedman, 1978.)

Pelvic Floor Changes During Labor

The birth canal is supported and is functionally closed by several layers of tissues that together form the pelvic floor. These anatomical structures are shown in detail in Chapter 2 (p. 22). The most important are the levator ani muscle and the fibromuscular connective tissue covering its upper and lower surfaces. There are marked changes in the biomechanical properties of these structures and of the vaginal wall during parturition. These result from altered extracellular matrix structure or composition (Lowder, 2007; Rahn, 2008). The levator ani consists of the pubovisceral, puborectalis, and iliococcygeus muscles, which close the lower end of the pelvic cavity as a diaphragm. Thereby, a concave upper and a convex lower surface are presented. The posterior and lateral portions of the pelvic floor, which are not spanned by the levator ani, are occupied bilaterally by the piriformis and coccygeus muscles.

The levator ani muscle varies in thickness from 3 to 5 mm, although its margins encircling the rectum and vagina are somewhat thicker. During pregnancy, the levator ani usually undergoes hypertrophy, forming a thick band that extends backward from the pubis and encircles the vagina about 2 cm above the plane of the hymen. On contraction, the levator ani draws both the rectum and the vagina forward and upward in the direction of the symphysis pubis and thereby acts to close the vagina.

In the first stage of labor, the membranes, when intact, and the fetal presenting part serve to dilate the upper vagina. The most marked change consists of stretching of the levator ani muscle
fibers. This is accompanied by thinning of the central portion of the perineum, which becomes transformed from a wedge-shaped, 5-cm-thick tissue mass to a thin, almost transparent membranous structure less than 1 cm thick. When the perineum is distended maximally, the anus becomes markedly dilated and presents an opening that varies from 2 to 3 cm in diameter and through which the anterior wall of the rectum bulges.

**Third Stage of Labor: Delivery of Placenta and Membranes**

This stage begins immediately after fetal delivery and involves separation and expulsion of the placenta and membranes. As the neonate is born, the uterus spontaneously contracts around its diminishing contents. Normally, by the time the newborn is completely delivered, the uterine cavity is nearly obliterated. The organ consists of an almost solid mass of muscle, several centimeters thick, above the thinner lower segment. The uterine fundus now lies just below the level of the umbilicus.

This sudden diminution in uterine size is inevitably accompanied by a decrease in the area of the placental implantation site (Fig. 21-9). For the placenta to accommodate itself to this reduced area, it increases in thickness, but because of limited placental elasticity, it is forced to buckle. The resulting tension pulls the weakest layer—decidua spongiosa—from that site. Thus, placental separation follows the disproportion created between the relatively unchanged placental size and the reduced size of the implantation site.
FIGURE 21-9 Diminution in size of the placental site after birth of the infant. A. Spatial relations before birth. B. Placental spatial relations after birth.

Cleavage of the placenta is aided greatly by the loose structure of the spongy decidua, which may be likened to the row of perforations between postage stamps. As separation proceeds, a hematoma forms between the separating placenta/decidua and the decidua that remains attached to the myometrium. The hematoma is usually the result rather than the cause of the separation, because in some cases bleeding is negligible.

Fetal Membrane Separation and Placental Extrusion. The great decrease in uterine cavity surface area simultaneously throws the fetal membranes—the amniochorion and the parietal decidua—into innumerable folds (Fig. 21-10). Membranes usually remain in situ until placental separation is nearly completed. These are then peeled off the uterine wall, partly by further contraction of the myometrium and partly by traction that is exerted by the separated placenta.
After the placenta has separated, it may be expelled by increased abdominal pressure. Completion of the third stage is also accomplished by alternately compressing and elevating the fundus, while exerting minimal traction on the umbilical cord (Fig. 27-12, p. 546). The retroplacental hematoma either follows the placenta or is found within the inverted sac formed by the membranes. In this process, known as the Schultze mechanism of placental expulsion, blood from the placental site pours into the membrane sac and does not escape externally until after extrusion of the placenta. In the other form of placental extrusion, known as the Duncan mechanism, the placenta separates first at the periphery and blood collects between the membranes and the uterine wall and escapes from the vagina. In this circumstance, the placenta descends sideways, and its maternal surface appears first.

Phase 4 of Parturition: The Puerperium

Immediately and for about an hour or so after delivery, the myometrium remains in a state of rigid and persistent contraction and retraction. This directly compresses large uterine vessels and allows thrombosis of their lumens to prevent hemorrhage (Fig. 2-11, p. 27). This is typically augmented by uterotonics (Chap. 27, p. 547).

Uterine involution and cervical repair, both remodeling processes that restore these organs to the nonpregnant state, follow in a timely fashion. These protect the reproductive tract from invasion by commensal microorganisms and restore endometrial responsiveness to normal hormonal cyclicity.

During the early puerperium, there is onset of lactogenesis and milk let-down in mammary glands, as described in Chapter 36 (p. 672). Reinstitution of ovulation signals preparation for the
This generally occurs within 4 to 6 weeks after birth, but it is dependent on the duration of breast feeding and lactation-induced, prolactin-mediated anovulation and amenorrhea.

PHYSIOLOGICAL AND BIOCHEMICAL PROCESSES REGULATING PARTURITION

There are two general contemporaneous theorems concerning labor initiation. Viewed simplistically, the first is the functional loss of pregnancy maintenance factors, whereas the second focuses on synthesis of factors that induce parturition. Some investigators also speculate that the mature fetus is the source of the initial signal for parturition commencement. Others suggest that one or more uterotonsins, produced in increased amounts, or an increased population of myometrial uterototonin receptors is the proximate cause. Indeed, an obligatory role for one or more uterotonsins is included in most parturition theories, as either a primary or a secondary phenomenon in the final events of childbirth. Both rely on careful regulation of smooth muscle contraction.

Myometrial Action

Anatomical and Physiological Considerations

There are unique characteristics of smooth muscle, including myometrium, compared with those of skeletal muscle that may confer advantages for uterine contraction efficiency and fetal delivery. First, the degree of smooth-muscle cell shortening with contractions may be one order of magnitude greater than that attained in striated muscle cells. Second, forces can be exerted in smooth muscle cells in multiple directions. In contrast, the contraction force generated by skeletal muscle is always aligned with the axis of the muscle fibers. Third, smooth muscle is not organized in the same manner as skeletal muscle. In myometrium, the thick and thin filaments are found in long, random bundles throughout the cells. This plexiform arrangement aids greater shortening and force-generating capacity. Last, greater multidirectional force generation in the uterine fundus compared with that of the lower uterine segment permits versatility in expulsive force directionality. These forces thus can be brought to bear irrespective of the fetal lie or presentation.

Regulation of Myometrial Contraction and Relaxation

Myometrial contraction is controlled by transcription of key genes, which produce proteins that repress or enhance cellular contractility. These proteins function to: (1) enhance the interactions between the actin and myosin proteins that cause muscle contraction, (2) increase excitability of individual myometrial cells, and (3) promote intracellular cross talk that allows development of synchronous contractions.

Actin-Myosin Interactions. The interaction of myosin and actin is essential to muscle contraction. This interaction requires that actin be converted from a globular to a filamentous form. Moreover, actin must be attached to the cytoskeleton at focal points in the cell membrane to allow development of tension (Fig. 21-11). Actin must partner with myosin, which is composed of multiple light and heavy chains. The interaction of myosin and actin activates adenosine triphosphatase (ATPase), hydrolyzes adenosine triphosphate, and generates force. This interaction is brought about by enzymatic phosphorylation of the 20-kDa light chain of myosin (Stull, 1988, 1998). This is catalyzed by the enzyme myosin light-chain kinase, which is activated by calcium.
Calcium binds to calmodulin, a calcium-binding regulatory protein, which in turn binds to and activates myosin light-chain kinase.

FIGURE 21-11 Uterine myocyte relaxation and contraction. A. Uterine relaxation is maintained by factors that increase myocyte cyclic adenosine monophosphate (cAMP). This activates protein kinase A (PKA) to promote phosphodiesterase activity with dephosphorylation of myosin light-chain kinase (MLCK). There are also processes that serve to maintain actin in a globular form, and thus to prevent fibril formation necessary for contractions. B. Uterine contractions result from reversal of these sequences. Actin now assumes a fibrillar form, and calcium enters the cell to combine with calmodulin to form complexes. These complexes activate MLCK to bring about phosphorylation of the myosin light chains. This generates ATPase activity to cause sliding of myosin over the actin fibrils, which is a uterine contractile. AC = adenylyl cyclase; Ca\textsuperscript{++} = calcium; DAG = diacylglycerol; Gs and Ga = G-receptor proteins; IP\textsubscript{3} = inositol triphosphate; LC20 = light chain 20; PIP\textsubscript{3} = phosphatidylinositol 3,4,5–triphosphate; PLC = phospholipase C; R-PKA = inactive protein kinase. (Redrawn from Smith, 2007.)

Intracellular Calcium. Agents that promote contraction act on myometrial cells to increase intracellular cytosolic calcium concentration—[Ca\textsuperscript{2+}]\textsubscript{i}. Or, they allow an influx of extracellular calcium through ligand- or voltage-regulated calcium channels (see Fig. 21-11). For example, prostaglandin F\textsubscript{2α} and oxytocin bind their respective receptors during labor to open ligand-activated calcium channels. Activation of these receptors also releases calcium from the sarcoplasmic reticulum to cause decreased electronegativity within the cell. Voltage-gated ion channels open, additional calcium ions move into the cell, and cellular depolarization follows.
The increase in $[\text{Ca}^{2+}]_i$ is often transient, but contractions can be prolonged through the inhibition of myosin phosphatase activity (Woodcock, 2004).

Conditions that decrease $[\text{Ca}^{2+}]_i$ and increase intracellular concentrations of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP) ordinarily promote uterine relaxation. Corticotropin-releasing hormone is one of several factors reported to regulate $[\text{Ca}^{2+}]_i$ and subsequently modulate expression of the large-conductance potassium channels (BKCa) in the human myometrium (Xu, 2011; You, 2012). Genetic studies in humans and transgenic overexpression in mice reveal that small-conductance calcium-activated K$^+$ isoform 3 (SK3) channels may also be important in maintenance of uterine relaxation (Day, 2011; Rada, 2012). SK3 channel expression declines at the end of term pregnancy as contractility is increased and overexpression of SK3 in transgenic mice dampens uterine contraction force to prevent delivery. Yet another potential mechanism for maintenance of relaxation shown in Figure 21-11 is the promotion of actin in a globular form rather than in fibrils required for contraction (Macphee, 2000; Yu, 1998).

In addition to myocyte contractility, myocyte excitability is also regulated by changes in the electrochemical potential gradient across the plasma membrane. Before labor, myocytes maintain a relatively high interior electronegativity. This state is maintained by the combined actions of the ATPase-driven sodium-potassium pump and the large conductance voltage- and Ca$^{2+}$-sensitive K channel—*maxi-K channel* (Parkington, 2001). During uterine quiescence, the maxi-K channel is open and allows potassium to leave the cell to maintain interior electronegativity. At the time of labor, changes in electronegativity lead to depolarization and contraction (Brainard, 2005; Chanrachakul, 2003). And, as parturition progresses, there is increased synchronization of electrical uterine activity.

**Myometrial Gap Junctions.** Cellular signals that control myometrial contraction and relaxation can be effectively transferred between cells through intercellular junctional channels. Communication is established between myocytes by gap junctions, which aid the passage of electrical or ionic coupling currents as well as metabolite coupling. The transmembrane channels that make up the gap junctions consist of two protein “hemi-channels” (Sáez, 2005). These *connexons* are each composed of six *connexin* subunit proteins (*Fig. 21-12*). These pairs of connexons establish a conduit between coupled cells for the exchange of small molecules that can be nutrients, waste, metabolites, second messengers, or ions.
The protein subunits of gap junction channels are called connexins. Six connexins form a hemichannel (connexon), and two connexons (one from each cell) form a gap junction channel. Connexons and gap junction channels can be formed from one or more connexin proteins. The composition of the gap junction channel is important for their selectivity with regard to passage of molecules and communication between cells.

Optimal numbers of gap junctions are believed to be important for electrical myometrial synchrony. Four described in the uterus are connexins 26, 40, 43, and 45. Connexin 43 junctions are scarce in the nonpregnant uterus, and they increase in size and abundance during human parturition (Chow, 1994). Also, mouse models deficient in connexin 43-enriched gap junctions exhibit delayed parturition, further supporting their role (Döring, 2006; Tong, 2009).

**Cell Surface Receptors.** There are various cell surface receptors that can directly regulate myocyte contractile state. Three major classes are G-protein-linked, ion channel-linked, and...
enzyme-linked. Multiple examples of each have been identified in human myometrium. These further appear to be modified during the phases of parturition. Most G-protein-coupled receptors are associated with adenylyl cyclase activation. Examples are the CRHR1α and the LH receptors (Fig. 21-13). Other G-protein-coupled myometrial receptors, however, are associated with G-protein-mediated activation of phospholipase C. Ligands for the G-protein-coupled receptors include numerous neuropeptides, hormones, and autacoids. Many of these are available to the myometrium during pregnancy in high concentration via endocrine or autocrine mechanisms (Fig. 21-14).

**FIGURE 21-13** G-protein-coupled receptor signal transduction pathways. A. Receptors coupled to heterotrimeric guanosine-triphosphate (GTP)-binding proteins (G proteins) are integral transmembrane proteins that transduce extracellular signals to the cell interior. G-protein-coupled receptors exhibit a common structural motif consisting of seven membrane-spanning regions. B. Receptor occupation promotes interaction between the receptor and the G protein on the interior surface of the membrane. This induces an exchange of guanosine diphosphate (GDP) for GTP on the G protein α subunit and dissociation of the α subunit from the βγ heterodimer. Depending on its isoform, the GTP-α subunit complex mediates intracellular signaling either indirectly by acting on effector molecules such as adenylyl cyclase (AC) or phospholipase C (PLC), or directly by regulating ion channel or kinase function. cAMP = cyclic adenosine monophosphate; DAG = diacylglycerol; IP3 = inositol triphosphate.

CRH = corticotropin-releasing hormone; hCG = human chorionic gonadotropin; PGE₂ = prostaglandin E₂; PGI₂ = prostaglandin I₂; PGDH = 15-hydroxyprostaglandin dehydrogenase.

Cervical Dilatation During Labor

There is a large influx of leukocytes into the cervical stroma with cervical dilatation (Sakamoto, 2004, 2005). Cervical tissue levels of leukocyte chemoattractants such as IL-8 are increased just after delivery, as are IL-8 receptor levels. Identification of genes upregulated just after vaginal delivery further suggests that dilatation and early stages of postpartum repair are aided by inflammatory responses, apoptosis, and activation of proteases that degrade extracellular matrix components (Hassan, 2006; Havelock, 2005). The composition of glycosaminoglycans.
proteoglycans, and poorly formed collagen fibrils that were necessary during ripening and dilatation must be rapidly removed to allow reorganization and recovery of cervical structure. In the days that follow parturition, recovery of cervical structure involves processes that resolve inflammation, promote tissue repair, and regenerate dense cervical connective tissue with structural integrity and mechanical strength.

### Phase 1: Uterine Quiescence and Cervical Competence

Myometrial quiescence is so remarkable and successful that it probably is induced by multiple independent and cooperative biomolecular processes. Individually, some of these processes may be redundant to ensure pregnancy continuance. It is likely that all manners of molecular systems—neural, endocrine, paracrine, and autocrine—are called on to implement and coordinate a state of relative uterine unresponsiveness. Moreover, a complementary “fail-safe” system that protects the uterus against agents that could perturb the tranquility of phase 1 also must be in place (see Fig. 21-14).

As shown in **Figure 21-15**, phase 1 of human parturition and its quiescence are likely the result of many factors that include: (1) actions of estrogen and progesterone via intracellular receptors, (2) myometrial cell plasma membrane receptor-mediated increases in cAMP, (3) generation of cGMP, and (4) other systems, including modification of myometrial-cell ion channels.
Progestosterone and Estrogen Contributions

In many species, the role of the sex steroid hormones is clear—progesterone inhibits and estrogen promotes the events leading to parturition. In humans, however, it seems most likely that both estrogen and progesterone are components of a broader-based molecular system that implements and maintains uterine quiescence. In many species, the removal of progesterone, that is, \textit{progesterone withdrawal}, directly precedes progression of phase 1 into phase 2 of parturition. In addition, providing progesterone to some species will delay parturition via a decrease in myometrial activity and continued cervical competency (Challis, 1994). Studies in these species have led to a better understanding of why the progesterone-replete myometrium of phase 1 is relatively noncontractile.

Plasma levels of estrogen and progesterone in normal pregnancy are enormous and in great excess of the affinity constants for their receptors. For this reason, it is difficult to comprehend how relatively subtle changes in the ratio of their concentrations could modulate physiological processes during pregnancy. The teleological evidence, however, for an increased progesterone-to-estrogen ratio in the maintenance of pregnancy and a decline in the progesterone-to-estrogen ratio for parturition is overwhelming. In all species studied to date, including humans, administration of the progesterone-receptor antagonists \textit{mifepristone (RU-486)} or \textit{onapristone} will promote some or all key features of parturition. These include cervical ripening, increased cervical distensibility, and increased uterine sensitivity to uterotonins (Bygdeman, 1994; Chwalisz, 1994a; Wolf, 1993).

The exact role of estrogen in regulating human uterine activity and cervical competency is less well understood. That said, it appears that estrogen can act to promote progesterone responsiveness and, in doing so, promote uterine quiescence. The estrogen receptor, acting via the estrogen-response element of the progesterone-receptor gene, induces progesterone-receptor synthesis, which allows increased progesterone-mediated function.

Myometrial Cell-to-Cell Communication. Progesterone maintains uterine quiescence by various mechanisms that cause decreased expression of the contraction-associated proteins (CAPs)(p. 410). Progesterone can promote expression of the inhibitory transcription factor ZEB1—zinc finger E-box binding homeobox protein 1—which can inhibit expression of the CAP genes, connexin 43, and oxytocin receptor (Renthal, 2010). As another mechanism, progesterone bound to the progesterone receptor (PR) can recruit coregulatory factors. These include PSF—polypyrimidine tract binding protein-associated splicing factor—and Sin3A/HDACs—yeast switch-dependent3 homologue A/histone deacetylase corepressor complex—which inhibit expression of the gene encoding the gap junctional protein connexin 43 in rat and human myocytes (Xie, 2012).

At the end of pregnancy, increased stretch along with increased estrogen dominance results in a decline in PSF and Sin/HDAC levels, thus abrogating the suppression of connexin 43 expression by progesterone. Additionally, with loss of progesterone function at term, ZEB1 levels decline due to increased production of small regulatory RNAs termed microRNAs. This releases inhibition of connexin 43 and oxytocin receptor levels to promote increased uterine contractility (Renthal, 2010; Williams, 2012b).
A number of G-protein-coupled receptors that normally are associated with G\(_{\alpha}\)s-mediated activation of adenylyl cyclase and increased levels of cAMP are present in myometrium. These receptors together with appropriate ligands may act in concert with sex steroid hormones as part of a fail-safe system to maintain uterine quiescence (Price, 2000; Sanborn, 1998).

**Beta-Adrenoreceptors.** These receptors are prototypical examples of cAMP signaling causing myometrium relaxation. Agents binding to these receptors have been used for tocolysis with preterm labor and include ritodrine and terbutaline (Chap. 42, p. 852). β-Adrenergic receptors mediate G\(_{\alpha}\)s-stimulated increases in adenylyl cyclase, increased levels of cAMP, and myometrial cell relaxation. The rate-limiting factor is likely the number of receptors expressed and the level of adenylyl cyclase expression.

**Luteinizing Hormone (LH) and Human Chorionic Gonadotropin (hCG) Receptors.** These hormones share the same receptor, and this G-protein-coupled receptor has been demonstrated in myometrial smooth muscle and blood vessels (Lei, 1992; Ziecik, 1992). Levels of myometrial LH-hCG receptors during pregnancy are greater before than during labor (Zuo, 1994). Chorionic gonadotropin acts to activate adenylyl cyclase by way of a plasma membrane receptor–G\(_{\alpha}\)s-linked system. This decreases contraction frequency and force and decreases the number of tissue-specific myometrial cell gap junctions (Ambrus, 1994; Eta, 1994). Thus, high circulating levels of hCG may be one mechanism causing uterine quiescence.

**Relaxin.** This peptide hormone consists of an A and B chain and is structurally similar to the insulin family of proteins (Bogic, 1995; Weiss, 1995). Relaxin mediates lengthening of the pubic ligament, cervical softening, vaginal relaxation, and inhibition of myometrial contractions. There are two separate human relaxin genes, designated H1 and H2. The H1 gene is primarily expressed in the decidua, trophoblast, and prostate, whereas the H2 gene is primarily expressed in the corpus luteum.

Relaxin in plasma of pregnant women is believed to originate exclusively from corpus luteum secretion. Plasma levels peak at approximately 1 ng/mL between 8 and 12 weeks’ gestation. Thereafter, they decline to lower levels that persist until term. Its plasma membrane receptor—relaxin family peptide receptor 1 (RXFP1)—mediates activation of adenylyl cyclase. Relaxin inhibits contractions of nonpregnant myometrial strips, but not those of uterine tissue taken from pregnant women. It also effects cervical remodeling through cell proliferation and modulation of extracellular matrix components such as collagen and hyaluronan (Park, 2005; Soh, 2012).

**Corticotropin-Releasing Hormone (CRH).** This hormone is synthesized in the placenta and hypothalamus. As discussed later, CRH plasma levels increase dramatically during the final 6 to 8 weeks of normal pregnancy and have been implicated in the mechanisms controlling the timing of human parturition (Smith, 2007; Wadhwa, 1998). CRH appears to promote myometrial quiescence during most of pregnancy and aids myometrial contractions with onset of parturition. Recent studies suggest that these opposing actions are achieved by differential actions of CRH via its receptor CRHR1. In the term nonlaboring myometrium, the interaction of CRH with its CRHR1 receptor results in activation of the Gs-adenylate cyclase-cAMP signaling pathway. This results in inhibition of inositol triphosphate (IP\(_3\)) production and a stabilization of [Ca\(^{2+}\)]\(_i\) (You, 2012). In term laboring myometrium, [Ca\(^{2+}\)]\(_i\) is increased by CRH activation of G proteins Gq and Gi and
leads to stimulation of IP$_3$ production and increased contractility. Another aspect of CRH regulation is union of CRH to its binding protein, which can limit bioavailability. CRH-binding protein levels are high during pregnancy and are reported to decline at the time of labor.

**Prostaglandins.** These interact with a family of eight different G-protein-coupled receptors, several of which are expressed in myometrium (Myatt, 2004). Prostaglandins usually are considered as uterotonins. However, their effects are diverse, and some act as smooth muscle relaxants.

The major synthetic pathways involved in prostaglandin biosynthesis are shown in Figure 21-16. Prostaglandins are produced using plasma membrane-derived arachidonic acid, which usually is released by the action of the phospholipases A$_2$ or C. Arachidonic acid can then act as substrate for both type 1 and type 2 prostaglandin H synthase (PGHS-1 and -2), which are also called cyclooxygenase-1 and -2 (COX-1 and -2). Both PGHS isoforms convert arachidonic acid to the unstable endo-peroxide prostaglandin G$_2$ and then to prostaglandin H$_2$. These enzymes are the target of many nonsteroidal antiinflammatory drugs (NSAIDs). Indeed, the tocolytic actions of specific NSAIDs, as discussed in Chapter 42 (p. 852), were considered promising until they were shown to have adverse fetal effects (Loudon, 2003; Olson, 2003, 2007).
Through prostaglandin isomerases, prostaglandin H\(_2\) is converted to active prostaglandins, including PGE\(_2\), PGF\(_{2\alpha}\), and PGI\(_2\). Isomerase expression is tissue-specific and thereby controls the relative production of various prostaglandins. Another important control point for prostaglandin activity is its metabolism, which most often is through the action of 15-hydroxyprostaglandin dehydrogenase (PGDH). Expression of this enzyme can be regulated in the uterus, which is important because of its ability to rapidly inactivate prostaglandins.

The effect of prostaglandins on tissue targets is complicated in that there are a number of G-
protein-coupled prostaglandin receptors (Coleman, 1994). This family of receptors is classified according to the binding specificity of a given receptor to a particular prostaglandin. Both PGE$_2$ and PG$_I_2$ could potentially act to maintain uterine quiescence by increasing cAMP signaling, yet PGE$_2$ can promote uterine contractility through binding to prostaglandin E receptors 1 and 3 (EP$_1$ and EP$_3$). Also, PGE$_2$, PGD$_2$, and PG$_I_2$ have been shown to cause vascular smooth muscle relaxation and vasodilatation in many circumstances. Thus, either the generation of specific prostaglandins or the relative expression of the various prostaglandin receptors may determine myometrial responses to prostaglandins (Lyall, 2002; Olson, 2003, 2007; Smith, 2001; Smith, 1998).

In addition to gestational changes, other studies show that there may be regional changes in the upper and lower uterine segments. COX-2 expression is spatially regulated in the myometrium and cervix in pregnancy and labor, with an increasing concentration gradient from the fundus to the cervix (Havelock, 2005). Thus, it is entirely possible that prostanoids contribute to myometrial relaxation at one stage of pregnancy and to regional fundal myometrial contractions after parturition initiation (Myatt, 2004).

**Atrial and Brain Natriuretic Peptides and Cyclic Guanosine Monophosphate (cGMP)**

Activation of guanylyl cyclase increases intracellular cGMP levels, which promotes smooth muscle relaxation (Word, 1993). Intracellular cGMP levels are increased in the pregnant myometrium and can be stimulated by atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP) receptors, and nitric oxide (Telfer, 2001). All of these factors and their receptors are expressed in the pregnant uterus. However, it remains unclear if these factors and intracellular cGMP play a role in uterine quiescence in normal pregnancy physiology (Itoh, 1994; Yallampalli, 1994a,b).

**Accelerated Uterotonin Degradation**

In addition to pregnancy-induced compounds that promote myometrial cell refractoriness, there are striking increases in the activity of enzymes that degrade or inactivate endogenously produced uterotons. Some of these and their degradative enzymes include: PGDH and prostaglandins enkephalinase and endothelins; oxytocinase and oxytocin; diamine oxidase and histamine; catechol $O$-methyltransferase and catecholamines; angiotensinases and angiotensin-II; and platelet-activating factor (PAF) acetylhydrolase and PAF. Activities of several of these enzymes are increased by progesterone, and many decrease late in gestation (Bates, 1979; Casey, 1980; Germain, 1994).

**Phase 2: Uterine Activation and Cervical Ripening**

**Classic Progesterone Withdrawal and Parturition**

Key factors in uterine activation are depicted in Figure 21-15. In species that exhibit progesterone withdrawal, parturition progression to labor can be blocked by administering progesterone to the mother. However, there are conflicting reports as to whether progesterone administration in pregnant women can delay the timely onset of parturition or prevent preterm labor. The possibility that progesterone-containing injections or vaginal suppositories may be used to prevent preterm labor has been studied in a number of randomized trials conducted during the past 15 years. These are discussed in Chapter 42 (p. 844), but in general, their use has marginal clinical benefits in
ProgestaTone Receptor Antagonists and Human Parturition

When the steroidal antiprogestin mifepristone (RU-486) is administered during the latter phase of the ovarian cycle, it induces menstruation prematurely. It is also an effective abortifacient during early pregnancy (Chap. 18, p. 368). Mifepristone is a classic steroid antagonist, acting at the level of the progesterone receptor. Although less effective in inducing abortion or labor in women later in pregnancy, mifepristone appears to have some effect on cervical ripening and on increasing myometrial sensitivity to uterotonicus (Berkane, 2005; Chwalisz, 1994a,b). These data suggest that humans have a mechanism for progesterone inactivation, whereby the myometrium and cervix become refractory to the inhibitory actions of progesterone.

Functional Progesterone Withdrawal in Human Parturition

As an alternative to classic progesterone withdrawal resulting from decreased secretion, research has focused on mechanisms that inhibit progesterone action in human pregnancy. Functional progesterone withdrawal or antagonism is possibly mediated through several mechanisms: (1) changes in the relative expression of the nuclear progesterone-receptor isoforms, PR-A, PR-B, and PR-C; (2) changes in the relative expression of membrane-bound progesterone receptors; (3) posttranslational modifications of the progesterone receptor; (4) alterations in PR activity through changes in the expression of coactivators or corepressors that directly influence receptor function; (5) local inactivation of progesterone by steroid-metabolizing enzymes or synthesis of a natural antagonist; and (6) microRNA regulation of progesterone-metabolizing enzymes and transcription factors that modulate uterine quiescence.

There is evidence that progesterone-receptor activity is decreased late in gestation. A series of studies have shown that the relative ratio of PR-A to PR-B within the myometrium, decidua, and chorion shifts late in gestation (Madsen, 2004; Mesiano, 2002; Pieber, 2001). Specifically, increased PR-A levels during parturition depress the antiinflammatory actions of PR-B and thereby promote proinflammatory gene expression at term (Tan, 2012). Moreover, these activities have been shown to be specific for the upper and lower uterine segments (Condon, 2003, 2006). Similarly, studies of cervical stroma suggest changes in receptor isoform concentrations (Stjernholm-Vladic, 2004). In addition, membrane PR isoforms are also expressed in the myometrium and placenta. However, it remains to be determined if they play a role to promote the transition from myometrial quiescence to activation (Chapman, 2006; Karteris, 2006; Zachariades, 2012). There is evidence in rodent models that local action of enzymes such as steroid 5α-reductase type 1 or 20α-hydroxysteroid dehydrogenase (20α-HSD) catabolize progesterone to metabolites that have a weak affinity for the progesterone receptor (Mahendroo, 1999; Piekorz, 2005). In the human cervix, decreased activity of 17β-hydroxysteroid dehydrogenase type 2 at term results in a net increase in estrogen and decline in progesterone levels (Andersson, 2008). Recent studies provide new insights into the regulatory role of small noncoding RNAs (microRNAs) in regulating expression of the steroid metabolizing enzyme 20α-HSD (Williams, 2012a). Increased expression of microRNA200a in the term myometrium blunts the expression of STAT5b, an inhibitor of 20α-HSD. Reduced STAT5b function allows increased 20α-HSD levels that result in increased progesterone metabolism and reduced progesterone function.

Taken together, all of these observations support the concept that multiple pathways exist for a functional progesterone withdrawal that includes changes in PR isoform and receptor coactivator levels, microRNA regulation, and increased local hormone metabolism to less active products.
Oxytocin Receptors

Because of its longstanding application for labor induction, it seemed logical that oxytocin must play a central role in spontaneous human labor. But this venerable hormone may have only a minor supporting role. Currently, it still is controversial whether oxytocin plays a role in the early phases of uterine activation or whether its sole function is in the expulsive phase of labor. Most studies of regulation of myometrial oxytocin-receptor synthesis have been performed in rodents. Disruption of the oxytocin receptor gene in the mouse does not affect parturition. This suggests that, at least in this species, multiple systems likely ensure that parturition occurs. There is little doubt, however, that there is an increase in myometrial oxytocin receptors during phase 2 of parturition. Moreover, their activation results in increased phospholipase C activity and subsequent increases in cytosolic calcium levels and uterine contractility.

Progesterone and estradiol appear to be the primary regulators of oxytocin receptor expression. Estradiol treatment in vivo or in myometrial explants increases myometrial oxytocin receptor concentrations. This action, however, is prevented by simultaneous treatment with progesterone (Fuchs, 1983). Progesterone also may act within the myometrial cell to increase oxytocin-receptor degradation and inhibit oxytocin activation of its receptor at the cell surface (Bogacki, 2002). These data indicate that one of the mechanisms whereby progesterone maintains uterine quiescence is through the inhibition of myometrial oxytocin response.

The increase in oxytocin receptor levels in nonhuman species appears to be mainly regulated either directly or indirectly by estradiol. Treatment of several species with estrogen leads to increased uterine oxytocin receptor levels (Blanks, 2003; Challis, 1994). Moreover, the level of oxytocin receptor mRNA in human myometrium at term is greater than that found in preterm myometrium (Wathes, 1999). Thus, increased receptors at term may be attributable to increased gene transcription. An estrogen response element, however, is not present in the oxytocin receptor gene, suggesting that the stimulatory effects of estrogen may be indirect.

Human studies suggest that inflammatory-related rapid-response genes may regulate oxytocin receptors (Bethin, 2003; Kimura, 1999; Massrieh, 2006). These receptors also are present in human endometrium and in decidua at term and stimulate prostaglandin production. In addition, these receptors are found in the myometrium and at lower levels in amniochorion-decidual tissues (Benedetto, 1990; Wathes, 1999).

Relaxin

Although relaxin may contribute to uterine quiescence, it also has roles in phase 2 of parturition. These include remodeling of the extracellular matrix of the uterus, cervix, vagina, breast, and pubic symphysis as well as promoting cell proliferation and inhibiting apoptosis. Its actions on cell proliferation and apoptosis are mediated through the G-protein-coupled receptor, RXFP1 whereas some but not all actions of relaxin on matrix remodeling are mediated through this receptor (Samuel, 2009; Yao, 2008). The precise mechanisms for modulation of matrix turnover have not been fully elucidated. However, relaxin appears to mediate glycosaminoglycan and proteoglycan synthesis and degrade matrix macromolecules such as collagen by induction of matrix metalloproteases. Relaxin promotes growth of the cervix, vagina, and pubic symphysis and is necessary for breast remodeling for lactation. Consistent with its proposed roles, mice deficient in relaxin or the RXFP1 receptor have protracted labor; show reduced growth of the cervix, vagina and symphysis; and are unable to nurse because of incomplete nipple development (Feng, 2005; Park, 2005; Rosa, 2012; Soh, 2012; Yao, 2008).
Fetal Contributions to Initiation of Parturition

It is intellectually intriguing to envision that the mature human fetus provides the signal to initiate parturition. Teleologically, this seems most logical because such a signal could be transmitted in several ways to suspend uterine quiescence. The fetus may provide a signal through a blood-borne agent that acts on the placenta. Research is ongoing to better understand the fetal signals that contribute to parturition initiation (Mendelson, 2009). Although signals may arise from the fetus, the uterus and cervix likely first must be prepared for labor before a uterotonin produced by or one whose release is stimulated by the fetus can be optimally effective (Casey, 1994).

Uterine Stretch and Parturition

There is now considerable evidence that fetal growth is an important component in uterine activation in phase 1 of parturition. In association with fetal growth, significant increases in myometrial tensile stress and amnionic fluid pressure follow (Fisk, 1992). With uterine activation, stretch is required for induction of specific contraction-associated proteins (CAPs). Specifically, stretch increases expression of the gap junction protein—connexin 43 and of oxytocin receptors. Gastrin-releasing peptide, a stimulatory agonist for smooth muscle, is increased by stretch in the myometrium (Tattersall, 2012). Others have hypothesized that stretch plays an integrated role with fetal-maternal endocrine cascades of uterine activation (Lyall, 2002; Ou, 1997, 1998).

Clinical support for a role of stretch comes from the observation that multifetal pregnancies are at a much greater risk for preterm labor than singletons. And preterm labor is also significantly more common in pregnancies complicated by hydramnios. Although the mechanisms causing preterm birth in these two examples are debated, a role for uterine stretch must be considered.

Cell signaling systems used by stretch to regulate the myometrial cell continue to be defined. This process—mechanotransduction—may include activation of cell-surface receptors or ion channels, transmission of signals through extracellular matrix, or release of autocrine molecules that act directly on myometrium (Shynlova, 2009; Young, 2011). For example, the extracellular matrix protein fibronectin and its cell-surface receptor, alpha 5 integrin receptor, are induced in the rodent by stretch (Shynlova, 2007). This interaction may aid force transduction during labor contraction by anchoring hypertrophied myocytes to the uterine extracellular matrix.

Fetal Endocrine Cascades Leading to Parturition

The ability of the fetus to provide endocrine signals that initiate parturition has been demonstrated in several species. Liggins and associates (1967, 1973) demonstrated that the fetus provides the signal for the timely onset of parturition in sheep. This signal was shown to come from the fetal hypothalamic-pituitary-adrenal axis (Whittle, 2001).

Defining the exact mechanisms regulating human parturition has proven more difficult, and all evidence suggests that it is not regulated in the exact manner seen in the sheep. Even so, activation of the human fetal hypothalamic-pituitary-adrenal-placental axis is considered a critical component of normal parturition. Moreover, premature activation of this axis is considered to prompt many cases of preterm labor (Challis, 2000, 2001). As in the sheep, steroid products of the human fetal adrenal gland are believed to have effects on the placenta and membranes that eventually transform myometrium from a quiescent to contractile state. A key component in the human may be the unique ability of the placenta to produce large amounts of CRH, as shown in Figure 21-17.
FIGURE 21-17 The placental–fetal adrenal endocrine cascade. In late gestation, placental corticotropin-releasing hormone (CRH) stimulates fetal adrenal production of dehydroepiandrosterone sulfate (DHEA-S) and cortisol. The latter stimulates production of placental CRH, which leads to a feed-forward cascade that enhances adrenal steroid hormone production. ACTH = adrenocorticotropic hormone.

Placental Corticotropin-Releasing Hormone Production. A CRH hormone identical to maternal and fetal hypothalamic CRH is synthesized by the placenta in relatively large amounts (Grino, 1987; Saijonmaa, 1988). One important difference is that, unlike hypothalamic CRH, which is under glucocorticoid negative feedback, cortisol has been shown to stimulate placental CRH production. This is by activation of the transcription factor, nuclear factor kappa B (NF-κB) (Jones, 1989; Marinoni, 1998; Thomson, 2013). This ability makes it possible to create a feed-forward endocrine cascade that does not end until delivery.

Maternal plasma CRH levels are low in the first trimester and rise from midgestation to term. In the last 12 weeks, CRH plasma levels rise exponentially, peaking during labor and then falling precipitously after delivery (Frim, 1988; Sasaki, 1987). Amnionic fluid CRH levels similarly increase in late gestation. CRH is the only trophic hormone-releasing factor to have a specific serum binding protein. During most of pregnancy, it appears that CRH-binding protein (CRH-BP) binds most maternal circulating CRH, and this inactivates it (Lowry, 1993). During late pregnancy, however, CRH-BP levels in both maternal plasma and amnionic fluid decline, leading to markedly increased levels of bioavailable CRH (Perkins, 1995; Petraglia, 1997).

In pregnancies in which the fetus can be considered to be “stressed” from various complications, concentrations of CRH in fetal plasma, amnionic fluid, and maternal plasma are increased compared with those seen in normal gestation (Berkowitz, 1996; Goland, 1993; McGrath, 2002; Perkins, 1995). The placenta is likely the source for this increased CRF concentration (Torricelli, 2011). For example, placental CRH content was fourfold higher in placentas from women with preeclampsia than in those from normal pregnancies (Perkins, 1995). Such increases in placental CRH production during normal gestation and the excessive secretion of placental CRH in complicated pregnancies may play a role in fetal adrenal cortisol synthesis (Murphy, 1982). They also may result in the supranormal levels of umbilical cord blood cortisol noted in stressed neonates (Falkenberg, 1999; Goland, 1994).
Placental CRH has been proposed to play several roles in parturition regulation. Placental CRH may enhance fetal cortisol production to provide positive feedback so that the placenta produces more CRH. Late in pregnancy—phase 2 or 3 of parturition—modification in the CRH receptor favors a switch from cAMP formation to increased myometrial cell calcium levels via protein kinase C activation (You, 2012). Oxytocin acts to attenuate CRH-stimulated accumulation of cAMP in myometrial tissue. And, CRH augments the contraction-inducing potency of a given dose of oxytocin in human myometrial strips (Quartero, 1991, 1992). CRH acts to increase myometrial contractile force in response to PGF$_2$α (Benedetto, 1994). Finally, CRH has been shown to stimulate fetal adrenal C$_{19}$-steroid synthesis, thereby increasing substrate for placental aromatization. Increased production of estrogens would shift the estrogen-to-progesterone ratio and promote the expression of a series of myometrial contractile proteins.

Some have proposed that the rising level of CRH at the end of gestation reflects a fetal-placental clock (McLean, 1995). CRH levels vary greatly among women, and it appears that the rate of increase in maternal CRH levels is a more accurate predictor of pregnancy outcome than is a single measurement (Leung, 2001; McGrath, 2002). In this regard, the placenta and fetus, through endocrinological events, influence the timing of parturition at the end of normal gestation.

### Fetal Lung Surfactant and Parturition

Surfactant protein A (SP-A) produced by the fetal lung is required for lung maturation. Its levels are increased in amnionic fluid at term in mice. Studies in the mouse suggest that the increasing SP-A concentrations in amnionic fluid activate fluid macrophages to migrate into the myometrium and induce NF-κB (Condon, 2004). This factor activates inflammatory response genes in the myometrium, which in turn promote uterine contractility. This model supports the supposition that fetal signals play a role in parturition initiation. SP-A is expressed by the human amnion and decidua, is present in the amnionic fluid, and prompts signaling pathways in human myometrial cells (Garcia-Verdugo, 2008; Lee, 2010; Snegovskikh, 2011). The exact mechanisms by which SP-A activates myometrial contractility in women, however, remains to be clarified (Leong, 2008). SP-A selectively inhibits prostaglandin F$_2$α in the term decidua, and amnionic fluid concentration of SP-A declines at term (Chaiworapongsa, 2008).

### Fetal Anomalies and Delayed Parturition

There is fragmentary evidence that pregnancies with markedly diminished estrogen production may be associated with prolonged gestation. These “natural experiments” include fetal anencephaly with adrenal hypoplasia and those with inherited placental sulfatase deficiency. The broad range of gestational length seen with these disorders calls into question the exact role of estrogen in human parturition initiation.

Other fetal abnormalities that prevent or severely reduce the entry of fetal urine into amnionic fluid—renal agenesis, or into lung secretions—pulmonary hypoplasia, do not prolong human pregnancy. Thus, a fetal signal through the paracrine arm of the fetal-maternal communication system does not appear to be mandated for parturition initiation.

Some brain anomalies of the fetal calf, fetal lamb, and sometimes the human fetus delay the normal timing of parturition. More than a century ago, Rea (1898) observed an association between fetal anencephaly and prolonged human gestation. Malpas (1933) extended these observations and described a pregnancy with an anencephalic fetus that was prolonged to 374 days.
—53 weeks. He concluded that the association between anencephaly and prolonged gestation was attributable to anomalous fetal brain-pituitary-adrenal function. The adrenal glands of the anencephalic fetus are very small and, at term, may be only 5 to 10 percent as large as those of a normal fetus. This is caused by developmental failure of the fetal zone that normally accounts for most of fetal adrenal mass and production of C$_{19}$-steroid hormones (Chap. 5, p. 108). Such pregnancies are associated with delayed labor and suggest that the fetal adrenal glands are important for the timely onset of parturition (Anderson, 1973).

Phase 3: Uterine Stimulation

This parturition phase is synonymous with uterine contractions that bring about progressive cervical dilatation and delivery. Current data favor the uterotonin theory of labor initiation. Increased uterotonin production would follow once phase 1 is suspended and uterine phase 2 processes are implemented. A number of uterotonins may be important to the success of phase 3, that is, active labor (see Fig. 21-15). Just as multiple processes likely contribute to myometrial unresponsiveness of phase 1 of parturition, other processes may contribute jointly to a system that ensures labor success.

Uterotonins that are candidates for labor induction include oxytocin, prostaglandins, serotonin, histamine, PAF, angiotensin II, and many others. All have been shown to stimulate smooth muscle contraction through G-protein coupling.

Oxytocin and Phase 3 of Parturition

Late in pregnancy, during phase 2 of parturition, there is a 50-fold or more increase in the number of myometrial oxytocin receptors (Fuchs, 1982; Kimura, 1996). This increase coincides with an increase in uterine contractile responsiveness to oxytocin. Moreover, prolonged gestation is associated with a delay in the increase of these receptors (Fuchs, 1984).

Oxytocin—literally, quick birth—was the first uterotonin to be implicated in parturition initiation. This nanopeptide is synthesized in the magnocellular neurons of the supraoptic and paraventricular neurons. The prohormone is transported with its carrier protein, neurophysin, along the axons to the neural lobe of the posterior pituitary gland in membrane-bound vesicles for storage and later release. The prohormone is converted enzymatically to oxytocin during transport (Gainer, 1988; Leake, 1990).

Role of Oxytocin in Phases 3 and 4 of Parturition. Because of successful labor induction with oxytocin, it was logically suspected in parturition initiation. First, in addition to its effectiveness in inducing labor at term, oxytocin is a potent uterotonin and occurs naturally in humans. Subsequent observations provide additional support for this theory: (1) the number of oxytocin receptors strikingly increases in myometrial and decidual tissues near the end of gestation; (2) oxytocin acts on decidual tissue to promote prostaglandin release; and (3) oxytocin is synthesized directly in decidual and extraembryonic fetal tissues and in the placenta (Chibbar, 1993; Zingg, 1995).

Although little evidence suggests a role for oxytocin in phase 2 of parturition, abundant data support its important role during second-stage labor and in the puerperium—phase 4 of parturition. Specifically, there are increased maternal serum oxytocin levels: (1) during second-stage labor, which is the end of phase 3 of parturition; (2) in the early puerperium; and (3) during breastfeeding (Nissen, 1995). Immediately after delivery of the fetus, placenta, and membranes, which completes parturition phase 3, firm and persistent uterine contractions and myometrial retraction are essential to prevent postpartum hemorrhage. Oxytocin likely causes persistent contractions.
Oxytocin infusion in women promotes increased levels of mRNAs from myometrial genes that encode proteins essential for uterine involution. These include interstitial collagenase, monocyte chemoattractant protein-1, interleukin-8, and urokinase plasminogen activator receptor. Therefore, oxytocin action at the end of labor may be involved in uterine involution.

**Prostaglandins and Phase 3 of Parturition**

Although their role in parturition phase 2 of noncomplicated pregnancies is less well defined, a critical role for prostaglandins in phase 3 of parturition is clear (MacDonald, 1993). First, levels of prostaglandins—or their metabolites—in amionic fluid, maternal plasma, and maternal urine are increased during labor (Fig. 21-18). Second, treatment of pregnant women with prostaglandins, by any of several administration routes, causes abortion or labor at all gestational stages. Moreover, administration of prostaglandin H synthase type 2 (PGHS-2) inhibitors to pregan women will delay spontaneous labor onset and sometimes arrest preterm labor (Loudon, 2003). Last, prostaglandin treatment of myometrial tissue in vitro sometimes causes contraction, dependent on the prostanoid tested and the physiological status of the tissue treated.

**FIGURE 21-18** Mean (±SD) concentrations of prostaglandin F$_{2\alpha}$ (PGF$_{2\alpha}$) and prostaglandin E$_2$ (PGE$_2$) in amnionic fluid at term before labor and in the upper and forebag compartments during labor at all stages of cervical dilatation. (Data from MacDonald, 1993.)

**Uterine Events Regulating Prostaglandin Production.** During labor, prostaglandin production within the myometrium and decidua is an efficient mechanism of activating contractions. For example, prostaglandin synthesis is high and unchanging in the decidua during phase 2 and 3 of
parturition. Moreover, the receptor level for PGF$_{2\alpha}$ is increased in the decidua at term, and this increase most likely is the regulatory step in prostaglandin action in the uterus. The myometrium synthesizes PGHS-2 with labor onset, but most prostaglandins likely come from the decidua.

The fetal membranes and placenta also produce prostaglandins. Primarily PGE$_2$, but also PGF$_{2\alpha}$, are detected in amnionic fluid at all gestational stages. As the fetus grows, prostaglandins levels in the amnionic fluid increase gradually. Their major increases in concentration within amnionic fluid, however, are demonstrable after labor begins (see Fig. 21-18). These higher levels likely result as the cervix dilates and exposes decidual tissue (Fig. 21-19). These increased levels in the forebag compared with those in the upper compartment are believed to follow an inflammatory response that signals the events leading to active labor. Together, the increases in cytokines and prostaglandins further degrade the extracellular matrix, thus weakening fetal membranes.

**FIGURE 21-19** Sagittal view of the exposed forebag and attached decidual fragments after cervical dilatation during labor. (Redrawn from MacDonald, 1996.)

Findings of Kemp and coworkers (2002) and Kelly (2002) support a possibility that inflammatory mediators aid cervical dilatation and alterations to the lower uterine segment. It can be envisioned that they, along with the increased prostaglandin levels measured in vaginal fluid during labor, add to the relatively rapid cervical changes that are characteristic of parturition.
**Endothelin-1**

The endothelins are a family of 21-amino acid peptides that powerfully induce myometrial contraction (Word, 1990). The endothelin A receptor is preferentially expressed in smooth muscle and effects an increase in intracellular calcium. Endothelin-1 is produced in myometrium of term gestations and is able to induce synthesis of other contractile mediators such as prostaglandins and inflammatory mediators (Momohara, 2004; Sutcliffe, 2009). The requirement of endothelin-1 in normal parturition physiology remains to be established. However, there is evidence of pathologies associated with aberrant endothelin-1 expression, such as premature birth and uterine leiomyomas (Tanfin, 2011, 2012).

**Angiotensin II**

There are two G-protein-linked angiotensin II receptors expressed in the uterus—AT1 and AT2. In nonpregnant women, the AT2 receptor is predominant, but the AT1 receptor is preferentially expressed in pregnant women (Cox, 1993). Angiotensin II binding to the plasma-membrane receptor evokes contraction. During pregnancy, the vascular smooth muscle that expresses the AT2 receptor is refractory to the pressor effects of infused angiotensin II (Chap. 4, p. 61). In myometrium near term, however, angiotensin II may be another component of the uterotonin system of parturition phase 3 (Anton, 2009).

**Contribution of Intrauterine Tissues to Parturition**

Although they have a potential role in parturition initiation, the amnion, chorion laeve, and decidua parietalis more likely have an alternative role. The membranes and decidua make up an important tissue shell around the fetus that serves as a physical, immunological, and metabolic shield to protect against untimely initiation of parturition. Late in gestation, however, the fetal membranes may indeed act to prepare for labor.

**Amnion**

Virtually all of the tensile strength—resistance to tearing and rupture—of the fetal membranes is provided by the amnion (Chap. 5, p. 98). This avascular tissue is highly resistant to penetration by leukocytes, microorganisms, and neoplastic cells. It also constitutes a selective filter to prevent fetal particulate-bound lung and skin secretions from reaching the maternal compartment. In this manner, maternal tissues are protected from amnionic fluid constituents that could worsen decidual or myometrial function or could promote adverse events such as amnionic-fluid embolism (Chap. 41, p. 812).

Several bioactive peptides and prostaglandins that cause myometrial relaxation or contraction are synthesized in amnion (Fig. 21-20). Late in pregnancy, amnionic prostaglandin biosynthesis is increased, and phospholipase A2 and PGHS-2 show increased activity (Johnson, 2002). Accordingly, many hypothesize that prostaglandins regulate events leading to parturition. It is likely that amnion is the major source for amnionic fluid prostaglandins, and their role in activation of cascades that promote membrane rupture is clear. The influence of amnion-derived prostaglandins on uterine quiescence and activation, however, is less clear. This is because prostaglandin transport from the amnion through the chorion to access maternal tissues is limited by expression of the inactivating enzyme, prostaglandin dehydrogenase.
The amnion synthesizes prostaglandins, and late in pregnancy, synthesis is increased by increased phospholipase A\textsubscript{2} and prostaglandin H synthase, type 2 (PGHS-2) activity. During pregnancy, the transport of prostaglandins from the amnion to maternal tissues is limited by expression of the inactivating enzymes, prostaglandin dehydrogenase (PGDH), in the chorion. During labor, PGDH levels decline, and amnion-derived prostaglandins can influence membrane rupture and uterine contractility. The role of decidual activation in parturition is unclear but may involve local progesterone metabolism and increased prostaglandin receptor concentrations, thus enhancing uterine prostaglandin actions and cytokine production. (Adapted from Smith, 2007.)

**Chorion Laeve**

This tissue layer also is primarily protective and provides immunological acceptance. The chorion laeve is also enriched with enzymes that inactivate uterotonins. Enzymes include prostaglandin dehydrogenase (PGDH), oxytocinase, and enkephalinase (Cheung, 1990; Germain, 1994). As noted, PGDH inactivates amnion-derived prostaglandins. With chorionic rupture, this barrier would be lost, and prostaglandins could readily influence adjacent decidua and myometrium.

There is also evidence that PGDH levels found in the chorion decline during labor. This would allow increased prostaglandin-stimulated matrix metalloproteinase activity associated with membrane rupture. It would further allow prostaglandin entry into the maternal compartment to promote myometrial contractility (Patel, 1999; Van Meir, 1996; Wu, 2000). It is likely that progesterone maintains chorion PGDH expression, whereas cortisol decreases its expression. Thus, PGDH levels would decrease late in gestation as fetal cortisol production increases and as part of progesterone withdrawal.

**Decidua**

A metabolic contribution of decidual activation to parturition initiation is an appealing possibility for both anatomical and functional reasons. The generation of decidual uterotonins that act in a paracrine manner on contiguous myometrium is intuitive. In addition, decidua expresses steroid metabolizing enzymes such as 20α-HSD and steroid 5αR1 that may regulate local progesterone withdrawal. Decidual activation is characterized by increased proinflammatory cells and increased expression of proinflammatory cytokines, prostaglandins, and uterotonins such as oxytocin receptors and connexin 43.

Cytokines produced in the decidua can either increase uterotonin production—principally...
prostaglandins. Or they can act directly on myometrium to cause contraction. Examples are tumor necrosis factor-α (TNF-α) and interleukins 1, 6, 8, and 12. These molecules also can act as chemokines that recruit to the myometrium neutrophils and eosinophils, which further increase contractions and labor (Keelan, 2003).

There is uncertainty whether prostaglandin concentration or output from the decidua increases with term labor onset. Olson and Ammann (2007) suggest that the major regulation of decidual prostaglandin action is not their synthesis but rather increased PGF$_{2\alpha}$ receptor expression.

**Summary: Regulation of Phase 3 and 4 of Parturition**

It is likely that multiple and possibly redundant processes contribute to the success of the three active labor phases once phase 1 of parturition is suspended and phase 2 is initiated. Phase 3 is highlighted by increased activation of G-protein-coupled receptors that inhibit cAMP formation, increase intracellular calcium stores, and promote interaction of actin and myosin and subsequent force generation. Simultaneously, cervical proteoglycan composition and collagen structure are altered to a form that promotes tissue distensibility and increased compliance. The net result is initiation of coordinated myometrial contractions of sufficient amplitude and frequency to dilate the prepared cervix and push the fetus through the birth canal. Multiple regulatory ligands orchestrate these processes and vary from endocrine hormones such as oxytocin to locally produced prostaglandins.

In phase 4 of parturition, a complicated series of repair processes are initiated to resolve inflammatory responses and remove glycosaminoglycans, proteoglycans, and structurally compromised collagen. Simultaneously, matrix and cellular components required for complete uterine involution are synthesized, and the dense connective tissue and structural integrity of the cervix is reformed.

MANAGEMENT OF THE FIRST STAGE OF LABOR

MANAGEMENT OF THE SECOND STAGE OF LABOR

LABOR MANAGEMENT PROTOCOLS

Labor is the process that leads to childbirth. It begins with the onset of regular uterine contractions and ends with delivery of the newborn and expulsion of the placenta. The term labor in the obstetrical context takes on several connotations from the English language. It is undoubtedly true that pregnancy and birth are physiological processes, and as such, labor and delivery should be considered to be normal for most women (Lawrence, 2012). This understanding of normal labor and delivery as a physiological process has come under some scrutiny in the past decade because pelvic floor disorders have been observed to be more prevalent among women who have delivered at least one child (Handa, 2011; Nygaard, 2008). Determining which aspects of childbirth contribute most to this risk has become an area of intense investigation and discussed further in Chapter 30 (p. 588).

MECHANISMS OF LABOR

At the onset of labor, the position of the fetus with respect to the birth canal is critical to the route of delivery and thus should be determined in early labor. Important relationships include fetal lie,
presentation, attitude, and position.

**Fetal Lie**

The relation of the fetal long axis to that of the mother is termed *fetal lie* and is either *longitudinal* or *transverse*. Occasionally, the fetal and the maternal axes may cross at a 45-degree angle, forming an *oblique lie*. This lie is unstable and becomes longitudinal or transverse during labor. A longitudinal lie is present in more than 99 percent of labors at term. Predisposing factors for transverse fetal position include multiparity, placenta previa, hydramnios, and uterine anomalies (Chap. 23, p. 468).

**Fetal Presentation**

The *presenting part* is that portion of the fetal body that is either foremost within the birth canal or in closest proximity to it. It typically can be felt through the cervix on vaginal examination. Accordingly, in longitudinal lies, the presenting part is either the fetal head or breech, creating *cephalic* and *breech presentations*, respectively. When the fetus lies with the long axis transversely, the *shoulder* is the presenting part. Table 22-1 describes the incidences of the various fetal presentations.

**Cephalic Presentation**

Such presentations are classified according to the relationship between the head and body of the fetus (Fig. 22-1). Ordinarily, the head is flexed sharply so that the chin is in contact with the thorax. The occipital fontanel is the presenting part, and this presentation is referred to as a *vertex* or *occiput presentation*. Much less commonly, the fetal neck may be sharply extended so that the occiput and back come in contact, and the face is foremost in the birth canal—*face presentation* (Fig. 23-6, p. 466). The fetal head may assume a position between these extremes, partially flexed in some cases, with the anterior (large) fontanel, or bregma, presenting—*sinciput presentation*—or partially extended in other cases, to have a *brow presentation* (Fig. 23-8, p. 468). These latter two presentations are usually transient. As labor progresses, sinciput and brow presentations almost always convert into vertex or face presentations by neck flexion or extension, respectively. Failure to do so can lead to dystocia, as discussed in Chapter 23 (p. 455).
Figure 22-1 Longitudinal lie. Cephalic presentation. Differences in attitude of the fetal body in (A) vertex, (B) sinciput, (C) brow, and (D) face presentations. Note changes in fetal attitude in relation to fetal vertex as the fetal head becomes less flexed.

The term fetus usually presents with the vertex, most logically because the uterus is piriform or pear shaped. Although the fetal head at term is slightly larger than the breech, the entire podalic pole of the fetus—that is, the breech and its flexed extremities—is bulkier and more mobile than the cephalic pole. The cephalic pole is composed of the fetal head only. Until approximately 32 weeks, the amnionic cavity is large compared with the fetal mass, and the fetus is not crowded by the uterine walls. Subsequently, however, the ratio of amnionic fluid volume decreases relative to the increasing fetal mass. As a result, the uterine walls are apposed more closely to the fetal parts.

If presenting by the breech, the fetus often changes polarity to make use of the roomier fundus for its bulkier and more mobile podalic pole. As discussed in Chapter 28 (p. 559), the incidence of breech presentation decreases with gestational age. It approximates 25 percent at 28 weeks, 17 percent at 30 weeks, 11 percent at 32 weeks, and then decreases to approximately 3 percent at term. The high incidence of breech presentation in hydrocephalic fetuses is in accord with this theory, as the larger fetal cephalic pole requires more room than its podalic pole.

Breech Presentation
When the fetus presents as a breech, the three general configurations are frank, complete, and footling presentations and are described in Chapter 28 (p. 559). Breech presentation may result from circumstances that prevent normal version from taking place. One example is a septum that protrudes into the uterine cavity (Chap. 3, p. 42). A peculiarity of fetal attitude, particularly extension of the vertebral column as seen in frank breeches, also may prevent the fetus from turning. If the placenta is implanted in the lower uterine segment, it may distort normal intrauterine anatomy and result in a breech presentation.

Fetal Attitude or Posture
In the later months of pregnancy, the fetus assumes a characteristic posture described as attitude or habitus as shown in Figure 22-1. As a rule, the fetus forms an ovoid mass that corresponds roughly to the shape of the uterine cavity. The fetus becomes folded or bent upon itself in such a manner that the back becomes markedly convex; the head is sharply flexed so that the chin is almost in contact with the chest; the thighs are flexed over the abdomen; and the legs are bent at the knees. In all cephalic presentations, the arms are usually crossed over the thorax or become parallel to the sides. The umbilical cord lies in the space between them and the lower extremities. This characteristic posture results from the mode of fetal growth and its accommodation to the uterine cavity.

Abnormal exceptions to this attitude occur as the fetal head becomes progressively more extended from the vertex to the face presentation (see Fig. 22-1). This results in a progressive change in fetal attitude from a convex (flexed) to a concave (extended) contour of the vertebral column.

### Fetal Position

Position refers to the relationship of an arbitrarily chosen portion of the fetal presenting part to the right or left side of the birth canal. Accordingly, with each presentation there may be two positions—right or left. The fetal occiput, chin (mentum), and sacrum are the determining points in vertex, face, and breech presentations, respectively (Figs. 22-2 to 22-6). Because the presenting part may be in either the left or right position, there are left and right occipital, left and right mental, and left and right sacral presentations. These are abbreviated as LO and RO, LM and RM, and LS and RS, respectively.
FIGURE 22-5  Longitudinal lie. Face presentation. Left and right mentum anterior and right mentum posterior positions.
Varieties of Presentations and Positions

For still more accurate orientation, the relationship of a given portion of the presenting part to the anterior, transverse, or posterior portion of the maternal pelvis is considered. Because the presenting part in right or left positions may be directed anteriorly (A), transversely (T), or posteriorly (P), there are six varieties of each of the three presentations as shown in Figures 22-2 to 22-6. Thus, in an occiput presentation, the presentation, position, and variety may be abbreviated in clockwise fashion as:
Approximately two thirds of all vertex presentations are in the left occiput position, and one third in the right.

In shoulder presentations, the acromion (scapula) is the portion of the fetus arbitrarily chosen for orientation with the maternal pelvis. One example of the terminology sometimes employed for this purpose is illustrated in Figure 22-7. The acromion or back of the fetus may be directed either posteriorly or anteriorly and superiorly or inferiorly. Because it is impossible to differentiate exactly the several varieties of shoulder presentation by clinical examination and because such specific differentiation serves no practical purpose, it is customary to refer to all transverse lies simply as shoulder presentations. Another term used is transverse lie, with back up or back down, which is clinically important when deciding incision type for cesarean delivery (Chap. 23, p. 468).
Several methods can be used to diagnose fetal presentation and position. These include abdominal palpation, vaginal examination, auscultation, and, in certain doubtful cases, sonography. Rarely, plain radiographs, computed tomography, or magnetic resonance imaging may be used.

**Abdominal Palpation—Leopold Maneuvers**
Abdominal examination can be conducted systematically employing the four maneuvers described by Leopold in 1894 and shown in Figure 22-8. The mother lies supine and comfortably positioned...
with her abdomen bared. These maneuvers may be difficult if not impossible to perform and interpret if the patient is obese, if there is excessive amnionic fluid, or if the placenta is anteriorly implanted.
FIGURE 22-8 Leopold maneuvers (A–D) performed in a fetus with a longitudinal lie in the left
occiput anterior position (LOA).

The first maneuver permits identification of which fetal pole—that is, cephalic or podalic—occupies the uterine fundus. The breech gives the sensation of a large, nodular mass, whereas the head feels hard and round and is more mobile and ballottable.

Performed after determination of fetal lie, the second maneuver is accomplished as the palms are placed on either side of the maternal abdomen, and gentle but deep pressure is exerted. On one side, a hard, resistant structure is felt—the back. On the other, numerous small, irregular, mobile parts are felt—the fetal extremities. By noting whether the back is directed anteriorly, transversely, or posteriorly, fetal orientation can be determined.

The third maneuver is performed by grasping with the thumb and fingers of one hand the lower portion of the maternal abdomen just above the symphysis pubis. If the presenting part is not engaged, a movable mass will be felt, usually the head. The differentiation between head and breech is made as in the first maneuver. If the presenting part is deeply engaged, however, the findings from this maneuver are simply indicative that the lower fetal pole is in the pelvis, and details are then defined by the fourth maneuver.

To perform the fourth maneuver, the examiner faces the mother’s feet and, with the tips of the first three fingers of each hand, exerts deep pressure in the direction of the axis of the pelvic inlet. In many instances, when the head has descended into the pelvis, the anterior shoulder may be differentiated readily by the third maneuver.

Abdominal palpation can be performed throughout the latter months of pregnancy and during and between the contractions of labor. With experience, it is possible to estimate the size of the fetus. According to Lydon-Rochelle and colleagues (1993), experienced clinicians accurately identify fetal malpresentation using Leopold maneuvers with a high sensitivity—88 percent, specificity—94 percent, positive-predictive value—74 percent, and negative-predictive value—97 percent.

Vaginal Examination

Before labor, the diagnosis of fetal presentation and position by vaginal examination is often inconclusive because the presenting part must be palpated through a closed cervix and lower uterine segment. With the onset of labor and after cervical dilatation, vertex presentations and their positions are recognized by palpation of the various fetal sutures and fontanels. Face and breech presentations are identified by palpation of facial features and fetal sacrum, respectively.

In attempting to determine presentation and position by vaginal examination, it is advisable to pursue a definite routine, comprising four movements. First, the examiner inserts two fingers into the vagina and the presenting part is found. Differentiation of vertex, face, and breech is then accomplished readily. Second, if the vertex is presenting, the fingers are directed posteriorly and then swept forward over the fetal head toward the maternal symphysis (Fig. 22-9). During this movement, the fingers necessarily cross the sagittal suture and its linear course is delineated. Next, the positions of the two fontanels are ascertained. For this, fingers are passed to the most anterior extension of the sagittal suture, and the fontanel encountered there is examined and identified. Then, with a sweeping motion, the fingers pass along the suture to the other end of the head until the other fontanel is felt and differentiated (Fig. 22-10). Last, the station, or extent to which the presenting part has descended into the pelvis, can also be established at this time (p. 449). Using these maneuvers, the various sutures and fontanels are located readily (Fig. 7-11, p. 139).
Sonography and Radiography

Sonographic techniques can aid fetal position identification, especially in obese women or in women with rigid abdominal walls. Zahalka and associates (2005) compared digital examinations with transvaginal and transabdominal sonography for fetal head position determination during second-stage labor and reported that transvaginal sonography was superior.

Occiput Anterior Presentation
In most cases, the vertex enters the pelvis with the sagittal suture lying in the transverse pelvic diameter. The fetus enters the pelvis in the left occiput transverse (LOT) position in 40 percent of labors and in the right occiput transverse (ROT) position in 20 percent (Caldwell, 1934). In occiput anterior positions—LOA or ROA—the head either enters the pelvis with the occiput rotated 45 degrees anteriorly from the transverse position, or this rotation occurs subsequently. The mechanism of labor in all these presentations is usually similar.

The positional changes of the presenting part required to navigate the pelvic canal constitute the mechanisms of labor. The cardinal movements of labor are engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion (Fig. 22-11). During labor, these movements not only are sequential but also show great temporal overlap. For example, as part of engagement, there is both flexion and descent of the head. It is impossible for the movements to be completed unless the presenting part descends simultaneously. Concomitantly, uterine contractions effect important modifications in fetal attitude, or habitus, especially after the head has descended into the pelvis. These changes consist principally of fetal straightening, with loss of dorsal convexity and closer application of the extremities to the body. As a result, the fetal ovoid is transformed into a cylinder, with the smallest possible cross section typically passing through the birth canal.
1. Head floating, before engagement

2. Engagement, descent, flexion

5. Complete extension

6. Restitution (external rotation)
Engagement

The mechanism by which the biparietal diameter—the greatest transverse diameter in an occiput presentation—passes through the pelvic inlet is designated *engagement*. The fetal head may engage during the last few weeks of pregnancy or not until after labor commencement. In many multiparous and some nulliparous women, the fetal head is freely movable above the pelvic inlet at labor onset. In this circumstance, the head is sometimes referred to as “floating.” A normally-sized head usually does not engage with its sagittal suture directed anteroposteriorly. Instead, the fetal head usually enters the pelvic inlet either transversely or obliquely. Segel and coworkers (2012) analyzed labor in 5341 nulliparous women and found that fetal head engagement before...
Asynclitism. The fetal head tends to accommodate to the transverse axis of the pelvic inlet, whereas the sagittal suture, while remaining parallel to that axis, may not lie exactly midway between the symphysis and the sacral promontory. The sagittal suture frequently is deflected either posteriorly toward the promontory or anteriorly toward the symphysis (Fig. 22-12). Such lateral deflection to a more anterior or posterior position in the pelvis is called asynclitism. If the sagittal suture approaches the sacral promontory, more of the anterior parietal bone presents itself to the examining fingers, and the condition is called anterior asynclitism. If, however, the sagittal suture lies close to the symphysis, more of the posterior parietal bone will present, and the condition is called posterior asynclitism. With extreme posterior asynclitism, the posterior ear may be easily palpated.

![Synclitism and asynclitism](image)

**FIGURE 22-12** Synclitism and asynclitism.

Moderate degrees of asynclitism are the rule in normal labor. However, if severe, the condition is a common reason for cephalopelvic disproportion even with an otherwise normal-sized pelvis. Successive shifting from posterior to anterior asynclitism aids descent.

**Descent**

This movement is the first requisite for birth of the newborn. In nulliparas, engagement may take place before the onset of labor, and further descent may not follow until the onset of the second stage. In multiparas, descent usually begins with engagement. Descent is brought about by one of
more of four forces: (1) pressure of the amnionic fluid, (2) direct pressure of the fundus upon the breech with contractions, (3) bearing-down efforts of maternal abdominal muscles, and (4) extension and straightening of the fetal body.

**Flexion**

As soon as the descending head meets resistance, whether from the cervix, pelvic walls, or pelvic floor, it normally flexes. With this movement, the chin is brought into more intimate contact with the fetal thorax, and the appreciably shorter suboccipitobregmatic diameter is substituted for the longer occipitofrontal diameter (Figs. 22-13 and 22-14).

**FIGURE 22-13** Lever action produces flexion of the head. Conversion from occipitofrontal to suboccipitobregmatic diameter typically reduces the anteroposterior diameter from nearly 12 to 9.5 cm.
Internal Rotation

This movement consists of a turning of the head in such a manner that the occiput gradually moves toward the symphysis pubis anteriorly from its original position or, less commonly, posteriorly toward the hollow of the sacrum (Figs. 22-15 to 22-17). Internal rotation is essential for
completion of labor, except when the fetus is unusually small.

**FIGURE 22-15** Mechanism of labor for the left occiput transverse position, lateral view. **A.** Engagement. **B.** After engagement, further descent. **C.** Descent and initial internal rotation. **D.** Rotation and extension.
FIGURE 22-16 Mechanism of labor for left occiput anterior position.
Calkins (1939) studied more than 5000 women in labor to ascertain the time of internal rotation. He concluded that in approximately two thirds, internal rotation is completed by the time the head reaches the pelvic floor; in about another fourth, internal rotation is completed shortly after the head reaches the pelvic floor; and in the remaining 5 percent, rotation does not take place. When the head fails to turn until reaching the pelvic floor, it typically rotates during the next one or two contractions in multiparas. In nulliparas, rotation usually occurs during the next three to five
contractions.

**Extension**

After internal rotation, the sharply flexed head reaches the vulva and undergoes extension. If the sharply flexed head, on reaching the pelvic floor, did not extend but was driven farther downward, it would impinge on the posterior portion of the perineum and would eventually be forced through the perineal tissues. When the head presses on the pelvic floor, however, two forces come into play. The first force, exerted by the uterus, acts more posteriorly, and the second, supplied by the resistant pelvic floor and the symphysis, acts more anteriorly. The resultant vector is in the direction of the vulvar opening, thereby causing head extension. This brings the base of the occiput into direct contact with the inferior margin of the symphysis pubis (see Fig. 22-16).

With progressive distention of the perineum and vaginal opening, an increasingly larger portion of the occiput gradually appears. The head is born as the occiput, bregma, forehead, nose, mouth, and finally the chin pass successively over the anterior margin of the perineum (see Fig. 22-17). Immediately after its delivery, the head drops downward so that the chin lies over the maternal anus.

**External Rotation**

The delivered head next undergoes *restitution* (see Fig. 22-11). If the occiput was originally directed toward the left, it rotates toward the left ischial tuberosity. If it was originally directed toward the right, the occiput rotates to the right. Restitution of the head to the oblique position is followed by external rotation completion to the transverse position. This movement corresponds to rotation of the fetal body and serves to bring its bisacromial diameter into relation with the anteroposterior diameter of the pelvic outlet. Thus, one shoulder is anterior behind the symphysis and the other is posterior. This movement apparently is brought about by the same pelvic factors that produced internal rotation of the head.

**Expulsion**

Almost immediately after external rotation, the anterior shoulder appears under the symphysis pubis, and the perineum soon becomes distended by the posterior shoulder. After delivery of the shoulders, the rest of the body quickly passes.

**Occiput Posterior Presentation**

In approximately 20 percent of labors, the fetus enters the pelvis in an *occiput posterior (OP)* position (Caldwell, 1934). The right occiput posterior (ROP) is slightly more common than the left (LOP). It appears likely from radiographic evidence that posterior positions are more often associated with a narrow forepelvis. They also are more commonly seen in association with anterior placentation (Gardberg, 1994a).

In most occiput posterior presentations, the mechanism of labor is identical to that observed in the transverse and anterior varieties, except that the occiput has to internally rotate to the symphysis pubis through 135 degrees, instead of 90 and 45 degrees, respectively (see Fig. 22-17).

Effective contractions, adequate head flexion, and average fetal size together permit most posteriorly positioned occiputs to rotate promptly as soon as they reach the pelvic floor, and labor is not lengthened appreciably. In perhaps 5 to 10 percent of cases, however, rotation may be
incomplete or may not take place at all, especially if the fetus is large (Gardberg, 1994b). Poor contractions, faulty head flexion, or epidural analgesia, which diminishes abdominal muscular pushing and relaxes pelvic floor muscles, may predispose to incomplete rotation. If rotation is incomplete, transverse arrest may result. If no rotation toward the symphysis takes place, the occiput may remain in the direct occiput posterior position, a condition known as persistent occiput posterior. Both persistent occiput posterior and transverse arrest represent deviations from the normal mechanisms of labor and are considered further in Chapter 23.

### Fetal Head Shape Changes

**Caput Succedaneum**

In vertex presentations, labor forces alter fetal head shape. In prolonged labors before complete cervical dilatation, the portion of the fetal scalp immediately over the cervical os becomes edematous (Fig. 33-1, p. 647). This swelling, known as the caput succedaneum, is shown in Figures 22-18 and 22-19. It usually attains a thickness of only a few millimeters, but in prolonged labors it may be sufficiently extensive to prevent differentiation of the various sutures and fontanels. More commonly, the caput is formed when the head is in the lower portion of the birth canal and frequently only after the resistance of a rigid vaginal outlet is encountered. Because it develops over the most dependent area of the head, one may deduce the original fetal head position by noting the location of the caput succedaneum.
FIGURE 22-18 Formation of caput succedaneum and head molding.
Molding

In addition to soft tissue changes, the bony fetal head shape is also altered by external compressive forces and is referred to as molding (see Fig. 22-19). Possibly related to Braxton Hicks contractions, some molding develops before labor. Most studies indicate that there is seldom overlapping of the parietal bones. A “locking” mechanism at the coronal and lambdoidal connections actually prevents such overlapping (Carlan, 1991). Molding results in a shortened suboccipitobregmatic diameter and a lengthened mentovertical diameter. These changes are of greatest importance in women with contracted pelves or asynclitic presentations. In these circumstances, the degree to which the head is capable of molding may make the difference between spontaneous vaginal delivery and an operative delivery. Some older literature cited severe head molding as a cause for possible cerebral trauma. Because of the multitude of associated factors, for example, prolonged labor with fetal sepsis and acidosis, it is impossible to link molding to any alleged fetal or neonatal neurological sequelae. Most cases of molding resolve within the week following delivery, although persistent cases have been described (Graham, 2006).

CHARACTERISTICS OF NORMAL LABOR

The greatest impediment to understanding normal labor is recognizing its start. The strict definition of labor—*uterine contractions that bring about demonstrable effacement and dilatation of the cervix*—does not easily aid the clinician in determining when labor has actually begun, because this diagnosis is confirmed only retrospectively. Several methods may be used to define its start. One defines onset as the clock time when painful contractions become regular. Unfortunately, uterine activity that causes discomfort, but that does not represent true labor, may develop at any time during pregnancy. False labor often stops spontaneously, or it may proceed rapidly into effective contractions.

A second method defines the onset of labor as beginning at the time of admission to the labor unit. In the United States, admission for labor is frequently based on the extent of cervical dilatation accompanied by painful contractions. If a woman has intact membranes, then a cervical dilatation of 3 to 4 cm or greater is presumed to be a reasonably reliable threshold for the diagnosis of labor. In this case, labor onset commences with the time of admission. This presumptive method obviates many of the uncertainties in diagnosing labor during earlier stages of cervical dilatation. Laughon and colleagues (2012) compared the duration of spontaneous labor at term in nulliparas delivered in the United States between 1959 and 1966 to that of those delivered from 2002 to 2008. As shown in Figure 22-20, the length of labor increased by approximately 2 hours during those 50 years.
Assuming that the diagnosis has been confirmed, what then are the expectations for the progress of normal labor? A scientific approach was begun by Friedman (1954), who described a characteristic sigmoid pattern for labor by graphing cervical dilatation against time. This graphical approach, based on statistical observations, changed labor management. Friedman developed the concept of three functional labor divisions to describe the physiological objectives of each division as shown in Figure 22-21. First, during the preparatory division, although the cervix dilates little, its connective tissue components change considerably (Chap. 21, p. 410). Sedation and conduction analgesia are capable of arresting this labor division. The dilatational division, during which dilatation proceeds at its most rapid rate, is unaffected by sedation. Last, the pelvic division commences with the deceleration phase of cervical dilatation. The classic labor mechanisms that involve the cardinal fetal movements of the cephalic presentation take place principally during this pelvic division. In actual practice, however, the onset of the pelvic division is seldom clearly identifiable.
Labor course divided functionally on the basis of dilatation and descent curves into: (1) a preparatory division, including latent and acceleration phases; (2) a dilatational division, occupying the phase of maximum slope; and (3) a pelvic division, encompassing both deceleration phase and second stage concurrent with the phase of maximum slope of descent. (Redrawn from Friedman, 1978.)

As shown in Figure 22-21, the pattern of cervical dilatation during the preparatory and dilatational divisions of normal labor is a sigmoid curve. Two phases of cervical dilatation are defined. The latent phase corresponds to the preparatory division, and the active phase to the dilatational division. And as shown in Figure 22-22, Friedman subdivided the active phase into the acceleration phase, the phase of maximum slope, and the deceleration phase.
FIGURE 22-22 Composite of the average dilatation curve for nulliparous labor. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts that include an acceleration phase, a phase of maximum slope, and a deceleration phase. (Redrawn from Friedman, 1978.)

**Latent Phase**

The onset of latent labor, as defined by Friedman (1972), is the point at which the mother perceives regular contractions. The latent phase for most women ends once dilatation of 3 to 5 cm is achieved. This threshold may be clinically useful, for it defines dilatation limits beyond which active labor can be expected.

This concept of a latent phase has great significance in understanding normal human labor, because labor is considerably longer when a latent phase is included. To better illustrate this, Figure 22-23 shows eight labor curves from nulliparas in whom labor was diagnosed beginning with their admission, rather than with the onset of regular contractions. When labor is defined similarly, there is remarkable similarity of individual labor curves.
FIGURE 22-23 Progress of labor in primigravid women from the time of admission. When the starting point on the abscissa begins with admission to the hospital, a latent phase is not observed.

**Prolonged Latent Phase.** Friedman and Sachtleben (1963) defined this by a latent phase exceeding 20 hours in the nullipara and 14 hours in the multipara. These times corresponded to the 95th percentiles. Factors that affected latent phase duration include excessive sedation or epidural analgesia; unfavorable cervical condition, that is, thick, uneffaced, or undilated; and false labor. In those who had been administered heavy sedation, 85 percent of women eventually entered active labor. In another 10 percent, uterine contractions ceased, suggesting that they had false labor. The remaining 5 percent experienced persistence of an abnormal latent phase and required oxytocin stimulation. Amniotomy was discouraged because of the 10-percent incidence of false labor. Sokol and associates (1977) reported a 3- to 4- percent incidence of prolonged latent phase, regardless of parity. Friedman (1972) reported that latent phase prolongation did not adversely influence fetal or maternal morbidity or mortality rates. However, Chelmow and coworkers (1993) disputed the long-held belief that prolongation of the latent phase is benign.

**Active Labor**

The progress of labor in nulliparas has particular significance because these curves all reveal a rapid change in the slope of cervical dilatation rates between 3 and 5 cm (see Fig. 22-23). Thus, cervical dilatation of 3 to 5 cm or more, in the presence of uterine contractions, can be taken to
reliably represent the threshold for active labor. Similarly, these curves provide useful
guidposts for labor management.

Turning again to Friedman (1955), the mean duration of active-phase labor in nulliparas was
4.9 hours. But the standard deviation of 3.4 hours is large, hence, the active phase was reported to
have a statistical maximum of 11.7 hours. Indeed, rates of cervical dilatation ranged from a
minimum of 1.2 up to 6.8 cm/hr. Friedman (1972) also found that multiparas progress somewhat
faster in active-phase labor, with a minimum normal rate of 1.5 cm/hr. His analysis of active-
phase labor concomitantly describes rates of fetal descent and cervical dilatation (see Fig. 22-21).
Descent begins in the later stage of active dilatation, commencing at 7 to 8 cm in nulliparas and
becoming most rapid after 8 cm.

Active-Phase Abnormalities. These have been reported to occur in 25 percent of nulliparous and
15 percent of multiparous labors (Sokol, 1977). Friedman (1972) subdivided active-phase
problems into protraction and arrest disorders. Protraction is defined as a slow rate of cervical
dilatation or descent, which for nulliparas was < 1.2 cm dilatation per hour or < 1 cm descent per
hour. For multiparas, protraction was defined as < 1.5 cm dilatation per hour or < 2 cm descent per
hour. Friedman defined arrest as a complete cessation of dilatation or descent. Arrest of
dilatation was defined as 2 hours with no cervical change, and arrest of descent as 1 hour without
fetal descent. The prognosis for protraction and arrest disorders differs considerably. Friedman
found that approximately 30 percent of women with protraction disorders had cephalopelvic
disproportion (CPD). This compared with a 45-percent CPD rate for women in whom an arrest
disorder developed. Abnormal labor patterns, diagnostic criteria, and treatment methods are
summarized in Chapter 23 (p. 456).

Hendricks and colleagues (1970) challenged Friedman’s conclusions about the course of
normal human labor. Their principal differences included: (1) absence of a latent phase, (2) no
deceleration phase, (3) brevity of labor, and (4) dilatation at similar rates for nulliparas and
multiparas after 4 cm. They disputed the concept of a latent phase because they observed that the
cervix dilated and effaced slowly during the 4 weeks preceding labor. They contended that the
latent phase actually progressed over several weeks. They also reported that labor was relatively
rapid. Specifically, the average time from admission to complete dilatation was 4.8 hours for
nulliparas and 3.2 hours for multiparas.

There have been other reports in which investigators have reassessed the Friedman labor
curves. Zhang and associates (2010) studied electronic labor records from 62,415 parturients with
spontaneous labor at term and vaginal birth. They found that normal labor may take more than 6
hours to progress from 4 to 5 cm and more than 3 hours to progress from 5 to 6 cm dilation.
Thereafter, labor accelerated much faster in multiparas. In a study performed at Parkland Hospital,
enalgesia was found to lengthen the active phase of the Friedman labor curve by 1 hour
(Alexander, 2002). This increase was the result of a slight but significant decrease in the rate of
cervical dilatation—1.4 cm/hr in women given epidural analgesia compared with 1.6 cm/hr in
those without such analgesia. There are now several reports that maternal obesity lengthens the
first stages of labor by 30 to 60 minutes (Chin, 2012; Kominiarek, 2011). Finally, Adams and
coworkers (2012) found that maternal fear increased labor by approximately 45 minutes.

Second Stage of Labor

This stage begins with complete cervical dilatation and ends with fetal delivery. The median
duration is approximately 50 minutes for nulliparas and about 20 minutes for multiparas, but it is
highly variable (Kilpatrick, 1989). In a woman of higher parity with a previously dilated vagina and perineum, two or three expulsive efforts after full cervical dilatation may suffice to complete delivery. Conversely, in a woman with a contracted pelvis, with a large fetus, or with impaired expulsive efforts from conduction analgesia or sedation, the second stage may become abnormally long. Robinson and colleagues (2011) found that increasing maternal body mass index did not interfere with the second stage of labor. Abnormalities of this labor stage are described in Chapter 23 (p. 456).

Duration of Labor

Our understanding of the normal duration of labor may be clouded by the many clinical variables that affect conduct of labor in modern obstetrical units. Kilpatrick and Laros (1989) reported that the mean length of first- and second-stage labor was approximately 9 hours in nulliparous women without regional analgesia, and that the 95th percentile upper limit was 18.5 hours. Corresponding times for multiparous women were a mean of 6 hours with a 95th percentile maximum of 13.5 hours. These authors defined labor onset as the time when a woman recalled regular, painful contractions every 3 to 5 minutes that led to cervical change.

Spontaneous labor was analyzed in nearly 25,000 women delivered at term at Parkland Hospital in the early 1990s. Almost 80 percent of women were admitted with a cervical dilatation of 5 cm or less. Parity—nulliparous versus multiparous—and cervical dilatation at admission were significant determinants of the length of spontaneous labor. The median time from admission to spontaneous delivery for all parturients was 3.5 hours, and 95 percent of all women delivered within 10.1 hours. These results suggest that normal human labor is relatively short. Zhang and associates (2009a,b) described similar findings in their study of 126,887 deliveries from 12 United States institutions.

Summary of Normal Labor

Labor is characterized by brevity and considerable biological variation. Active labor can be reliably diagnosed when cervical dilatation is 3 cm or more in the presence of uterine contractions. Once this cervical dilatation threshold is reached, normal progression to delivery can be expected, depending on parity, in the ensuing 4 to 6 hours. Anticipated progress during a 1- to 2-hour second stage is monitored to ensure fetal safety. Finally, most women in spontaneous labor, regardless of parity, if left unaided, will deliver within approximately 10 hours after admission for spontaneous labor. Insufficient uterine activity is a common and correctable cause of abnormal labor progress. Therefore, when the length of otherwise normal labor exceeds the expected norm, interventions other than cesarean delivery—for example, oxytocin administration—must be first considered.

MANAGEMENT OF NORMAL LABOR

The ideal management of labor and delivery requires two potentially opposing viewpoints on the part of clinicians. First, birthing should be recognized as a normal physiological process that most women experience without complications. Second, intrapartum complications, often arising quickly and unexpectedly, should be anticipated. Thus, clinicians must simultaneously make every woman and her supporters feel comfortable, yet ensure safety for the mother and newborn should
complications suddenly develop. Principles such as these are the basis for a recent “Call to Action” by seven national organizations intended to emphasize quality patient care in labor and delivery (Lawrence, 2012). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) have collaborated in the development of Guidelines for Perinatal Care. These provide detailed information on the appropriate content of intrapartum care, including both personnel and facility requirements. Shown in Table 22-2 are the recommended nurse-to-patient ratios recommended for labor and delivery. Shown in Table 22-3 are the recommended room dimensions for these functions.

| TABLE 22-2. Recommended Nurse/Patient Ratios for Labor and Delivery |
|-----------------------------|-----------------------------|
| Ratio | Clinical Setting |
| 1:2 | Patients in labor |
| 1:1 | Patients in second-stage labor |
| 1:1 | Patients with medical/obstetrical complications |
| 1:2 | Oxytocin induction/augmentation |
| 1:1 | During epidural analgesia initiation |
| 1:1 | Circulation for cesarean delivery |

| TABLE 22-3. Recommended Minimum Room Dimensions for Labor and Delivery |
|-----------------------------|-----------------------------|
| Function | Net Floor Space (square feet) |
| LDR | 340 |
| Intensive care | 200 |
| Vaginal delivery | 340 |
| Cesarean delivery | 440 |

LDR = labor, delivery, and recovery.

Admission Procedures

Pregnant women should be urged to report early in labor rather than to procrastinate until delivery is imminent for fear that they might be experiencing false labor. Early admittance to the labor and delivery unit is important, especially if during antepartum care the woman, her fetus, or both have been identified as being at risk.

Identification of Labor

Although the differentiation between false and true labor is difficult at times, the diagnosis usually
can be clarified by contraction frequency and intensity and by cervical dilatation. In those instances when a diagnosis of labor cannot be established with certainty, observation for a longer period is often wise.

Pates and associates (2007) studied the commonly used recommendations given to pregnant women that, in the absence of ruptured membranes or bleeding, uterine contractions 5 minutes apart for 1 hour—that is, ≥ 12 contractions in 1 hour—may signify labor onset. Among 768 women studied at Parkland Hospital, active labor defined as cervical dilatation ≥ 4 cm was diagnosed within 24 hours in three fourths of women with ≥ 12 contractions per hour. Bailit and coworkers (2005) compared labor outcomes of 6121 women who presented in active labor defined as uterine contractions plus cervical dilatation ≥ 4 cm with those of 2697 women who presented in the latent phase. Women admitted during latent-phase labor had more active-phase arrest, more frequent need for oxytocin labor stimulation, and higher rates of chorioamnionitis. It was concluded that physician interventions in women presenting in the latent phase may have been the cause of subsequent labor abnormalities.

Emergency Medical Treatment and Labor Act—EMTALA

Congress enacted EMTALA in 1986 to ensure public access to emergency services regardless of the ability to pay. All Medicare-participating hospitals with emergency services must provide an appropriate screening examination for any pregnant woman experiencing contractions and presenting to the emergency department for evaluation.

The definition of an emergency condition makes specific reference to a pregnant woman who is having contractions. Labor is defined as “the process of childbirth beginning with the latent phase of labor continuing through delivery of the placenta. A woman experiencing contractions is in true labor unless a physician certifies that after a reasonable time of observation the woman is in false labor.” A woman in true labor is considered “unstable” for interhospital transfer purposes until the newborn and placenta are delivered. An unstable woman may, however, be transferred at the direction of the patient or by a physician who certifies that the benefits of treatment at another facility outweigh the transfer risks. Physicians and hospitals violating these federal requirements are subject to civil penalties up to $50,000 and termination from the Medicare program.

Electronic Fetal Heart Rate Monitoring

As discussed in Chapter 24 (p. 473), electronic fetal heart rate monitoring is routinely used for high-risk pregnancies commencing at admission. Some investigators recommend monitoring women with low-risk pregnancies upon admission as a test of fetal well-being—the so-called fetal admission test. If no fetal heart rate abnormalities are detected, continuous electronic monitoring is replaced by intermittent assessment for the remainder of labor. We are of the view that electronic fetal heart rate monitoring is reasonable in the preadmission evaluation of women, including those who subsequently are discharged. At Parkland Hospital, external electronic monitoring is performed for at least 1 hour before discharging the woman who was ascertained to have false labor.

Home Births

A major emphasis of obstetrical care during the 20th century was the movement to birthing in hospitals rather than in homes. In 2006, 98.9 percent of births in the United States took place in hospitals.
hospitals (Martin, 2011). Of the other 1.1 percent, 67.2 percent were in homes, and 27.6 percent were in birthing centers. Between 2004 and 2008, more than half of all states had an increase in home births (MacDorman, 2011). As discussed in Chapter 1 (p. 11) most studies suggest increased risks with home deliveries (Berghella, 2008; Cheng, 2013; de Jonge, 2013; Grunebaum, 2013) Indeed, Chervenak and colleagues (2013) have questioned the ethics of physicians voluntarily involved in home births.

**Initial Evaluation**

Maternal blood pressure, temperature, pulse, and respiratory rate are recorded. The pregnancy record is promptly reviewed to identify complications. Problems identified or anticipated during prenatal care should be displayed prominently in the pregnancy record. Most often, *unless there has been bleeding in excess of bloody show*, a vaginal examination is performed. The gloved index and second fingers are then introduced into the vagina while avoiding the anal region (Fig. 22-24). The number of vaginal examinations correlates with infection-related morbidity, especially in cases of early membrane rupture.

![FIGURE 22-24](image)

*FIGURE 22-24* To perform vaginal examination, the labia have been separated with one hand, and the first and second fingers of the other hand are carefully inserted into the introitus.
Ruptured Membranes

The woman should be instructed during the antepartum period to be aware of fluid leakage from the vagina and to report such an event promptly. Rupture of the membranes is significant for three reasons. First, if the presenting part is not fixed in the pelvis, the possibility of umbilical cord prolapse and compression is greatly increased. Second, labor is likely to begin soon if the pregnancy is at or near term. Third, if delivery is delayed after membrane rupture, intrauterine infection is more likely as the time interval increases (Herbst, 2007).

Upon sterile speculum examination, ruptured membranes are diagnosed if amnionic fluid pools in the posterior fornix or clear fluid flows from the cervical canal. Although several diagnostic tests for the detection of ruptured membranes have been recommended, none is completely reliable. If the diagnosis remains uncertain, another method involves pH determination of vaginal fluid. The pH of vaginal secretions normally ranges from 4.5 to 5.5, whereas that of amnionic fluid is usually 7.0 to 7.5. The use of the indicator nitrazine to identify ruptured membranes is a simple and fairly reliable method. Test papers are impregnated with the dye, and the color of the reaction between these paper strips and vaginal fluids is interpreted by comparison with a standard color chart. A pH above 6.5 is consistent with ruptured membranes. False-positive test results may occur with coexistent blood, semen, or bacterial vaginosis, whereas false-negative tests may result with scant fluid.

Other tests include arborization or ferning of vaginal fluid, which suggests amnionic rather than cervical fluid. Amnionic fluid crystallizes to form a fernlike pattern due to its relative concentrations of sodium chloride, proteins, and carbohydrates (Fig. 4-2, p. 49). Detection of alpha-fetoprotein in the vaginal vault has been used to identify amnionic fluid (Yamada, 1998). Although rarely required, identification may also follow injection of indigo carmine into the amnionic sac via abdominal amniocentesis.

Cervical Assessment

The degree of cervical effacement usually is expressed in terms of the length of the cervical canal compared with that of an uneffaced cervix. When the length of the cervix is reduced by one half, it is 50-percent effaced. When the cervix becomes as thin as the adjacent lower uterine segment, it is completely, or 100-percent, effaced.

Cervical dilatation is determined by estimating the average diameter of the cervical opening by sweeping the examining finger from the margin of the cervical opening on one side to that on the opposite side. The diameter traversed is estimated in centimeters. The cervix is said to be dilated fully when the diameter measures 10 cm, because the presenting part of a term-size newborn usually can pass through a cervix this widely dilated.

The position of the cervix is determined by the relationship of the cervical os to the fetal head and is categorized as posterior, mid-position, or anterior. Along with position, the consistency of cervix is determined to be soft, firm, or intermediate between these two.

The level—or station—of the presenting fetal part in the birth canal is described in relationship to the ischial spines, which are halfway between the pelvic inlet and the pelvic outlet. When the lowermost portion of the presenting fetal part is at the level of the spines, it is designated as being at zero (0) station. In the past, the long axis of the birth canal above and below the ischial spines was arbitrarily divided into thirds by some and into fifths (approximately 1 cm) by other groups. In 1989, the American College of Obstetricians and Gynecologists adopted the classification of station that divides the pelvis above and below the spines into fifths. Each fifth represents 1 cm above or below the spines. Thus, as the presenting fetal part descends from the
inlet toward the ischial spines, the designation is –5, –4, –3, –2, –1, then 0 station. Below the spines, as the presenting fetal part descends, it passes +1, +2, +3, +4, and +5 stations to delivery. Station +5 cm corresponds to the fetal head being visible at the introitus.

If the leading part of the fetal head is at 0 station or below, most often the fetal head has engaged—thus, the biparietal plane has passed through the pelvic inlet. *If the head is unusually molded or if there is an extensive caput formation or both, engagement might not have taken place although the head appears to be at 0 station.*

In a study done at five teaching centers in Denver, residents, nurses, and faculty were surveyed to determine what definitions were being used to describe fetal station (Carollo, 2004). Four different definitions were in use. Disturbingly, these investigators found that few caregivers were aware that others were using different definitions of station! Dupuis and colleagues (2005) tested the reliability of clinical estimations of station using the position of the leading part in centimeters above or below the spines as recommended by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012). A birth simulator was used in which station could be precisely measured and compared with the vaginal examination done by clinicians. They reported that the clinical examiners were incorrect a third of the time.

These five characteristics: cervical dilatation, effacement, consistency, position, and fetal station are assessed when tabulating the Bishop score. This score is commonly used to predict labor induction outcome and is discussed in Chapter 26 (p. 526).

**Laboratory Studies**

When a woman is admitted in labor, most often the hematocrit or hemoglobin concentration should be rechecked. The hematocrit can be measured easily and quickly. At Parkland Hospital, blood is collected in a standard collection tube with anticoagulant. From this, a heparinized capillary tube is filled to spin in a microhematocrit centrifuge in the labor and delivery unit. This provides a hematocrit value within 3 minutes. The initial collection tube is also sent to the hematology laboratory for evaluation. Another labeled tube of blood is allowed to clot and sent to the blood bank for blood type and antibody screen, if needed. A final sample is collected for syphilis and human immunodeficiency virus (HIV) serology. We obtain a urine specimen for protein determination in hypertensive women only (Chap. 40, p. 729). In some labor units, however, a clean-catch voided specimen is examined in all women for protein and glucose.

Women who have had no prenatal care should be considered to be at risk for syphilis, hepatitis B, and HIV (Chap. 65, p. 1265). In those with no prior prenatal care, these laboratory studies, as well as a blood type and antibody screen, should be performed (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). Some states, for example Texas, require routine testing for syphilis, hepatitis B, and HIV in all women admitted to labor and delivery units, even if these were done during prenatal care.

**Management of the First Stage of Labor**

As soon as possible after admittance, the remainder of a general examination is completed. Whether a pregnancy is normal can best be determined when all examinations, including record and laboratory review, are completed. A rational plan for monitoring labor can then be established based on the needs of the fetus and the mother. Because there are marked individual variations in labor lengths, precise statements as to its anticipated duration are unwise.
Intrapartum Fetal Monitoring
This is discussed in detail in Chapter 24. Briefly, the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2012) recommend that during first-stage labor, in the absence of any abnormalities, the fetal heart rate should be checked immediately after a contraction at least every 30 minutes and then every 15 minutes during the second stage. If continuous electronic monitoring is used, the tracing is evaluated at least every 30 minutes during the first stage and at least every 15 minutes during second-stage labor. For women with pregnancies at risk, fetal heart auscultation is performed at least every 15 minutes during first-stage labor and every 5 minutes during the second stage. Continuous electronic monitoring may be used with evaluation of the tracing every 15 minutes during the first stage of labor, and every 5 minutes during the second stage.

Uterine Contractions
Although usually assessed by electronic monitoring as also discussed in Chapter 24, contractions can be both quantitatively and qualitatively evaluated manually. With the palm of the hand resting lightly on the uterus, the time of contraction onset is determined. Its intensity is gauged from the degree of firmness the uterus achieves. At the acme of effective contractions, the finger or thumb cannot readily indent the uterus during a “firm” contraction. The time at which the contraction disappears is noted next. This sequence is repeated to evaluate the frequency, duration, and intensity of uterine contractions.

Maternal Vital Signs
Temperature, pulse, and blood pressure are evaluated at least every 4 hours. If membranes have been ruptured for many hours before labor onset or if there is a borderline temperature elevation, the temperature is checked hourly. Moreover, with prolonged membrane rupture, defined as greater than 18 hours, antimicrobial administration for prevention of group B streptococcal infections is recommended. This is discussed in Chapter 64 (p. 1249).

Subsequent Cervical Examinations
During the first stage of labor, the need for subsequent vaginal examinations to monitor cervical change and presenting part position will vary considerably. When the membranes rupture, an examination to exclude cord prolapse should be performed expeditiously if the fetal head was not definitely engaged at the previous examination. The fetal heart rate should also be checked immediately and during the next uterine contraction to help detect occult umbilical cord compression. At Parkland Hospital, periodic pelvic examinations are typically performed at 2- to 3-hour intervals to evaluate labor progress.

Oral Intake
Food should be withheld during active labor and delivery. Gastric emptying time is remarkably prolonged once labor is established and analgesics are administered. As a consequence, ingested food and most medications remain in the stomach and are not absorbed. Instead, they may be vomited and aspirated (Chap. 25, p. 519). According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007), sips of clear liquids, occasional ice chips, and lip moisturizers are permitted.

Intravenous Fluids
Although it has become customary in many hospitals to establish an intravenous infusion system routinely early in labor, there is seldom any real need for this in the normal pregnant woman, at least until analgesia is administered. An intravenous infusion system is advantageous during the immediate puerperium to administer oxytocin prophylactically and at times therapeutically when uterine atony persists. Moreover, with longer labors, the administration of glucose, sodium, and water to the otherwise fasting woman at the rate of 60 to 120 mL/hr prevents dehydration and acidosis. Shrivastava and associates (2009) noted shorter labors in nulliparas delivering vaginally who were provided an intravenous normal saline with dextrose solution compared with those given saline solution only. Garite and coworkers (2000) randomly assigned 195 women in labor to receive either 125 or 250 mL/hr of lactated Ringer or isotonic sodium chloride solution. The mean volume of total intravenous fluid was 2008 mL in the 125 mL/hr group and 2487 mL in the 250 mL/hr group. Labor lasted > 12 hours in significantly more (26 versus 13 percent) of the women given a 125 mL/hr infusion compared with those given 250 mL/hr—26 versus 13 percent, respectively.

**Maternal Position**

The normal laboring woman need not be confined to bed early in labor. A comfortable chair may be beneficial psychologically and perhaps physiologically. In bed, the laboring woman should be allowed to assume the position she finds most comfortable—this will be lateral recumbency most of the time. She must not be restricted to lying supine because of resultant aortocaval compression and its potential to lower uterine perfusion (Chap. 4, p. 60). Bloom and colleagues (1998) conducted a randomized trial of walking during labor in more than 1000 women with low-risk pregnancies. They found that walking neither enhanced nor impaired active labor and that it was not harmful. Lawrence and associates (2009) reached similar findings in their Cochrane database review.

**Analgesia**

This is discussed in detail in Chapter 25. In general, pain relief should depend on the needs and desires of the woman. The American College of Obstetricians and Gynecologists (2009) has specified optimal goals for anesthesia care in obstetrics.

**Amniotomy**

If the membranes are intact, there is a great temptation, even during normal labor, to perform amniotomy. The presumed benefits are more rapid labor, earlier detection of meconium-stained amniotic fluid, and the opportunity to apply an electrode to the fetus or insert a pressure catheter into the uterine cavity for monitoring. The advantages and disadvantages of amniotomy are discussed in Chapter 26 (p. 531). Importantly, the fetal head must be well applied to the cervix and not be dislodged from the pelvis during the procedure to avert umbilical cord prolapse.

**Urinary Bladder Function**

Distention of the bladder should be avoided because it can hinder descent of the fetal presenting part and lead to subsequent bladder hypotonia and infection. During each abdominal examination, the suprapubic region should be inspected and palpated to detect distention. If the bladder is readily seen or palpated above the symphysis, the woman should be encouraged to void. At times, those who may be unable to void on a bedpan may be able to ambulate with assistance to a toilet and successfully void. If the bladder is distended and voiding is not possible, catheterization is
indicated. Carley and coworkers (2002) found that 51 of 11,332 vaginal deliveries (1 in 200) were complicated by urinary retention. Most women resumed normal voiding before discharge from the hospital. Musselwhite and associates (2007) reported retention in 4.7 percent of women who had labor epidural analgesia. Risk factors for retention were primiparity, oxytocin-induced or -augmented labor, perineal lacerations, operative vaginal delivery, catheterization during labor, and labor duration > 10 hours.

### Management of the Second Stage of Labor

With full cervical dilatation, which signifies the onset of the second stage, a woman typically begins to bear down. With descent of the presenting part, she develops the urge to defecate. Uterine contractions and the accompanying expulsive forces may now last 1 minutes and recur at an interval no longer than 1½ minute. As discussed on page 447, the median duration of the second stage is 50 minutes in nulliparas and 20 minutes in multiparas, although the interval can be highly variable. Monitoring of the fetal heart rate is discussed on page 450, and interpretation of second-stage electronic fetal heart rate patterns is discussed in Chapter 24 (p. 487).

### Expulsive Efforts

In most cases, bearing down is reflexive and spontaneous during second-stage labor. Occasionally, a woman may not employ her expulsive forces to good advantage and coaching is desirable. Her legs should be half-flexed so that she can push with them against the mattress. When the next uterine contraction begins, she is instructed to exert downward pressure as though she were straining at stool. A woman is not encouraged to push beyond the completion of each contraction. Instead, she and her fetus should be allowed to rest and recover. During this period of actively bearing down, the fetal heart rate auscultated immediately after the contraction is likely to be slow but should recover to normal range before the next expulsive effort.

Several positions during the second stage have been recommended to augment pushing efforts. Eason and colleagues (2000) performed an extensive review of various positions and their effect on the incidence of perineal trauma. They found that the supported upright position had no advantages over the recumbent one. Upright positions include sitting, kneeling, squatting, or resting with the back at a 30-degree elevation. Conversely, in their systematic review, Berghella and coworkers (2008) reported good-quality data that supported the upright position. Fetal and obstetrical outcomes appear to be unaffected whether pushing is coached or uncoached during second-stage labor (Bloom, 2006; Tuuli, 2012). The maternal effects of coached pushing were reported by Schaffer and colleagues (2005), who performed urodynamic testing in primigravidas 3 months following delivery. Women coached to push during second-stage labor had decreased bladder capacity and decreased first urge to void compared with women encouraged to push or rest as desired. The long-term effects of this practice are yet to be defined.

As the head descends through the pelvis, the perineum begins to bulge and the overlying skin becomes stretched. Now the scalp of the fetus may be visible through the vulvar opening. At this time, the woman and her fetus are prepared for delivery, which is described in Chapter 27 (p. 537).
An orderly and systematic approach to labor management results in reproducible maternal and perinatal outcomes. This was proven by Althabe and coworkers (2008), who randomized implementation of evidence-based care in 19 hospitals in Argentina and Uruguay. Several labor management protocols are subsequently presented. These include those from the National Maternity Hospital in Dublin, the World Health Organization, and from Parkland Hospital.

### Active Management of Labor

More than 30 years ago, O’Driscoll and associates (1984) pioneered the concept that a disciplined, standardized labor management protocol reduced the number of cesarean deliveries for dystocia. Their overall cesarean delivery rate was 5 percent in the 1970s and 1980s with such management. The approach is now referred to as active management of labor. Two of its components—amniotomy and oxytocin—have been widely used, especially in English-speaking countries outside the United States. With this protocol, labor is diagnosed when painful contractions are accompanied by complete cervical effacement, bloody “show,” or ruptured membranes. Women with such findings are committed to delivery within 12 hours. Pelvic examination is performed each hour for the next 3 hours, and thereafter at 2-hour intervals. When dilatation has not increased by at least 1 cm/hr, amniotomy is performed. Progress is again assessed at 2 hours and high-dose oxytocin infusion, described in Chapter 26 (p. 530), is started unless dilatation of at least 1 cm/hr is documented. Women are constantly attended by midwives. If membranes rupture before admission, oxytocin is begun for no progress at the 1-hour mark.

López-Zeno and colleagues (1992) prospectively compared such active management with their “traditional” approach to labor management at Northwestern Memorial Hospital in Chicago. They randomly assigned 705 nulliparas with uncomplicated pregnancies in spontaneous labor at term. The cesarean delivery rate was significantly lower with active versus traditional management—10.5 versus 14.1 percent, respectively. Subsequent studies did not show this. Wei and associates (2009) in a Cochrane database review found a modest reduction in cesarean delivery rates when active management of labor was compared with standard care. Frigoletto and coworkers (1995) reported another randomized trial with 1934 nulliparous women at Brigham and Women’s Hospital in Boston. Although they found that such management somewhat shortened labor, it did not affect the cesarean delivery rate. These observations have since been reported by many others (Brown, 2008).

### World Health Organization Partograph

A partograph was designed by the World Health Organization (WHO) for use in developing countries (Dujardin, 1992). According to Orji (2008), the partograph is similar for nulliparas and multiparas. Labor is divided into a latent phase, which should last no longer than 8 hours, and an active phase. The active phase starts at 3 cm dilatation, and progress should be no slower than 1 cm/hr. A 4-hour wait is recommended before intervention when the active phase is slow. Labor is graphed, and analysis includes use of alert and action lines. Lavender and colleagues (2006) randomized 3000 nulliparous women to labor interventions at 2 hours versus 4 hours as recommended by WHO. Their cesarean delivery rate was unaffected, and they concluded that interventions such as amniotomy and oxytocin were needlessly increased using the 2-hour time interval. After their Cochrane Database review, Lavender and associates (2008) do not recommend use of the partograph for standard labor management.
Women are admitted if active labor—defined as cervical dilatation of 3 to 4 cm or more in the presence of uterine contractions—is diagnosed or if ruptured membranes are confirmed. Management guidelines summarized in Figure 22-25 stipulate that a pelvic examination be performed approximately every 2 hours. Ineffective labor is suspected when the cervix does not dilate within approximately 2 hours of admission. Amniotomy is then performed, and labor progress determined at the next 2-hour evaluation. In women whose labors do not progress, an intrauterine pressure catheter is placed to assess uterine function. Hypotonic contractions and no cervical dilatation after an additional 2 to 3 hours result in stimulation of labor using the high-dose oxytocin regimen described in Chapter 26 (p. 530). The goal is uterine activity of 200 to 250 Montevideo units for 2 to 4 hours before dystocia can be diagnosed.

FIGURE 22-25 Schematic of labor management protocol in use at Parkland Hospital. The total admission-to-delivery times are shorter than the potential sum of the intervention intervals because not every woman requires every intervention.

Dilatation rates of 1 to 2 cm/hr are accepted as evidence of progress after satisfactory uterine activity has been established with oxytocin. This can require up to 8 hours or more before cesarean delivery is performed for dystocia. The cumulative time required to effect this stepwise management approach permits many women to establish effective labor. This management protocol has been evaluated in more than 20,000 women with uncomplicated pregnancies. Importantly,
these labor interventions and the relatively infrequent use of cesarean delivery did not jeopardize the fetus-newborn.

COMPLICATIONS WITH DYSTOCIA

DYSTOCIA

There are several labor abnormalities that may interfere with the orderly progression to spontaneous delivery. Generally, these are referred to as dystocia. Dystocia literally means difficult labor and is characterized by abnormally slow labor progress. It arises from four distinct abnormalities that may exist singly or in combination. First, expulsive forces may be abnormal. For example, uterine contractions may be insufficiently strong or inappropriately coordinated to efface and dilate the cervix—uterine dysfunction. Also, there may be inadequate voluntary maternal muscle effort during second-stage labor. Second, fetal abnormalities of presentation, position, or development may slow labor. Also, abnormalities of the maternal bony pelvis may create a contracted pelvis. And last, soft tissue abnormalities of the reproductive tract may form an obstacle to fetal descent. More simply, these abnormalities can be mechanistically simplified into three categories that include abnormalities of the powers—uterine contractility and maternal
expulsive effort; the *passenger*—the fetus; and the *passage*—the pelvis. Common clinical findings in women with these labor abnormalities are summarized in Table 23-1.

**TABLE 23-1. Common Clinical Findings in Women with Ineffective Labor**

Inadequate cervical dilation or fetal descent:
- Protracted labor—slow progress
- Arrested labor—no progress
- Inadequate expulsive effort—ineffective pushing

Fetopelvic disproportion:
- Excessive fetal size
- Inadequate pelvic capacity
- Malpresentation or position of the fetus

Ruptured membranes without labor

---

**Dystocia Descriptors**

Abnormalities that are shown in Table 23-1 often interact in concert to produce dysfunctional labor. Commonly used expressions today such as *cephalopelvic disproportion* and *failure to progress* are used to describe ineffective labors. Of these, *cephalopelvic disproportion* is a term that came into use before the 20th century to describe obstructed labor resulting from disparity between the fetal head size and maternal pelvis. But the term originated at a time when the main indication for cesarean delivery was overt pelvic contracture due to rickets (Olah, 1994). Such absolute disproportion is now rare, and most cases result from malposition of the fetal head within the pelvis (asynclitism) or from ineffective uterine contractions. True disproportion is a tenuous diagnosis because two thirds or more of women undergoing cesarean delivery for this reason subsequently deliver even larger newborns vaginally. A second phrase, *failure to progress* in either spontaneous or stimulated labor, has become an increasingly popular description of inefficual labor. This term reflects lack of progressive cervical dilatation or lack of fetal descent. Neither of these two expressions is specific. Terms presented in Table 23-2 and their diagnostic criteria more precisely describe abnormal labor.

**TABLE 23-2. Abnormal Labor Patterns, Diagnostic Criteria, and Methods of Treatment**
Mechanisms of Dystocia

Dystocia as described by Williams (1903) in the first edition of this text is still true today. Figure 23-1 demonstrates the mechanical process of labor and potential obstacles. The cervix and lower uterus are shown at the end of pregnancy and at the end of labor. At the end of pregnancy, the fetal head, to traverse the birth canal, must encounter a relatively thick lower uterine segment and undilated cervix. The uterine fundus muscle is less developed and presumably less powerful. Uterine contractions, cervical resistance, and the forward pressure exerted by the leading fetal part are the factors influencing the progress of first-stage labor.

CPD = cephalopelvic disproportion.
Modified from Cohen, 1983.
As also shown in Figure 23-1B, after complete cervical dilatation, the mechanical relationship between the fetal head size and position and the pelvic capacity, namely fetopelvic proportion, becomes clearer as the fetus descends. Because of this, abnormalities in fetopelvic proportions become more apparent once the second stage is reached.

Uterine muscle malfunction can result from uterine overdistention or obstructed labor or both. Thus, ineffective labor is generally accepted as a possible warning sign of fetopelvic disproportion. Although artificial separation of labor abnormalities into pure uterine dysfunction and fetopelvic disproportion simplifies classification, it is an incomplete characterization because these two abnormalities are so closely interlinked. Indeed, according to the American College of Obstetricians and Gynecologists (2013), the bony pelvis rarely limits vaginal delivery. In the absence of objective means of precisely distinguishing these two causes of labor failure, clinicians must rely on a trial of labor to determine if labor can be successful in effecting vaginal delivery.

Revised Dystocia Diagnosis

In 2009, the total cesarean delivery rate for all births in the United States reached a record high of 32.9 percent (Martin, 2011). This was the 13th consecutive year in which the cesarean rate increased, and it represented a nearly 60-percent increase compared with 20.7 percent in 1996. The 2010 rate of 32.8 percent could suggest that this long trend of increasing cesarean rates may now be moderating (Martin, 2012). Given that many repeat cesarean deliveries are performed after primary operations for dystocia, it is estimated that 60 percent of all cesarean deliveries in the United States are ultimately attributable to the diagnosis of abnormal labor (American College...
To address this increasing cesarean delivery rate, a workshop was convened by the National Institute of Child Health and Human Development (NICHD) and the American College of Obstetricians and Gynecologists (Spong, 2012). The workshop recommended new definitions for arrest of labor progress to prevent unnecessary first cesarean deliveries. Specifically, it concluded that “adequate time for normal latent and active phases of the first stage and for the second stage should be allowed as long as the maternal and fetal conditions permit. The adequate time for each of these stages appears to be longer than traditionally estimated.” The implication of this viewpoint is that changing the diagnostic criteria of abnormal labor will reduce the excessive cesarean birth rate. Shown in Table 23-3 is a synopsis of some of these workshop recommendations for revised labor management criteria. According to the workshop, these definitions “vary somewhat from published criteria and are recommended in recognition of more recent findings regarding labor progress that challenge our long-held practices based on the Friedman curve.”

These proposed new criteria listed in Table 23-3 for normal, and therefore also abnormal labor, were heavily dependent on results of the NICHD-sponsored Safe Labor Consortium and on an NICHD-sponsored report on second-stage labor duration (Rouse, 2009; Zhang, 2010). Shown in Table 23-4 is a comparison of active labor phase duration in the Safe Labor Consortium compared with other contemporary reports. It is important to note that almost half of the Consortium cohort received oxytocin and 84 percent had received epidural analgesia—both factors associated with longer active-phase labor. Indeed, cases using oxytocin and epidural analgesia in the studies of Graseck (2012) and Alexander (2002) had similar active-labor phase durations to those from the Consortium. Importantly, all these reports were based on contemporary obstetrical practices.

From Spong, 2012.
The Safe Labor Consortium report by Zhang and associates (2010) was a multicenter retrospective study using abstracted 2002 to 2008 data from electronic medical records in 19 hospitals across the United States. One purpose of this study was to analyze labor patterns and develop contemporary criteria for labor progress in nulliparas. Shown in Figure 23-2 is a synopsis of the study cohort, which formed the basis of the proposed new criteria for labor progress. Importantly, all women with cesarean delivery were excluded as were all of those with compromised newborn infants. Because of these major exclusions, the pattern of labor now defined as normal is problematic given that only women who achieved vaginal birth with a normal infant outcome were included. It is also problematic to conclude that these revised labor criteria will reduce the cesarean rate when the overall rate in the Safe Labor Consortium was 30.5 percent using the newly proposed first-stage labor intervals. The authors of a report from the Maternal Fetal Medicine Units Network of the NICHD analyzed labor management practices in 8546 women undergoing primary cesarean delivery for dystocia in a wide cross section of hospitals in the United States (Alexander, 2003). Approximately 92 percent of the cesareans for dystocia were performed in the active phase of labor defined as ≥ 4 cm cervical dilatation. The median admission to delivery interval was 17 hours, and the median cervical dilation was 6 cm before the dystocia diagnosis in women in active-phase labor. Oxytocin was used in 90 percent of women diagnosed with dystocia. It was concluded that bona-fide efforts were being made in contemporary practice to achieve active labor before diagnosing dystocia leading to cesarean delivery.
The report by Rouse and colleagues (2009) on second-stage labor was a secondary analysis of 4126 nulliparous women who reached the second stage during a randomized trial to study fetal pulse oximetry. Of the 360 women—9 percent—whose second stage was > 3 hours, 95 percent had received epidural analgesia. A third of these 360 women—3.5 percent of the whole cohort—had a second stage > 4 hours. The results of this study were interpreted as support for extending the duration of the second stage in nulliparas to beyond the current recommended 3 hours when epidural analgesia is used (American College of Obstetricians and Gynecologists, 2013). The investigators concluded that a fetus born after a > 3-hour second stage had a higher—albeit still low—neonatal intensive care unit (NICU) admission rate and a low risk for brachial plexus injury (Rouse, 2009).

These latter results are in contrast to those associated with prolonged second-stage labors at Parkland Hospital (Bleich, 2012). This study included 21,991 women of whom 7 percent had
second-stage labor > 3 hours. Most of the 2 percent of women reaching 4 hours in the second stage had been given epidural analgesia and were awaiting cesarean delivery that was decided on at the 3-hour time point. Typically, oxytocin had been discontinued, and they also had reassuring fetal heart rate tracings that permitted temporization awaiting operative space. Thus, such prolonged second stages were unintentional in that further efforts to effect vaginal delivery were not made. Despite these caveats, virtually every adverse infant outcome analyzed increased significantly when the second stage exceeded 3 hours in women with labor epidural analgesia (Table 23-5).

We conclude that at this time, an improved definition of the adequacy of a trial of labor before diagnosing dystocia remains an elusive goal. The newly proposed criteria for first-stage labor are already in use in contemporary practice, and thus they are unlikely to have much impact on the cesarean delivery rate for abnormal labor. Importantly, the purported safety of the proposed new criteria for second-stage labor management should be viewed with caution until more published experiences accrue.

**ABNORMALITIES OF THE EXPULSIVE FORCES**
Cervical dilatation and propulsion and expulsion of the fetus are brought about by contractions of the uterus, which are reinforced during the second stage by voluntary or involuntary muscular action of the abdominal wall—“pushing.” The diagnosis of uterine dysfunction in the latent phase is difficult and sometimes can be made only in retrospect (Chap. 22, p. 446). Women who are not yet in active labor commonly are erroneously treated for uterine dysfunction.

Beginning in the 1960s, there have been at least three significant advances in the treatment of uterine dysfunction. First is the realization that undue labor prolongation may contribute to maternal and perinatal morbidity and mortality rates. Second, dilute intravenous infusion of oxytocin is used for treatment of certain types of uterine dysfunction. Last, cesarean delivery is selected rather than difficult midforceps delivery when oxytocin fails or its use is inappropriate.

### Types of Uterine Dysfunction

Reynolds and coworkers (1948) emphasized that uterine contractions of normal labor are characterized by a gradient of myometrial activity. These forces are greatest and last longest at the fundus—considered *fundal dominance*—and they diminish toward the cervix. Caldeyro-Barcia and colleagues (1950) from Montevideo, Uruguay, inserted small balloons into the myometrium at various levels (Chap. 24, p. 498). They reported that in addition to a gradient of activity, there was a time differential in the onset of the contractions in the fundus, mid-zone, and lower uterine segments. Larks (1960) described the stimulus as starting in one cornu and then several milliseconds later in the other. The excitation waves then join and sweep over the fundus and down the uterus. Normal spontaneous contractions often exert pressures approximating 60 mm Hg (Hendricks, 1959). Even so, the Montevideo group ascertained that the lower limit of contraction pressure required to dilate the cervix is 15 mm Hg.

From these observations, it is possible to define two types of uterine dysfunction. In the more common *hypotonic uterine dysfunction*, there is no basal hypertonus and uterine contractions have a normal gradient pattern (synchronous), but pressure during a contraction is insufficient to dilate the cervix. In the second type, *hypertonic uterine dysfunction* or *incoordinate uterine dysfunction*, either basal tone is elevated appreciably or the pressure gradient is distorted. Gradient distortion may result from more forceful contraction of the uterine midsegment than the fundus or from complete asynchrony of the impulses originating in each cornu or a combination of these two.

### Active-Phase Disorders

Labor abnormalities are divided into either a slower-than-normal progress—*protraction disorder*—or a complete cessation of progress—*arrest disorder*. A woman must be in the active phase of labor with cervical dilatation to at least 3 to 4 cm to be diagnosed with either of these. Handa and Laros (1993) diagnosed active-phase arrest, defined as no dilatation for 2 hours or more, in 5 percent of term nulliparas. This incidence has not changed since the 1950s (Friedman, 1978). Inadequate uterine contractions, defined as less than 180 Montevideo units, calculated as shown in Figure 23-3, were diagnosed in 80 percent of women with active-phase arrest.
Montevideo units are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window and adding the pressures generated by each contraction. In the example shown, there were five contractions, producing pressure changes of 52, 50, 47, 44, and 49 mm Hg, respectively. The sum of these five contractions is 242 Montevideo units.

Protraction disorders are less well described, and the time necessary before diagnosing slow progress is undefined. The World Health Organization (1994) has proposed a labor management partograph in which protraction is defined as less than 1 cm/hr cervical dilatation for a minimum of 4 hours. Criteria for the diagnosis of protraction and arrest disorders have been recommended by the American College of Obstetricians and Gynecologists (2013). These criteria were adapted from those of Cohen and Friedman (1983), shown in Table 23-2.

Hauth and coworkers (1986, 1991) reported that when labor is effectively induced or augmented with oxytocin, 90 percent of women achieve 200 to 225 Montevideo units, and 40 percent achieve at least 300 Montevideo units. These results suggest that there are certain minimums of uterine activity that should be achieved before performing cesarean delivery for dystocia. Accordingly, the American College of Obstetricians and Gynecologists (2013) has suggested that before the diagnosis of first-stage labor arrest is made, specific criteria should be met. First, the latent phase has been completed, and the cervix is dilated 4 cm or more. Also, a uterine contraction pattern of 200 Montevideo units or more in a 10-minute period has been present for 2 hours without cervical change. Rouse and associates (1999) have challenged the “2-hour rule” on the grounds that a longer time, that is, at least 4 hours, is necessary before concluding that the active phase of labor has failed. We agree.

### Second-Stage Disorders

As discussed in Chapter 21 (p. 415), fetal descent largely follows complete dilatation. Moreover, the second stage incorporates many of the cardinal movements necessary for the fetus to negotiate the birth canal. Accordingly, disproportion of the fetus and pelvis frequently becomes apparent.
During second-stage labor.

Until recently, there have been largely unquestioned second-stage rules that limited its duration. These rules were established in American obstetrics by the beginning of the 20th century. They stemmed from concerns about maternal and fetal health, likely regarding infection, and led to difficult forceps operations. The second stage in nulliparas was limited to 2 hours and extended to 3 hours when regional analgesia was used. For multiparas, 1 hour was the limit, extended to 2 hours with regional analgesia.

Cohen (1977) investigated the fetal effects of second-stage labor length at Beth Israel Hospital. He included 4403 term nulliparas in whom electronic fetal heart rate monitoring was performed. The neonatal mortality rate was not increased in women whose second-stage labor exceeded 2 hours. Epidural analgesia was used commonly, and this likely accounted for the large number of pregnancies with a prolonged second stage. These data influenced decisions to permit an additional hour for the second stage when regional analgesia is used.

Menticoglou and coworkers (1995a,b) challenged the prevailing dictums on second-stage duration. These arose because of grave neonatal injuries associated with forceps rotations to shorten second-stage labor. As a result, they allowed a longer second stage to decrease the operative vaginal delivery rate. Between 1988 and 1992, second-stage labor exceeded 2 hours in a fourth of 6041 nulliparas at term. Labor epidural analgesia was used in 55 percent. The length of the second stage, even in those lasting up to 6 hours or more, was not related to neonatal outcome. These results were attributed to careful use of electronic monitoring and scalp pH measurements. These investigators concluded that there is no compelling reason to intervene with a possibly difficult forceps or vacuum extraction because a certain number of hours have elapsed. They observed, however, that after 3 hours in the second stage, delivery by cesarean or other operative method increased progressively. By 5 hours, the prospects for spontaneous delivery in the subsequent hour are only 10 to 15 percent.

Adverse maternal outcomes, however, are increased with prolonged second-stage labor. Myles and Santolaya (2003) analyzed both the maternal and neonatal consequences of this in 7818 women in Chicago between 1996 and 1999. Adverse maternal outcomes in relation to the duration of second-stage labor were increased as shown in Table 23-6. Neonatal mortality and morbidity rates were not related to the length of the second stage.

Adapted from Myles, 2003.
**Relationship between First- and Second-Stage Labor Duration**

It is possible that prolonged first-stage labor presages that with the second stage. Nelson and associates (2013) studied the relationships between the lengths of the first and second stages of labor in 12,523 nulliparous women at term delivered at Parkland Hospital. The length of the second stage significantly increased concomitantly with increasing length of the first stage. The 95th percentile was 15.6 and 2.9 hours for the first and second stages, respectively. Women with first stages lasting longer than 15.6 hr (> 95th percentile) had a 16.3 percent rate of a second-stage labor lasting 3 hr (95th percentile) compared with a 4.5-percent rate in women with first-stage labors lasting less than the 95th percentile.

**Maternal Pushing Efforts**

With full cervical dilatation, most women cannot resist the urge to “bear down” or “push” each time the uterus contracts (Chap. 22, p. 451). The combined force created by contractions of the uterus and abdominal musculature propels the fetus downward. Bloom and colleagues (2006) studied effects of actively coaching expulsive efforts. They reported that although the second stage was slightly shorter in coached women, there were no other maternal advantages.

At times, force created by abdominal musculature is compromised sufficiently to slow or even prevent spontaneous vaginal delivery. Heavy sedation or regional analgesia may reduce the reflex urge to push and may impair the ability to contract abdominal muscles sufficiently. In other instances, the inherent urge to push is overridden by the intense pain created by bearing down. Two approaches to second-stage pushing in women with epidural analgesia have yielded contradictory results. The first advocates pushing forcefully with contractions after complete dilation, regardless of the urge to push. With the second, analgesia infusion is stopped and pushing begun only after the woman regains the sensory urge to bear down. Fraser and coworkers (2000) found that delayed pushing reduced difficult operative deliveries, whereas Manyonda and associates (1990) reported the opposite. Hansen and colleagues (2002) randomly assigned 252 women with epidural analgesia to one of the two approaches. There were no adverse maternal or neonatal outcomes linked to delayed pushing despite significantly prolonging second-stage labor. Plunkett and coworkers (2003), in a similar study, confirmed these findings.

**Fetal Station at Onset of Labor**

Descent of the leading edge of the presenting part to the level of the ischial spines (0 station) is defined as engagement. Friedman and Sachtleben (1965, 1976) reported a significant association between higher station at the onset of labor and subsequent dystocia. Handa and Laros (1993) found that fetal station at the time of arrested labor was also a risk factor for dystocia. Roshanfekr and associates (1999) analyzed fetal station in 803 nulliparous women at term in active labor. At admission, the third with the fetal head at or below 0 station had a 5-percent cesarean delivery rate. This is compared with a 14-percent rate for those with higher stations. The prognosis for dystocia, however, was not related to incrementally higher fetal head stations above the pelvic midplane (0 station). Importantly, 86 percent of nulliparous women without fetal head engagement at diagnosis of active labor delivered vaginally. These observations apply especially for parous women because the head typically descends later in labor.

**Reported Causes of Uterine Dysfunction**
Epidural Analgesia

Various labor factors have been implicated as causes of uterine dysfunction. Of these, epidural analgesia can slow labor (Sharma, 2000). As shown in Table 23-7, epidural analgesia has been associated with lengthening of both first- and second-stage labor and with slowing of the rate of fetal descent. This is documented further in Chapter 25 (p. 515).

Chorioamnionitis

Because of the association of prolonged labor with maternal intrapartum infection, some clinicians have suggested that infection itself contributes to abnormal uterine activity. Satin and coworkers (1992) studied the effects of chorioamnionitis on oxytocin stimulation in 266 pregnancies. Infection diagnosed late in labor was found to be a marker of cesarean delivery performed for dystocia, whereas this was not a marker in women diagnosed as having chorioamnionitis early in labor. Specifically, 40 percent of women developing chorioamnionitis after requiring oxytocin for dysfunctional labor later required cesarean delivery for dystocia. It is likely that uterine infection in this clinical setting is a consequence of dysfunctional, prolonged labor rather than a cause of dystocia.

Maternal Position During Labor

Advocacy for recumbency or ambulation during labor has vacillated. Proponents of walking report it to shorten labor, decrease rates of oxytocin augmentation, decrease the need for analgesia, and lower the frequency of operative vaginal delivery (Flynn, 1978; Read, 1981). But other observations do not support this. According to Miller (1983), the uterus contracts more frequently but with less intensity with the mother lying on her back rather than on her side. Conversely, contraction frequency and intensity have been reported to increase with sitting or standing. Lupe and Gross (1986) concluded, however, that there is no conclusive evidence that upright maternal posture or ambulation improves labor. They reported that women preferred to lie on their side or sit in bed. Few chose to walk, fewer to squat, and none wanted the knee-chest position. They tended to assume fetal positions in later labor. Most women enthusiastic about ambulation returned to bed when active labor began (Carlson, 1986; Williams, 1980).
Bloom and colleagues (1998) conducted a randomized trial to study the effects of walking during first-stage labor. In 1067 women with uncomplicated term pregnancies delivered at Parkland Hospital, these investigators reported that ambulation did not affect labor duration. Ambulation did not reduce the need for analgesia, nor was it harmful to the perinate. Because of these observations, we give women without complications the option to select either recumbency or supervised ambulation during labor. This policy is in agreement with the American College of Obstetricians and Gynecologists (2013), which has concluded that ambulation in labor is not harmful, and mobility may result in greater comfort.

**Birthing Position in Second-Stage Labor**

Considerable interest has been shown in alternative second-stage labor birth positions and their effect on labor. Gupta and Hofmeyr (2004) in their Cochrane database review compared upright positions with supine or lithotomy positions. Upright positions included sitting in a “birthing chair,” kneeling, squatting, or resting with the back at a 30-degree elevation. With these positions, they found a 4-minute shorter interval to delivery, less pain, and a lower incidence both of nonreassuring fetal heart rate patterns and of operative vaginal delivery. There was, however, an increased rate of blood loss > 500 mL with the upright positions. Berghella and colleagues (2008) hypothesized that parity, less intense aortocaval compression, improved fetal alignment, and larger pelvic outlet diameters might explain these findings. In an earlier study, Russell (1969) described a 20- to 30-percent increase in the area of the pelvic outlet with squatting compared with that in the supine position. Finally, Babayer and associates (1998) cautioned that prolonged sitting or squatting during the second stage may cause common fibular nerve neuropathy.

**Water Immersion**

A birthing tub or bath has been advocated as a means of relaxation that may contribute to more efficient labor. Cluett and coworkers (2004) randomly assigned 99 laboring women at term in first-stage labor identified to have dystocia to immersion in a birthing pool or to oxytocin augmentation. Water immersion lowered the rate of epidural analgesia use but did not alter the rate of operative delivery. More infants of women in the immersion group were admitted to the NICU. These findings were similar to their subsequent Cochrane database review, except that NICU admission rates were not increased (Cluett, 2009).

Robertson and associates (1998) reported that immersion was not associated with chorioamnionitis or uterine infection. Moreover, Kwee and coworkers (2000) studied the effects of immersion in 20 women and reported that blood pressure decreased, whereas fetal heart rate was unaffected. Neonatal complications unique to underwater birth that have been described include drowning, hyponatremia, waterborne infection, cord rupture, and polycythemia (Austin, 1997; Pinette, 2004).

**PREMATURELY RUPTURED MEMBRANES AT TERM**

Membrane rupture at term without spontaneous uterine contractions complicates approximately 8 percent of pregnancies. Until recently, management generally included labor stimulation if contractions did not begin after 6 to 12 hours. This intervention evolved more than 50 years ago because of maternal and fetal complications due to chorioamnionitis (Calkins, 1952). Such routine intervention was the accepted practice until challenged by Kappy and colleagues (1979). These
investigators reported excessive cesarean delivery in term pregnancies with ruptured membranes managed with labor stimulation compared with those expectantly managed.

Subsequent research included that of Hannah (1996) and Peleg (1999) and their associates, who enrolled a total of 5042 pregnancies with ruptured membranes in a randomized investigation. They measured the effects of induction versus expectant management and also compared induction using intravenous oxytocin with that using prostaglandin E$_2$ gel. There were approximately 1200 pregnancies in each of the four study arms. They concluded that labor induction with intravenous oxytocin was the preferred management. This determination was based on significantly fewer intrapartum and postpartum infections in women whose labor was induced. There were no significant differences in cesarean delivery rates. Subsequent analysis by Hannah and coworkers (2000) indicated increased adverse outcomes when expectant management at home was compared with in-hospital observation. Mozurkewich and associates (2009) reported lower rates of chorioamnionitis, metritis, and NICU admissions for women with term ruptured membranes whose labors were induced compared with those managed expectantly. At Parkland Hospital, labor is induced soon after admission when ruptured membranes are confirmed at term. The benefit of prophylactic antibiotics in women with ruptured membranes before labor at term is unclear (Passos, 2012).

**PRECIPITOUS LABOR AND DELIVERY**

Labor can be too slow, but it also can be abnormally rapid. *Precipitous labor and delivery* is extremely rapid labor and delivery. It may result from an abnormally low resistance of the soft parts of the birth canal, from abnormally strong uterine and abdominal contractions, or rarely from the absence of painful sensations and thus a lack of awareness of vigorous labor.

According to Hughes (1972), precipitous labor terminates in expulsion of the fetus in < 3 hours. Using this definition, 89,047 live births—2 percent—were complicated by precipitous labor in the United States during 2006 (Martin, 2009). Despite this incidence, there is little published information concerning adverse effects.

**Maternal Effects**

Precipitous labor and delivery seldom are accompanied by serious maternal complications if the cervix is effaced appreciably and compliant, if the vagina has been stretched previously, and if the perineum is relaxed. Conversely, vigorous uterine contractions combined with a long, firm cervix and a noncompliant birth canal may lead to uterine rupture or extensive lacerations of the cervix, vagina, vulva, or perineum. It is in these latter circumstances that the rare condition of amnionic-fluid embolism most likely develops (Chap. 41, p. 812).

Precipitous labor is frequently followed by uterine atony. *The uterus that contracts with unusual vigor before delivery is likely to be hypotonic after delivery.* Postpartum hemorrhage from uterine atony is discussed in Chapter 41 (p. 784).

Mahon and colleagues (1994) described 99 pregnancies delivered within 3 hours of labor onset. *Short labors* were defined as a rate of cervical dilatation of 5 cm/hr or faster for nulliparas and 10 cm/hr for multiparas. Such short labors were more common in multiparas who typically had contractions at intervals less than 2 minutes and were associated with placental abruption, meconium, postpartum hemorrhage, cocaine abuse, and low Apgar scores.
Fetal and Neonatal Effects

Adverse perinatal outcomes from precipitous labor may be increased considerably for several reasons. The tumultuous uterine contractions, often with negligible intervals of relaxation, prevent appropriate uterine blood flow and fetal oxygenation. Resistance of the birth canal may rarely cause intracranial trauma. Acker and coworkers (1988) reported that Erb or Duchenne brachial palsy was associated with such labors in a third of cases (Chap. 33, p. 648). Finally, during an unattended birth, the newborn may fall to the floor and be injured, or it may need resuscitation that is not immediately available.

Treatment

Unusually forceful spontaneous uterine contractions are not likely to be modified to a significant degree by analgesia. The use of tocolytic agents such as magnesium sulfate is unproven in these circumstances. Use of general anesthesia with agents that impair uterine contractibility, such as isoflurane, is often excessively heroic. Certainly, any oxytocin agents being administered should be stopped immediately.

FETOPELVIC DISPROPORTION

Pelvic Capacity

Fetopelvic disproportion arises from diminished pelvic capacity, excessive fetal size, or more usually both. Any contraction of the pelvic diameters that diminishes its capacity can create dystocia during labor. There may be a contraction of the pelvic inlet, the midpelvis, or the pelvic outlet, or a generally contracted pelvis may be caused by combinations of these. Normal pelvic dimension are additionally discussed in Chapter 2 (p. 32).

Contracted Inlet

The pelvic inlet usually is considered to be contracted if its shortest anteroposterior diameter is < 10 cm or if the greatest transverse diameter is < 12 cm. The anteroposterior diameter of the inlet is commonly approximated by manually measuring the diagonal conjugate, which is approximately 1.5 cm greater (Chap. 2, p. 33). Therefore, inlet contraction usually is defined as a diagonal conjugate < 11.5 cm.

Using clinical and at times, imaging pelvimetry, it is important to identify the shortest anteroposterior diameter through which the fetal head must pass. Occasionally, the body of the first sacral vertebra is displaced forward so that the shortest distance may actually be between this abnormal sacral promontory and the symphysis pubis.

Before labor, the fetal biparietal diameter has been shown to average from 9.5 to as much as 9.8 cm. Therefore, it might prove difficult or even impossible for some fetuses to pass through an inlet that has an anteroposterior diameter of less than 10 cm. Mengert (1948) and Kaltreider (1952), employing x-ray pelvimetry, demonstrated that the incidence of difficult deliveries is increased to a similar degree when either the anteroposterior diameter of the inlet is < 10 cm or the transverse diameter is < 12 cm. As expected, when both diameters are contracted, dystocia is much greater than when only one is contracted.
A small woman is likely to have a small pelvis, but she is also likely to have a small neonate. Thoms (1937) studied 362 nulliparas and found that the mean birthweight of their offspring was significantly lower—280 g—in women with a small pelvis than in those with a medium or large pelvis. In veterinary obstetrics, in most species, maternal size rather than paternal size is the important determinant of fetal size.

Normally, cervical dilatation is aided by hydrostatic action of the unruptured membranes or after their rupture, by direct application of the presenting part against the cervix (Fig. 21-7, p. 414). In contracted pelves, however, because the head is arrested in the pelvic inlet, the entire force exerted by the uterus acts directly on the portion of membranes that contact the dilating cervix. Consequently, early spontaneous rupture of the membranes is more likely.

After membrane rupture, absent pressure by the head against the cervix and lower uterine segment predisposes to less effective contractions. Hence, further dilatation may proceed very slowly or not at all. Cibils and Hendricks (1965) reported that the mechanical adaptation of the fetal passenger to the bony passage plays an important part in determining the efficiency of contractions. The better the adaptation, the more efficient the contractions. Thus, cervical response to labor provides a prognostic view of labor outcome in women with inlet contraction.

A contracted inlet also plays an important part in the production of abnormal presentations. In normal nulliparas, the presenting part at term commonly descends into the pelvic cavity before labor onset. When the inlet is contracted considerably or there is marked asynclitism, descent usually does not take place until after labor onset, if at all. Cephalic presentations still predominate, but the head floats freely over the pelvic inlet or rests more laterally in one of the iliac fossae. Accordingly, very slight influences may cause the fetus to assume other presentations. In women with contracted pelves, face and shoulder presentations are encountered three times more frequently, and the cord prolapses four to six times more often.

## Contracted Midpelvis

This finding is more common than inlet contraction. It frequently causes transverse arrest of the fetal head, which potentially can lead to a difficult midforceps operation or to cesarean delivery.

The obstetrical plane of the midpelvis extends from the inferior margin of the symphysis pubis through the ischial spines and touches the sacrum near the junction of the fourth and fifth vertebrae (Chap. 2, p. 33). A transverse line theoretically connecting the ischial spines divides the midpelvis into anterior and posterior portions. The former is bounded anteriorly by the lower border of the symphysis pubis and laterally by the ischiopubic rami. The posterior portion is bounded dorsally by the sacrum and laterally by the sacrospinous ligaments, forming the lower limits of the sacrosciatic notch.

Average midpelvis measurements are as follows: transverse, or interischial spinous, 10.5 cm; anteroposterior, from the lower border of the symphysis pubis to the junction of $S_{4-5}$, 11.5 cm; and posterior sagittal, from the midpoint of the interspinous line to the same point on the sacrum, 5 cm. The definition of midpelvic contractions has not been established with the same precision possible for inlet contractions. Even so, the midpelvis is likely contracted when the sum of the interspinous and posterior sagittal diameters of the midpelvis—normally, 10.5 plus 5 cm, or 15.5 cm—falls to 13.5 cm or less. This concept was emphasized by Chen and Huang (1982) in evaluating possible midpelvic contraction. There is reason to suspect midpelvic contraction whenever the interspinous diameter is < 10 cm. When it measures < 8 cm, the midpelvis is contracted.

Although there is no precise manual method of measuring midpelvic dimensions, a suggestion of
contraction sometimes can be inferred if the spines are prominent, the pelvic sidewalls converge, or the sacrosciatic notch is narrow. Moreover, Eller and Mengert (1947) noted that the relationship between the intertuberous and interspinous diameters of the ischium is sufficiently constant that narrowing of the interspinous diameter can be anticipated when the intertuberous diameter is narrow. A normal intertuberous diameter, however, does not always exclude a narrow interspinous diameter.

**Contracted Outlet**

This finding usually is defined as an interischial tuberous diameter of 8 cm or less. The pelvic outlet may be roughly likened to two triangles, with the interischial tuberous diameter constituting the base of both. The sides of the anterior triangle are the pubic rami, and its apex is the inferoposterior surface of the symphysis pubis. The posterior triangle has no bony sides but is limited at its apex by the tip of the last sacral vertebra—not the tip of the coccyx. Diminution of the intertuberous diameter with consequent narrowing of the anterior triangle must inevitably force the fetal head posteriorly. Floberg and associates (1987) reported that outlet contractions were found in almost 1 percent of more than 1400 unselected nulliparas with term pregnancies. A contracted outlet may cause dystocia not so much by itself but by an often-associated midpelvic contraction. *Outlet contraction without concomitant midplane contraction is rare.*

Although the disproportion between the fetal head and the pelvic outlet is not sufficiently great to give rise to severe dystocia, it may play an important part in perineal tears. With increased narrowing of the pubic arch, the occiput cannot emerge directly beneath the symphysis pubis but is forced farther down upon the ischiopubic rami. The perineum, consequently, becomes increasingly distended and thus exposed to risk of laceration.

**Pelvic Fractures**

Vallier (2012) reviewed experiences with pelvic fractures and pregnancy. Trauma from automobile collisions was the most common cause. Moreover, they note that fracture pattern, minor malalignment, and retained hardware are not absolute indications for cesarean delivery. A history of pelvic fracture warrants careful review of previous radiographs and possibly pelvimetry later in pregnancy.

**Estimation of Pelvic Capacity**

The techniques for clinical evaluation using digital examination of the bony pelvis during labor are described in detail in Chapter 2 (p. 32). Briefly, the examiner attempts to judge the anteroposterior diameter of the inlet—the diagonal conjugate, the interspinous diameter of the midpelvis, and the intertuberous distances of the pelvic outlet. A narrow pelvic arch of less than 90 degrees can signify a narrow pelvis. An unengaged fetal head can indicate either excessive fetal head size or reduced pelvic inlet capacity.

The value of radiologic imaging to assess pelvic capacity has also been examined. First, with x-ray pelvimetry alone, the prognosis for successful vaginal delivery in any given pregnancy cannot be established (Mengert, 1948). Thus, the American College of Obstetricians and Gynecologists (2009) considers x-ray pelvimetry to be of limited value in the management of labor with a cephalic presentation.

Advantages of pelvimetry with computed tomography (CT), such as that shown in Figure 23-4, compared with those of conventional x-ray pelvimetry include reduced radiation exposure, greater
accuracy, and easier performance. With either method, costs are comparable, and x-ray exposure is small (Chap. 46, p. 934). Depending on the machine and technique employed, fetal doses with CT pelvimetry may range from 250 to 1500 mrad (Moore, 1989).
Advantages of magnetic resonance (MR) pelvimetry include lack of ionizing radiation, accurate measurements, complete fetal imaging, and the potential for evaluating soft tissue dystocia (McCarthy, 1986; Stark, 1985). Zaretzky and colleagues (2005) used MR imaging to measure pelvic and fetal head volume to identify those women at greatest risk of undergoing cesarean delivery for dystocia. Although significant associations were found with some of the measures and cesarean delivery for dystocia, these researchers could not with accuracy predict which individual women would require cesarean delivery. Others have reported similar findings (Sporri, 1997).
Fetal Dimensions in Fetopelvic Disproportion

Fetal size alone is seldom a suitable explanation for failed labor. Even with the evolution of current technology, a fetal size threshold to predict fetopelvic disproportion is still elusive. Most cases of disproportion arise in fetuses whose weight is well within the range of the general obstetrical population. As shown in Figure 23-5, two thirds of neonates who required cesarean delivery after failed forceps delivery weighed less than 3700 g. Thus, other factors—for example, malposition of the head—obstruct fetal passage through the birth canal. These include asynclitism, occiput posterior position, and face and brow presentations.

![Birthweight distribution of 362 newborns born by cesarean delivery at Parkland Hospital (1989–1999) after a failed forceps attempt. Only 12 percent (n = 44) of the newborns weighed > 4000 g (dark bars).](image)

**FIGURE 23-5** Birthweight distribution of 362 newborns born by cesarean delivery at Parkland Hospital (1989–1999) after a failed forceps attempt. Only 12 percent (n = 44) of the newborns weighed > 4000 g (dark bars).

Estimation of Fetal Head Size

Estimation of fetal head size based on clinical and radiographic techniques have proved disappointing. Mueller (1885) and Hillis (1930) described a clinical maneuver to predict disproportion. The fetal brow and the suboccipital region are grasped through the abdominal wall with the fingers, and firm pressure is directed downward in the axis of the inlet. If no disproportion exists, the head readily enters the pelvis, and vaginal delivery can be predicted. Thorp and coworkers (1993) performed a prospective evaluation of the Mueller-Hillis maneuver and concluded that there was no relationship between dystocia and failed descent during the maneuver.

Measurements of fetal head diameters using plain radiographic techniques are not used because of parallax distortions. The biparietal diameter and head circumference can be measured.
sonographically, and there have been attempts to use this information in the management of dystocia. Thurnau and colleagues (1991) used the *fetal-pelvic index* to identify labor complications. Unfortunately, the sensitivity of such measurements to predict cephalopelvic disproportion is poor (Ferguson, 1998). We are of the view that there is no currently satisfactory method for accurate prediction of fetopelvic disproportion based on head size.

**Face Presentation**

With this presentation, the head is hyperextended so that the occiput is in contact with the fetal back, and the chin (mentum) is presenting (Fig. 23-6). The fetal face may present with the chin (mentum) anteriorly or posteriorly, relative to the maternal symphysis pubis (Chap. 22, p. 436). Although some mentum posterior presentations persist, most convert spontaneously to anterior even in late labor (Duff, 1981). If not, the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion of the fetal head necessary to negotiate the birth canal. Thus, a mentum posterior presentation is undeliverable except with a very preterm fetus.
Face presentations rarely deliver as such vaginally. Cruikshank and White (1973) reported an incidence of 1 in 600, or 0.17 percent. As shown in Table 22-1 (p. 434), among more than 70,000 singleton newborns delivered at Parkland Hospital, approximately 1 in 2000 had a face presentation at delivery.

Etiology

Causes of face presentations are numerous and include conditions that favor extension or prevent head flexion. Preterm infants, with their smaller head dimensions, can engage before conversion to vertex position (Shaffer, 2006). In exceptional instances, marked enlargement of the neck or coils of cord around the neck may cause extension. Bashiri and associates (2008) reported that fetal malformations and hydramnios were risk factors for face or brow presentations. Anencephalic fetuses naturally present by the face.

Extended positions develop more frequently when the pelvis is contracted or the fetus is very large. In a series of 141 face presentations studied by Hellman and coworkers (1950), the incidence of inlet contraction was 40 percent. This high incidence of pelvic contraction should be kept in mind when considering management.

High parity is a predisposing factor to face presentation (Fuchs, 1985). In these cases, a pendulous abdomen permits the back of the fetus to sag forward or laterally, often in the same direction in which the occiput points. This promotes extension of the cervical and thoracic spine.

Diagnosis

Face presentation is diagnosed by vaginal examination and palpation of facial features. As discussed in Chapter 28 (p. 560), it is possible to mistake a breech for a face presentation because the anus may be mistaken for the mouth and the ischial tuberosities for the malar prominences. The radiographic demonstration of the hyperextended head with the facial bones at or below the pelvic inlet is characteristic.

Mechanism of Labor

Face presentations rarely are observed above the pelvic inlet. Instead, the brow generally presents early and is usually converted to present the face after further extension of the head during descent. The mechanism of labor in these cases consists of the cardinal movements of descent, internal rotation, and flexion, and the accessory movements of extension and external rotation (Fig. 23-7). Descent is brought about by the same factors as in cephalic presentations. Extension results from the relation of the fetal body to the deflected head, which is converted into a two-armed lever, the longer arm of which extends from the occipital condyles to the occiput. When resistance is encountered, the occiput must be pushed toward the back of the fetus while the chin descends.
The objective of internal rotation of the face is to bring the chin under the symphysis pubis. Only in this way can the neck traverse the posterior surface of the symphysis pubis. If the chin rotates directly posteriorly, the relatively short neck cannot span the anterior surface of the sacrum, which measures about 12 cm in length. Moreover, the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion necessary to negotiate the birth canal. Hence, birth of the head from a mentum posterior position is impossible unless the shoulders enter
the pelvis at the same time, an event that is impossible except when the fetus is extremely small or macerated. Internal rotation results from the same factors as in vertex presentations.

After anterior rotation and descent, the chin and mouth appear at the vulva, the undersurface of the chin presses against the symphysis, and the head is delivered by flexion. The nose, eyes, brow (bregma), and occiput then appear in succession over the anterior margin of the perineum. After birth of the head, the occiput sags backward toward the anus. Next, the chin rotates externally to the side toward which it was originally directed, and the shoulders are born as in cephalic presentations.

Edema may sometimes significantly distort the face. At the same time, the skull undergoes considerable molding, manifested by an increase in length of the occipitomental diameter of the head.

**Management**

In the absence of a contracted pelvis, and with effective labor, successful vaginal delivery usually will follow. Fetal heart rate monitoring is probably better done with external devices to avoid damage to the face and eyes. Because face presentations among term-size fetuses are more common when there is some degree of pelvic inlet contraction, cesarean delivery frequently is indicated. Attempts to convert a face presentation manually into a vertex presentation, manual or forceps rotation of a persistently posterior chin to a mentum anterior position, and internal podalic version and extraction are dangerous and should not be attempted.

### Brow Presentation

This rare presentation is diagnosed when that portion of the fetal head between the orbital ridge and the anterior fontanel presents at the pelvic inlet. As shown in Figure 23-8, the fetal head thus occupies a position midway between full flexion (occiput) and extension (face). Except when the fetal head is small or the pelvis is unusually large, engagement of the fetal head and subsequent delivery cannot take place as long as the brow presentation persists.
Etiology and Diagnosis
The causes of persistent brow presentation are the same as those for face presentation. A brow presentation is commonly unstable and often converts to a face or an occiput presentation (Cruikshank, 1973). The presentation may be recognized by abdominal palpation when both the occiput and chin can be palpated easily, but vaginal examination is usually necessary. The frontal sutures, large anterior fontanel, orbital ridges, eyes, and root of the nose are felt on vaginal examination, but neither the mouth nor the chin is palpable.

Mechanism of Labor
With a very small fetus and a large pelvis, labor is generally easy, but with a larger fetus, it is usually difficult. This is because engagement is impossible until there is marked molding that shortens the occipitomental diameter or more commonly, until there is either flexion to an occiput
presentation or extension to a face presentation. The considerable molding essential for vaginal delivery of a persistent brow characteristically deforms the head. The caput succedaneum is over the forehead, and it may be so extensive that identification of the brow by palpation is impossible. In these instances, the forehead is prominent and squared, and the occipitomental diameter is diminished.

In transient brow presentations, the prognosis depends on the ultimate presentation. If the brow persists, prognosis is poor for vaginal delivery unless the fetus is small or the birth canal is large. Principles of management are the same as those for a face presentation.

Transverse Lie

In this position, the long axis of the fetus is approximately perpendicular to that of the mother. When the long axis forms an acute angle, an oblique lie results. The latter is usually only transitory, because either a longitudinal or transverse lie commonly results when labor supervenes. For this reason, the oblique lie is called an unstable lie in Great Britain.

In a transverse lie, the shoulder is usually positioned over the pelvic inlet. The head occupies one iliac fossa, and the breech the other. This creates a shoulder presentation in which the side of the mother on which the acromion rests determines the designation of the lie as right or left acromial. And because in either position the back may be directed anteriorly or posteriorly, superiorly or inferiorly, it is customary to distinguish varieties as dorsoanterior and dorsoposterior (Fig. 23-9).

Transverse lie was found once in 322 singleton deliveries (0.3 percent) at both the Mayo Clinic
and the University of Iowa Hospital (Cruikshank, 1973; Johnson, 1964). This is remarkably similar to the incidence at Parkland Hospital of approximately 1 in 335 singleton fetuses.

**Etiology**

Some of the more common causes of transverse lie include: (1) abdominal wall relaxation from high parity, (2) preterm fetus, (3) placenta previa, (4) abnormal uterine anatomy, (5) hydramnios, and (6) contracted pelvis.

Women with four or more deliveries have a tenfold incidence of transverse lie compared with nulliparas. A relaxed and pendulous abdomen allows the uterus to fall forward, deflecting the long axis of the fetus away from the axis of the birth canal and into an oblique or transverse position. Placenta previa and pelvic contraction act similarly. A transverse or oblique lie occasionally develops in labor from an initial longitudinal position.

**Diagnosis**

A transverse lie is usually recognized easily, often by inspection alone. The abdomen is unusually wide, whereas the uterine fundus extends to only slightly above the umbilicus. No fetal pole is detected in the fundus, and the ballottable head is found in one iliac fossa and the breech in the other. The position of the back is readily identifiable. When the back is anterior (Fig. 23-9, p. 469), a hard resistance plane extends across the front of the abdomen. When it is posterior, irregular nodulations representing fetal small parts are felt through the abdominal wall.

On vaginal examination, in the early stages of labor, if the side of the thorax can be reached, it may be recognized by the “gridiron” feel of the ribs. With further dilatation, the scapula and the clavicle are distinguished on opposite sides of the thorax. The position of the axilla indicates the side of the mother toward which the shoulder is directed.

**Mechanism of Labor**

Spontaneous delivery of a fully developed newborn is impossible with a persistent transverse lie. After rupture of the membranes, if labor continues, the fetal shoulder is forced into the pelvis, and the corresponding arm frequently prolapses (Fig. 23-10). After some descent, the shoulder is arrested by the margins of the pelvic inlet, with the head in one iliac fossa and the breech in the other. As labor continues, the shoulder is impacted firmly in the upper part of the pelvis. The uterus then contracts vigorously in an unsuccessful attempt to overcome the obstacle. With time, a retraction ring rises increasingly higher and becomes more marked. With this neglected transverse lie, the uterus will eventually rupture. Even without this complication, morbidity is increased because of the frequent association with placenta previa, the increased likelihood of cord prolapse, and the necessity for major operative efforts.
Neglected shoulder presentation. A thick muscular band forming a pathological retraction ring has developed just above the thin lower uterine segment. The force generated during a uterine contraction is directed centripetally at and above the level of the pathological retraction ring. This serves to stretch further and possibly to rupture the thin lower segment below the retraction ring.

If the fetus is small—usually < 800 g—and the pelvis is large, spontaneous delivery is possible despite persistence of the abnormal lie. The fetus is compressed with the head forced against its abdomen. A portion of the thoracic wall below the shoulder thus becomes the most dependent part, appearing at the vulva. The head and thorax then pass through the pelvic cavity at the same time. The fetus, which is doubled upon itself and thus sometimes referred to as conduplicato corpore, is expelled.

**Management**

Active labor in a woman with a transverse lie is usually an indication for cesarean delivery. Before labor or early in labor, with the membranes intact, attempts at external version are
worthwhile in the absence of other complications. If the fetal head can be maneuvered by abdominal manipulation into the pelvis, it should be held there during the next several contractions in an attempt to fix the head in the pelvis.

With cesarean delivery, because neither the feet nor the head of the fetus occupies the lower uterine segment, a low transverse incision into the uterus may lead to difficult fetal extraction. This is especially true of dorsoanterior presentations. Therefore, a vertical incision is typically indicated (Chap. 30, p. 598).

### Compound Presentation

#### Incidence and Etiology

In a compound presentation, an extremity prolapses alongside the presenting part, and both present simultaneously in the pelvis (Fig. 23-11). Goplerud and Eastman (1953) identified a hand or arm prolapsed alongside the head once in every 700 deliveries. Much less common was prolapse of one or both lower extremities alongside a cephalic presentation or a hand alongside a breech. At Parkland Hospital, compound presentations were identified in only 68 of more than 70,000 singleton fetuses—an incidence of approximately 1 in 1000. Causes of compound presentations are conditions that prevent complete occlusion of the pelvic inlet by the fetal head, including preterm labor.
FIGURE 23-11 Compound presentation. **A.** The left hand is lying in front of the vertex. With further labor, the hand and arm may retract from the birth canal, and the head may then descend normally. **B.** Photograph of a small 34-week fetus with a compound presentation that delivered uneventfully with the hand presenting first. (Photograph contributed by Dr. Elizabeth Mosier.)

**Management and Prognosis**
In most cases, the prolapsed part should be left alone, because most often it will not interfere with labor. If the arm is prolapsed alongside the head, the condition should be observed closely to ascertain whether the arm retracts out of the way with descent of the presenting part. If it fails to retract and if it appears to prevent descent of the head, the prolapsed arm should be pushed gently upward and the head simultaneously downward by fundal pressure. Tebes and coworkers (1999) described a tragic outcome in a newborn delivered spontaneously with the hand alongside the head. The infant developed ischemic necrosis of the presenting forearm, which required amputation. In general, rates of perinatal mortality and morbidity are increased as a result of concomitant preterm delivery, prolapsed cord, and traumatic obstetrical procedures.

**COMPLICATIONS WITH DYSTOOCIA**

**Maternal Complications**
Dystocia, especially if labor is prolonged, is associated with an increased incidence of several common obstetrical and neonatal complications. Intrapartum chorioamnionitis and postpartum pelvic infection are more common with desultory and prolonged labors. Postpartum hemorrhage from atony is increased with prolonged and augmented labors. There is also a higher incidence of uterine tears with hysterotomy if the fetal head is impacted in the pelvis.

**Uterine Rupture**
Abnormal thinning of the lower uterine segment creates a serious danger during prolonged labor, particularly in women of high parity and in those with a prior cesarean delivery (Chap. 41, p. 790). When disproportion is so pronounced that there is no engagement or descent, the lower uterine segment becomes increasingly stretched, and rupture may follow. In such cases, there is usually an exaggeration of the normal contraction ring shown in Figure 23-1.

**Pathological Retraction Ring.** Localized rings or constrictions of the uterus develop in association with prolonged obstructed labors that are seldom encountered today. The pathological retraction ring of Bandl is associated with marked stretching and thinning of the lower uterine segment. The ring may be seen clearly as a uterine indentation and signifies impending rupture of the lower uterine segment.

Following birth of a first twin, a pathological ring may still develop occasionally as hourglass constrictions of the uterus. The ring can sometimes be relaxed and delivery effected with appropriate general anesthesia, but occasionally prompt cesarean delivery offers a better prognosis for the second twin (Chap. 45, p. 917).

**Fistula Formation**
With dystocia, the presenting part is firmly wedged into the pelvic inlet and does not advance for a considerable time. Tissues of the birth canal lying between the leading part and the pelvic wall may be subjected to excessive pressure. Because of impaired circulation, necrosis may result and become evident several days after delivery as vesicovaginal, vesicocervical, or rectovaginal fistulas. Most often, pressure necrosis follows a very prolonged second stage. They are rarely seen today except in undeveloped countries.

**Pelvic Floor Injury**

During childbirth, the pelvic floor is exposed to direct compression from the fetal head and to downward pressure from maternal expulsive efforts. These forces stretch and distend the pelvic floor, resulting in functional and anatomical alterations in the muscles, nerves, and connective tissues. There is accumulating evidence that such effects on the pelvic floor during childbirth lead to urinary incontinence and to pelvic organ prolapse (Handa, 2011). As discussed in Chapter 27 (p. 548), the anal sphincter is torn in 3 to 6 percent of deliveries, and many of these women report subsequent fecal or gas incontinence. Many of these long-term sequelae have contributed to the current trend of *cesarean delivery on maternal request* discussed in Chapter 30 (p. 589).

**Postpartum Lower Extremity Nerve Injury**

Wong and colleagues (2003) reviewed neurological injury involving the lower extremities in association with labor and delivery. The most common mechanism is external compression of the common fibular (formerly common peroneal) nerve. This is usually caused by inappropriate leg positioning in stirrups, especially during prolonged second-stage labor. These and other injuries are discussed in Chapter 36 (p. 676). Fortunately, symptoms resolve within 6 months of delivery in most women.

**Perinatal Complications**

Similar to the mother, the incidence of peripartum fetal sepsis is increased with longer labors. *Caput succedaneum* and *molding* develop commonly and may be impressive (Fig. 22-19, p. 444) (Buchmann, 2008). Mechanical trauma such as nerve injury, fractures, and cephalohematoma are also more frequent and discussed fully in Chapter 33 (p. 645).

INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY

Following earlier work by Hon (1958), continuous electronic fetal monitoring (EFM) was introduced into obstetrical practice in the late 1960s. No longer were intrapartum fetal surveillance and the suspicion of fetal distress based on periodic auscultation with a fetoscope. Instead, the continuous graph-paper portrayal of the fetal heart rate was potentially diagnostic in assessing pathophysiological events affecting the fetus. Indeed, there were great expectations: (1) that electronic fetal heart rate monitoring provided accurate information, (2) that the information was of value in diagnosing fetal distress, (3) that it would direct intervention to prevent fetal death or morbidity, and (4) that continuous electronic fetal heart rate monitoring was superior to intermittent methods.

When first introduced, electronic fetal heart rate monitoring was used primarily in complicated pregnancies, but gradually became used in most pregnancies. By 1978, it was estimated that nearly two thirds of American women were being monitored electronically during labor (Banta, 1979). Currently, more than 85 percent of all live births in the United States undergo electronic fetal monitoring (Ananth, 2013). Indeed, fetal monitoring has become the most prevalent obstetrical procedure in this country.

ELECTRONIC FETAL MONITORING

Internal (Direct) Electronic Monitoring
The fetus can be monitored electronically by direct or indirect methods. Direct fetal heart measurement is accomplished by attaching a bipolar spiral electrode directly to the fetus (Fig. 24-1). The wire electrode penetrates the fetal scalp, and the second pole is a metal wing on the electrode. Vaginal body fluids create a saline electrical bridge that completes the circuit and permits measurement of the voltage differences between the two poles. The two wires of the bipolar electrode are attached to a reference electrode on the maternal thigh to eliminate electrical interference. The electrical fetal cardiac signal—P wave, QRS complex, and T wave—is amplified and fed into a cardiotachometer for heart rate calculation. The peak R-wave voltage is the portion of the fetal electrocardiogram most reliably detected.
An example of the method of fetal heart rate processing employed when a scalp electrode is used is shown in Figure 24-2. Time (t) in milliseconds between fetal R waves is fed into a cardiotachometer, where a new fetal heart rate is set with the arrival of each new R wave. As also shown in Figure 24-2, a premature atrial contraction is computed as a heart rate acceleration because the interval (t₂) is shorter than the preceding one (t₁). The phenomenon of continuous R-to-R wave fetal heart rate computation is known as *beat-to-beat variability*. The physiological event being counted, however, is not a mechanical event corresponding to a heartbeat but rather an electrical event.
Electrical cardiac complexes detected by the electrode include those generated by the mother. Although the maternal electrocardiogram (ECG) signal is approximately five times stronger than the fetal ECG, its amplitude is diminished when it is recorded through the fetal scalp electrode. In a live fetus, this low maternal ECG signal is detected but masked by the fetal ECG. If the fetus is dead, the weaker maternal signal will be amplified and displayed as the “fetal” heart rate (Freeman, 2003). Shown in Figure 24-3 are simultaneous recordings of maternal chest wall ECG signals and fetal scalp electrode ECG signals. This fetus is experiencing premature atrial contractions, which cause the cardiotachometer to rapidly and erratically seek new heart rates, resulting in the “spiking” shown in the standard fetal monitor tracing. Importantly, when the fetus is dead, the maternal R waves are still detected by the scalp electrode as the next best signal and are counted by the cardiotachometer (Fig. 24-4).
The second panel displays accompanying contractions. The bottom two tracings represent cardiac electrical complexes detected from fetal scalp and maternal chest wall electrodes. ECG = electrocardiogram; F = fetus; M = mother; PAC = fetal premature atrial contraction.

FIGURE 24-4 Placental abruption. In the upper panel, the fetal scalp electrode first detected the heart rate of the dying fetus. After fetal death, the maternal electrocardiogram complex is detected and recorded. The second panel displays an absence of uterine contractions.

External (Indirect) Electronic Monitoring

Membrane rupture may be avoided by use of external detectors to monitor fetal heart action. External monitoring, however, does not provide the precision of fetal heart rate measurement afforded by internal monitoring (Nunes, 2014).

The fetal heart rate is detected through the maternal abdominal wall using the ultrasound Doppler principle (Fig. 24-5). Ultrasound waves undergo a shift in frequency as they are reflected from moving fetal heart valves and from pulsatile blood ejected during systole (Chap. 10, p. 209). The unit consists of a transducer that emits ultrasound and a sensor to detect a shift in frequency of the reflected sound. The transducer is placed on the maternal abdomen at a site where fetal heart action is best detected. A coupling gel must be applied because air conducts ultrasound waves poorly. The device is held in position by a belt. Care should be taken that maternal arterial pulsations are not confused with fetal cardiac motion (Neilson, 2008).
Ultrasound Doppler signals are edited electronically before fetal heart rate data are printed onto monitor paper. Reflected ultrasound signals from moving fetal heart valves are analyzed through a microprocessor that compares incoming signals with the most recent previous signal. This process, called *autocorrelation*, is based on the premise that the fetal heart rate has regularity whereas “noise” is random and without regularity. Several fetal heart motions must be deemed electronically acceptable by the microprocessor before the fetal heart rate is printed. Such electronic editing has greatly improved the tracing quality of the externally recorded fetal heart rate.

**Fetal Heart Rate Patterns**

It is now generally accepted that interpretation of fetal heart rate patterns can be problematic because of the lack of agreement on definitions and nomenclature (American College of Obstetricians and Gynecologists, 2013b). In one example, Blackwell and colleagues (2011) asked three maternal-fetal medicine specialists to independently interpret 154 fetal heart rate tracings. Interobserver agreement was poor for the most ominous tracings and “moderate” for less severe patterns. The authors cautioned that their results represented idealized circumstances that should not be considered reflective of routine clinical practice.

The National Institute of Child Health and Human Development (NICHD) Research Planning Workshop (1997) brought together investigators with expertise in the field to propose standardized, unambiguous definitions for interpretation of fetal heart rate patterns during labor.
This workshop was repeated in 2008. The definitions proposed and shown in Table 24-1 as a result of this second workshop are used in this chapter. First, it is important to recognize that interpretation of electronic fetal heart rate data is based on the visual pattern of the heart rate as portrayed on chart recorder graph paper. Thus, the choice of vertical and horizontal scaling greatly affects the appearance of the fetal heart rate. Scaling factors recommended by the workshop are 30 beats per minute (beats/min or bpm) per vertical cm (range, 30 to 240 bpm) and 3 cm/min chart recorder paper speed. Fetal heart rate variation is falsely displayed at the slower 1 cm/min paper speed compared with that of the smoother baseline recorded at 3 cm/min (Fig. 24-6). Thus, pattern recognition can be considerably distorted depending on the scaling factors used.

</tr>
</tbody>
</table>

• The nadir of the deceleration occurs at the same time as the peak of the contraction.
Late deceleration
- The nadir of the deceleration occurs at the same time as the peak of the contraction
- In most cases the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively
- Visually apparent usually symmetrical gradual decrease and return of the FHR associated with a uterine contraction
- A gradual FHR decrease is defined as from the onset to the FHR nadir of ≥ 30 sec
- The decrease in FHR is calculated from the onset to the nadir of the deceleration
- The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction
- In most cases the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively

Variable deceleration
- Visually apparent abrupt decrease in FHR
- An abrupt FHR decrease is defined as from the onset to the FHR nadir of < 30 sec
- The decrease in FHR is calculated from the onset to the nadir of the deceleration
- The decrease in FHR is ≥ 15 bpm, lasting ≥ 15 sec, and < 2 min in duration
- When variable decelerations are associated with uterine contraction, their onset, depth, and duration commonly vary with successive uterine contractions

Prolonged deceleration
- Visually apparent decrease in the FHR below the baseline
- Decrease in FHR from the baseline that is ≥ 15 bpm, lasting ≥ 2 min but < 10 min in duration
- If a deceleration lasts ≥ 10 min, it is a baseline change

Sinusoidal pattern
- Visually apparent, smooth, sine wave-line undulating pattern in FHR baseline with a cycle frequency of 3-5 per minute which persists for 20 min or more

bpm = beats per minute; FHR = fetal heart rate.
Baseline Fetal Heart Activity

This refers to the modal characteristics that prevail apart from periodic accelerations or decelerations associated with uterine contractions. Descriptive characteristics of baseline fetal heart activity include rate, beat-to-beat variability, fetal arrhythmia, and distinct patterns such as sinusoidal or saltatory fetal heart rates.

Rate

With increasing fetal maturation, the heart rate decreases. This continues postnatally such that the average rate is 90 bpm by age 8 (Behrman, 1992). Pillai and James (1990) longitudinally studied fetal heart rate characteristics in 43 normal pregnancies. The baseline fetal heart rate decreased an average of 24 bpm between 16 weeks and term, or approximately 1 beat/min per week. This normal gradual slowing of the fetal heart rate is thought to correspond to maturation of parasympathetic (vagal) heart control (Renou, 1969).
The baseline fetal heart rate is the approximate mean rate rounded to increments of 5 bpm during a 10-minute tracing segment. In any 10-minute window, the minimum interpretable baseline duration must be at least 2 minutes. If the baseline fetal heart rate is less than 110 bpm, it is termed bradycardia. If the baseline rate is greater than 160 bpm, it is termed tachycardia. The average fetal heart rate is considered the result of tonic balance between accelerator and decelerator influences on pacemaker cells. In this concept, the sympathetic system is the accelerator influence, and the parasympathetic system is the decelerator factor mediated via vagal slowing of heart rate (Dawes, 1985). Heart rate also is under the control of arterial chemoreceptors such that both hypoxia and hypercapnia can modulate rate. More severe and prolonged hypoxia, with a rising blood lactate level and severe metabolic acidemia, induces a prolonged fall in heart rate (Thakor, 2009).

**Bradycardia.** In the third trimester, the normal mean baseline fetal heart rate has generally been accepted to range between 120 and 160 bpm. The lower normal limit is disputed internationally, with some investigators recommending 110 bpm (Manassiev, 1996). Pragmatically, a rate between 100 and 119 bpm, in the absence of other changes, usually is not considered to represent fetal compromise. Such low but potentially normal baseline heart rates also have been attributed to head compression from occiput posterior or transverse positions, particularly during second-stage labor (Young, 1976). Such mild bradycardias were observed in 2 percent of monitored pregnancies and averaged approximately 50 minutes in duration. Freeman and associates (2003) have concluded that bradycardia within the range of 80 to 120 bpm with good variability is reassuring. Interpretation of rates less than 80 bpm is problematic, and such rates generally are considered nonreassuring.

Some causes of fetal bradycardia include congenital heart block and serious fetal compromise (Jaeggi, 2008; Larma, 2007). Figure 24-7 shows bradycardia in a fetus dying from placental abruption. Maternal hypothermia under general anesthesia for repair of a cerebral aneurysm or during maternal cardiopulmonary bypass for open-heart surgery also can cause fetal bradycardia. Sustained fetal bradycardia in the setting of severe pyelonephritis and maternal hypothermia also has been reported (Hankins, 1997). These infants apparently are not harmed by several hours of such bradycardia.
Tachycardia. Fetal tachycardia is defined as a baseline heart rate greater than 160 bpm. The most common explanation for fetal tachycardia is maternal fever from chorioamnionitis, although fever from any source can increase baseline fetal heart rate. Such infections also have been observed to induce fetal tachycardia before overt maternal fever is diagnosed (Gilstrap, 1987). Fetal tachycardia caused by maternal infection typically is not associated with fetal compromise unless there are associated periodic heart rate changes or fetal sepsis.

Other causes of fetal tachycardia include fetal compromise, cardiac arrhythmias, and maternal administration of parasympathetic (atropine) or sympathomimetic (terbutaline) drugs. The key feature to distinguish fetal compromise in association with tachycardia seems to be concomitant heart rate decelerations. Prompt relief of the compromising event, such as correction of maternal hypotension caused by epidural analgesia, can result in fetal recovery.

Wandering Baseline. This baseline rate is unsteady and “wanders” between 120 and 160 bpm (Freeman, 2003). This rare finding is suggestive of a neurologically abnormal fetus and may occur as a preterminal event.
Beat-to-Beat Variability

Baseline variability is an important index of cardiovascular function and appears to be regulated largely by the autonomic nervous system (Kozuma, 1997). That is, a sympathetic and parasympathetic “push and pull” mediated via the sinoatrial node produces moment-to-moment or beat-to-beat oscillation of the baseline heart rate. Such heart rate change is defined as baseline variability. Variability can be further divided into short term and long term, although these terms have fallen out of use. Short-term variability reflects the instantaneous change in fetal heart rate from one beat—or R wave—to the next. This variability is a measure of the time interval between cardiac systoles (Fig. 24-8). Short-term variability can most reliably be determined to be normally present only when electrocardiac cycles are measured directly with a scalp electrode. Long-term variability is used to describe the oscillatory changes during 1 minute and result in the waviness of the baseline (Fig. 24-9). The normal frequency of such waves is three to five cycles per minute (Freeman, 2003).

![FIGURE 24-8](image1)

**FIGURE 24-8** Schematic representation of short-term beat-to-beat variability measured by a fetal scalp electrode. \( t \) = time interval between successive fetal R waves. (Adapted from Klavan, 1977.)

![FIGURE 24-9](image2)

**FIGURE 24-9** Schematic representation of long-term beat-to-beat variability of the fetal heart rate ranging between 125 and 135 bpm. (Adapted from Klavan, 1977.)

It should be recognized that precise quantitative analysis of both short- and long-term variability presents a number of frustrating problems due to technical and scaling factors. For example, Parer and coworkers (1985) evaluated 22 mathematical formulas designed to quantify heart rate variability and found most to be unsatisfactory. Consequently, most clinical interpretation is based on visual analysis with subjective judgment of the smoothness or flatness of the baseline. According to Freeman and colleagues (2003), there is no current evidence that the distinction between short- and long-term variability has any clinical relevance. Similarly, the NICHD Workshop (1997) did not recommend differentiating short- and long-term variability because in actual practice they are visually determined as a unit. The workshop panel defined baseline variability as those baseline fluctuations of two cycles per minute or greater. They recommended the criteria shown in Figure 24-10 for quantification of variability. Normal beat-to-
beat variability was accepted to be 6 to 25 bpm.
FIGURE 24-10 Grades of baseline fetal heart rate variability shown in the following five panels. 1. Undetectable, absent variability. 2. Minimal variability, ≤ 5 bpm. 3. Moderate (normal) variability, 6 to 25 bpm. 4. Marked variability, > 25 bpm. 5. Sinusoidal pattern. This differs from variability in that it has a smooth, sinelike pattern of regular fluctuation and is excluded in the definition of fetal heart rate variability. (Adapted from National Institute of Child Health and Human Development Research Planning Workshop, 1997.)

Increased Variability. Several physiological and pathological processes can affect or interfere with beat-to-beat variability. Dawes and associates (1981) described increased variability during fetal breathing. In healthy infants, short-term variability is attributable to respiratory sinus arrhythmia (Divon, 1986). Fetal body movements also affect variability (Van Geijn, 1980). Pillai and James (1990) reported increased baseline variability with advancing gestation. Up to 30 weeks, baseline characteristics were similar during both fetal rest and activity. After 30 weeks, fetal inactivity was associated with diminished baseline variability and conversely, variability was increased during fetal activity. Fetal gender does not affect heart rate variability (Ogueh, 1998).

The baseline fetal heart rate becomes more physiologically fixed (less variable) as the rate increases. Conversely, there is more instability or variability of the baseline at lower heart rates. This phenomenon presumably reflects less cardiovascular physiological wandering as beat-to-beat intervals shorten due to increasing heart rate.

Decreased Variability. Diminished beat-to-beat variability can be an ominous sign indicating a seriously compromised fetus. Paul and coworkers (1975) reported that loss of variability in combination with decelerations was associated with fetal acidemia. They analyzed variability in the 20 minutes preceding delivery in 194 pregnancies. Decreased variability was defined as 5 or fewer bpm excursion of the baseline (see Fig. 24-10), whereas acceptable variability exceeded this range. Fetal scalp pH was measured 1119 times in these pregnancies, and mean values were
found to be increasingly acidemic when decreased variability was added to progressively intense heart rate decelerations. For example, mean fetal scalp pH of approximately 7.10 was found when severe decelerations were combined with 5 bpm or less variability, compared with a pH of approximately 7.20 when greater variability was associated with similarly severe decelerations. Severe maternal acidemia also can cause decreased fetal beat-to-beat variability, as shown in Figure 24-11 in a mother with diabetic ketoacidosis.

![Diagram](image)

**FIGURE 24-11** A. External fetal heart recording showing lack of long-term variability at 31 weeks during maternal diabetic ketoacidosis (pH 7.09). B. Recovery of fetal long-term variability after correction of maternal acidemia.

The precise pathological mechanisms by which fetal hypoxemia results in diminished beat-to-beat variability are not totally understood. Interestingly, mild degrees of fetal hypoxemia have been reported actually to *increase* variability, at least at the outset of the hypoxic episode (Murotsuki, 1997). According to Dawes (1985), it seems probable that the loss of variability is a result of metabolic acidemia that causes depression of the fetal brainstem or the heart itself. Thus,
diminished beat-to-beat variability, when it reflects fetal compromise, likely reflects acidemia rather than hypoxia.

A common cause of diminished beat-to-beat variability is administration of analgesic drugs during labor (Chap. 25, p. 506). Various central nervous system depressant drugs can cause transient diminished beat-to-beat variability. Included are narcotics, barbiturates, phenothiazines, tranquilizers, and general anesthetics. Variability regularly diminishes within 5 to 10 minutes following intravenous meperidine administration, and the effects may last up to 60 minutes or longer depending on the dosage given (Petrie, 1993). Butorphanol given intravenously diminishes fetal heart rate reactivity (Schucker, 1996). In a study performed at Parkland Hospital, Hill and colleagues (2003) found that 5 bpm or less variability occurred in 30 percent of women given continuous intravenous meperidine compared with 7 percent in those given continuous labor epidural analgesia.

Magnesium sulfate, widely used in the United States for tocolysis as well as management of hypertensive women, has been arguably associated with diminished beat-to-beat variability. Hallak and associates (1999) randomly assigned 34 normal, nonlaboring women to standard magnesium sulfate infusion versus isotonic saline. Magnesium sulfate was associated with statistically decreased variability only in the third hour of the infusion. The average decrease in variability was deemed clinically insignificant, however, because the mean variability was 2.7 bpm in the third hour of magnesium infusion compared with 2.8 bpm at baseline. Magnesium sulfate also blunted the frequency of accelerations.

It is generally believed that reduced baseline heart rate variability is the single most reliable sign of fetal compromise. Smith and coworkers (1988) performed a computerized analysis of beat-to-beat variability in growth-restricted fetuses before labor. They observed that diminished variability (4.2 bpm or less) that was maintained for 1 hour was diagnostic of developing acidemia and imminent fetal death. By contrast, Samueloff and associates (1994) evaluated variability as a predictor of fetal outcome during labor in 2200 consecutive deliveries. They concluded that variability by itself could not be used as the only indicator of fetal well-being. Conversely, they also concluded that good variability should not be interpreted as necessarily reassuring. Blackwell and associates (2011) found that even experts often disagreed as to whether variability was absent or minimal (< 5 beats per minute).

In summary, beat-to-beat variability is affected by various pathological and physiological mechanisms. Variability has considerably different meaning depending on the clinical setting. The development of decreased variability in the absence of decelerations is unlikely to be due to fetal hypoxia (Davidson, 1992). A persistently flat fetal heart rate baseline—absent variability—within the normal baseline rate range and without decelerations may reflect a previous insult to the fetus that has resulted in neurological damage (Freeman, 2003).

Cardiac Arrhythmia

When fetal cardiac arrhythmias are first suspected using electronic monitoring, findings can include baseline bradycardia, tachycardia, or most commonly in our experience, abrupt baseline spiking (Fig. 24-12). Intermittent baseline bradycardia is frequently due to congenital heart block. As discussed in Chapter 59 (p. 1172), conduction defects, most commonly complete atrioventricular (AV) block, usually are found in association with maternal connective-tissue diseases. An arrhythmia can only be documented, practically speaking, when scalp electrodes are used. Some fetal monitors can be adapted to output the scalp electrode signals into an electrocardiographic recorder. Because only a single lead is obtained, analysis and interpretation of rhythm and rate disturbances are severely limited.
Internal fetal monitoring at term demonstrated occasional abrupt beat-to-beat fetal heart rate spiking due to erratic extrasystoles shown in the corresponding fetal electrocardiogram. The normal infant was delivered spontaneously and had normal cardiac rhythm in the nursery.

Southall and associates (1980) studied antepartum fetal cardiac rate and rhythm disturbances in 934 normal pregnancies between 30 and 40 weeks. Arrhythmias, episodes of bradycardia < 100 bpm, or tachycardia > 180 bpm were encountered in 3 percent. Most supraventricular arrhythmias are of little significance during labor unless there is coexistent heart failure as evidenced by fetal hydrops. Many supra-ventricular arrhythmias disappear in the immediate neonatal period, although some are associated with structural cardiac defects (Api, 2008). Copel and coworkers (2000) used echocardiography to evaluate 614 fetuses referred for auscultated irregular heart rate without hydrops. Only 10 fetuses (2 percent) were found to have significant arrhythmias, and all but one of these infants survived.

Boldt and colleagues (2003) followed 292 consecutive fetuses diagnosed with a cardiac arrhythmia through birth and into childhood. Atrial extrasystoles were the most common arrhythmia (68 percent), followed by atrial tachycardias (12 percent), atioventricular block (12 percent), sinus bradycardia (5 percent), and ventricular extrasystoles (2.5 percent). Chromosomal anomalies were found in 1.7 percent of the fetuses. Fetal hydrops developed in 11 percent, and 2 percent had intrauterine death. Fetal hydrops was a bad prognostic finding. Overall, 93 percent of the study population was alive at a median follow-up period of 5 years, and 3 percent—seven infants—had neurological handicaps. Of the infants with atrial extrasystoles, 97 percent lived, and none suffered neurological injury. Only 6 percent required postnatal cardiac medications. Lopriore and associates (2009) found low rates of death and long-term neurological impairment in fetuses with...
supraventricular tachycardia or atrial flutter. In contrast, higher mortality rates were noted in those with atrioventricular block.

Although most fetal arrhythmias are of little consequence during labor when there is no evidence of fetal hydrops, such arrhythmias impair interpretation of intrapartum heart rate tracings. Sonographic evaluation of fetal anatomy and echocardiography may be useful. Some clinicians use fetal scalp sampling as an adjunct. Generally, in the absence of fetal hydrops, neonatal outcome is not measurably improved by pregnancy intervention. At Parkland Hospital, intrapartum fetal cardiac arrhythmias, especially those associated with clear amniotic fluid, are managed conservatively. Freeman and colleagues (2003) have extensively reviewed interpretation of the fetal electrocardiogram during labor.

**Sinusoidal Heart Rate**

A true sinusoidal pattern such as that shown in panel 5 of Figure 24-10 may be observed with fetal intracranial hemorrhage, with severe fetal asphyxia, and with severe fetal anemia from Rh alloimmunization, fetomaternal hemorrhage, twin-twin transfusion syndrome, or vasa previa with bleeding (Modanlou, 2004). Insignificant sinusoidal patterns have been reported following administration of meperidine, morphine, alphaprodine, and butorphanol (Angel, 1984; Egley, 1991; Epstein, 1982). Shown in Figure 24-13 is a sinusoidal pattern seen with maternal meperidine administration. An important characteristic of this pattern when due to narcotics is the sine frequency of 6 cycles per minute. A sinusoidal pattern also has been described with chorioamnionitis, fetal distress, and umbilical cord occlusion (Murphy, 1991). Young (1980a) and Johnson (1981) with their coworkers concluded that intrapartum sinusoidal fetal heart patterns were not generally associated with fetal compromise.

![Figure 24-13](image)

**FIGURE 24-13** Sinusoidal fetal heart rate pattern associated with maternal intravenous meperidine administration. Sine waves are occurring at a rate of 6 cycles per minute.

Modanlou and Freeman (1982), based on their extensive review, proposed adoption of a strict definition:

1. Stable baseline heart rate of 120 to 160 bpm with regular oscillations,
2. Amplitude of 5 to 15 bpm (rarely greater),
3. Long-term variability frequency of 2 to 5 cycles per minute,
4. Fixed or flat short-term variability,
5. Oscillation of the sinusoidal waveform above or below a baseline, and
6. Absent accelerations.

Although these criteria were selected to define a sinusoidal pattern that is most likely ominous, they observed that the pattern associated with alphaprodine is indistinguishable. Other investigators have proposed a classification of sinusoidal heart rate patterns into mild—amplitude 5 to 15 bpm, intermediate—16 to 24 bpm, and major—25 or more bpm to quantify fetal risk (Murphy, 1991; Neesham, 1993).

Some investigators have defined intrapartum sine wavelike baseline variation with periods of acceleration as pseudosinusoidal. Murphy and colleagues (1991) reported that pseudosinusoidal patterns were seen in 15 percent of monitored labors. Mild pseudosinusoidal patterns were associated with use of meperidine and epidural analgesia. Intermediate pseudosinusoidal patterns were linked to fetal sucking or transient episodes of fetal hypoxia caused by umbilical cord compression. Egley and associates (1991) reported that 4 percent of fetuses demonstrated sinusoidal patterns transiently during normal labor. These authors observed patterns for up to 90 minutes in some cases and also in association with oxytocin or alphaprodine usage, or both.

The pathophysiology of sinusoidal patterns is unclear, in part due to various definitions. There seems to be general agreement that antepartum sine wave baseline undulation portends severe fetal anemia. Still, few D-alloimmunized fetuses develop this pattern (Nicolaides, 1989). The sinusoidal pattern has been reported to develop or disappear after fetal transfusion (Del Valle, 1992; Lowe, 1984). Ikeda and associates (1999) have proposed, based on studies in fetal lambs, that the sinusoidal fetal heart rate pattern is related to waves of arterial blood pressure, reflecting oscillations in the baroreceptor-chemoreceptor feedback mechanism for control of the circulation.

### Periodic Fetal Heart Rate Changes

The periodic fetal heart rate refers to deviations from baseline that are temporally related to uterine contractions. **Acceleration** refers to an increase in fetal heart rate above baseline and **deceleration** to a decrease below the baseline rate. The nomenclature most commonly used in the United States is based on the **timing** of the deceleration in relation to contractions—thus, early, late, or variable in onset related to the corresponding uterine contraction. The waveform of these decelerations is also significant for pattern recognition. In early and late decelerations, the slope of fetal heart rate change is gradual, resulting in a curvilinear and uniform or symmetrical waveform. With variable decelerations, the slope of fetal heart rate change is abrupt and erratic, giving the waveform a jagged appearance. The 1997 workshop proposed that decelerations be defined as **recurrent** if they occur with 50 percent or more of contractions in any 20-minute period.

Another system now used less often to describe decelerations is based on the pathophysiological events considered most likely to cause the pattern. In this system, early decelerations are termed **head compression**, late decelerations are termed **uteroplacental insufficiency**, and variable decelerations become **cord compression patterns**.

### Accelerations
These are visually apparent abrupt increases—defined as onset of acceleration to a peak in less than 30 seconds—in the fetal heart rate baseline (American College of Obstetricians and Gynecologists, 2013b). At 32 weeks’ gestation and beyond, the acceleration has a peak of 15 bpm with a duration of 15 seconds or more but less than 2 minutes (see Table 24-1). Before 32 weeks, a peak of 10 bpm for 15 seconds to 2 minutes is considered normal. Prolonged acceleration was defined as 2 minutes or more but less than 10 minutes.

According to Freeman and coworkers (2003), accelerations most often occur antepartum, in early labor, and in association with variable decelerations. Proposed mechanisms for intrapartum accelerations include fetal movement, stimulation by uterine contractions, umbilical cord occlusion, and fetal stimulation during pelvic examination. Fetal scalp blood sampling and acoustic stimulation also incite fetal heart rate acceleration (Clark, 1982). Finally, accelerations can occur during labor without any apparent stimulus. Indeed, they are common in labor and are nearly always associated with fetal movement. These accelerations are virtually always reassuring and almost always confirm that the fetus is not acidemic at that time.

Accelerations seem to have the same physiological explanations as beat-to-beat variability in that they represent intact neurohormonal cardiovascular control mechanisms linked to fetal behavioral states. Krebs and colleagues (1982) analyzed electronic heart rate tracings in nearly 2000 fetuses and found sporadic accelerations during labor in 99.8 percent. Fetal heart accelerations during the first or last 30 minutes during labor, or both, was a favorable sign for fetal well-being. The absence of such accelerations during labor, however, is not necessarily an unfavorable sign unless coincidental with other nonreassuring changes. There is an approximately 50-percent chance of acidemia in the fetus who fails to respond to stimulation in the presence of an otherwise nonreassuring pattern (Clark, 1984; Smith, 1986).

Early Deceleration

This consists of a gradual decrease and return to baseline associated with a contraction (Fig. 24-14). Such early deceleration was first described by Hon (1958), who observed that there was a heart rate drop with contractions and that this was related to cervical dilatation. He considered these findings to be physiological.
FIGURE 24-14 Features of early fetal heart rate deceleration. Characteristics include a gradual decline in the heart rate with both onset and recovery coincident with the onset and recovery of the contraction. The nadir of the deceleration is 30 seconds or more after the deceleration onset.

Freeman and associates (2003) defined early decelerations as those generally seen in active labor between 4 and 7 cm dilatation. In their definition, the degree of deceleration is generally proportional to the contraction strength and rarely falls below 100 to 110 bpm or 20 to 30 bpm below baseline. Such decelerations are common during active labor and not associated with tachycardia, loss of variability, or other fetal heart rate changes. Importantly, early decelerations are not associated with fetal hypoxia, acidemia, or low Apgar scores.

Head compression probably causes vagal nerve activation as a result of dural stimulation, and this mediates the heart rate deceleration (Paul, 1964). Ball and Parer (1992) concluded that fetal head compression is a likely cause not only of the deceleration shown in Figure 24-14 but also of those shown in Figure 24-15, which typically occur during second-stage labor. Indeed, they observed that head compression is the likely cause of many variable decelerations classically attributed to cord compression.
FIGURE 24-15 Two different fetal heart rate patterns during second-stage labor that are likely both due to head compression (upper panel). Maternal pushing efforts (lower panel) correspond to the spikes with uterine contractions. Fetal heart rate deceleration (C) is consistent with the pattern of head compression shown in Figure 24-14. Deceleration (B), however, is “variable” in appearance because of its jagged configuration and may alternatively represent cord occlusion.

**Late Deceleration**

The fetal heart rate response to uterine contractions can be an index of either uterine perfusion or placental function. A late deceleration is a smooth, gradual, symmetrical decrease in fetal heart rate beginning at or after the contraction peak and returning to baseline only after the contraction has ended. A gradual decrease is defined as 30 seconds or more from the onset of the deceleration to the nadir. In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively (Fig. 24-16). The magnitude of late decelerations is seldom more than 30 to 40 bpm below baseline and typically not more than 10 to 20 bpm. Late decelerations usually are not accompanied by accelerations.
FIGURE 24-16 Features of late fetal heart rate deceleration. Characteristics include gradual decline in the heart rate with the contraction nadir, and recovery occurring after the end of the contraction. The nadir of the deceleration occurs 30 seconds or more after the onset of the deceleration.

Myers and associates (1973) studied monkeys in which they compromised uteroplacental perfusion by lowering maternal aortic blood pressure. The interval or lag from the contraction onset until the late deceleration onset was directly related to basal fetal oxygenation. They demonstrated that the length of the lag phase was predictive of the fetal $P_{O_2}$ but not fetal pH. The lower the fetal $P_{O_2}$ before contractions, the shorter the lag phase to onset of late decelerations. This lag period reflected the time necessary for the fetal $P_{O_2}$ to fall below a critical level necessary to stimulate arterial chemoreceptors, which mediated decelerations.

Murata and coworkers (1982) also showed that a late deceleration was the first fetal heart rate consequence of uteroplacental-induced hypoxia. During the course of progressive hypoxia that led to death over 2 to 13 days, monkey fetuses invariably exhibited late decelerations before development of acidemia. Variability of the baseline heart rate disappeared as acidemia developed.

Numerous clinical circumstances can result in late decelerations. Generally, any process that causes maternal hypotension, excessive uterine activity, or placental dysfunction can induce late decelerations. The two most common causes are hypotension from epidural analgesia and uterine hyperactivity caused by oxytocin stimulation. Maternal diseases such as hypertension, diabetes, and collagen-vascular disorders can cause chronic placental dysfunction. Placental abruption can cause acute late decelerations (Fig. 24-17).
FIGURE 24-17 Late decelerations due to uteroplacental insufficiency resulting from placental abruption. Immediate cesarean delivery was performed. Umbilical artery pH was 7.05 and the $P_O_2$ was 11 mm Hg.

**Variable Deceleration**

The most common deceleration patterns encountered during labor are variable decelerations attributed to umbilical cord occlusion. Melchior and Bernard (1985) identified variable decelerations in 40 percent of more than 7000 monitor tracings when labor had progressed to 5 cm dilatation and in 83 percent by the end of the first stage of labor. Variable deceleration is defined as an abrupt decrease in the fetal heart rate beginning with the onset of the contraction and reaching a nadir in less than 30 seconds. The decrease must last between $\geq 15$ seconds and 2 minutes and must be $\geq 15$ bpm in amplitude. The onset of deceleration typically varies with successive contractions (Fig. 24-18).
FIGURE 24-18 Features of variable fetal heart rate decelerations. Characteristics include an abrupt decline in the heart rate, and onset that commonly varies with successive contractions. The decelerations measure ≥ 15 bpm for ≥ 15 seconds and have an onset-to-nadir phase of < 30 seconds. Total duration is < 2 minutes.

Very early in the development of electronic monitoring, Hon (1959) tested the effects of umbilical cord compression on fetal heart rate (Fig. 24-19). Similar complete occlusion of the umbilical cord in experimental animals produces abrupt, jagged-appearing deceleration of the fetal heart rate (Fig. 24-20). Concomitantly, fetal aortic pressure increases. Itskovitz and colleagues (1983) observed that variable decelerations in fetal lambs occurred only after umbilical blood flow was reduced by at least 50 percent.
FIGURE 24-19 A. The effects of 25-second cord compression compared with those of 40 seconds in panel (B). (Redrawn from Hon, 1959, with permission.)
FIGURE 24-20 Total umbilical cord occlusion (arrow) in the sheep fetus is accompanied by an increase in fetal aortic blood pressure. Blood pressure changes in the umbilical vessels are also shown. (Redrawn from Künzel, 1985, with permission.)

Two types of variable decelerations are shown in Figure 24-21. The deceleration denoted by “A” is very much like that seen with complete umbilical cord occlusion in experimental animals.
Deceleration “B,” however, has a different configuration because of the “shoulders” of acceleration before and after the deceleration component. Lee and coworkers (1975) proposed that this form of variable deceleration was caused by differing degrees of partial cord occlusion. In this physiological scheme, occlusion of only the vein reduces fetal blood return, thereby triggering a baroreceptor-mediated acceleration. With increasing intrauterine pressure and subsequent complete cord occlusion, fetal systemic hypertension develops due to obstruction of umbilical artery flow. This stimulates a baroreceptor-mediated deceleration. Presumably, the aftercoming shoulder of acceleration represents the same events occurring in reverse (Fig. 24-22).

FIGURE 24-21 Varying (variable) fetal heart rate decelerations. Deceleration (B) exhibits “shoulders” of acceleration compared with deceleration (A). (Adapted from Künzel, 1985, with permission.)
Ball and Parer (1992) concluded that variable decelerations are mediated vagally and that the vagal response may be due to chemoreceptor or baroreceptor activity or both. Partial or complete cord occlusion produces an increase in afterload (baroreceptor) and a decrease in fetal arterial oxygen content (chemoreceptor). These both result in vagal activity leading to deceleration. In fetal monkeys, the baroreceptor reflexes appear to operate during the first 15 to 20 seconds of umbilical cord occlusion followed by decline in $P_{O_2}$ at approximately 30 seconds, which then serves as a chemoreceptor stimulus (Mueller-Heubach, 1982).

Thus, variable decelerations represent fetal heart rate reflexes that reflect either blood pressure...
changes due to interruption of umbilical flow or changes in oxygenation. It is likely that most fetuses have experienced brief but recurrent periods of hypoxia due to umbilical cord compression during gestation. The frequency and inevitability of cord occlusion undoubtedly have provided the fetus with these physiological mechanisms as a means of coping. The great dilemma for the obstetrician in managing variable fetal heart rate decelerations is determining when variable decelerations are pathological. According to the American College of Obstetricians and Gynecologists (2013a), recurrent variable decelerations with minimal to moderate variability are indeterminate, whereas those with absent variability are abnormal.

Other fetal heart rate patterns have been associated with umbilical cord compression. Saltatory baseline heart rate (Fig. 24-23) was first described by Hammacher and colleagues (1968) and linked to umbilical cord complications during labor. The pattern consists of rapidly recurring couplets of acceleration and deceleration causing relatively large oscillations of the baseline fetal heart rate. We also observed a relationship between cord occlusion and the saltatory pattern (Leveno, 1984). In the absence of other fetal heart rate findings, these do not signal fetal compromise. Lambda is a pattern involving an acceleration followed by a variable deceleration with no acceleration at the end of the deceleration. This pattern typically is seen in early labor and is not ominous (Freeman, 2003). This lambda pattern may result from mild cord compression or stretch. Overshoot is a variable deceleration followed by acceleration. The clinical significance of this pattern is controversial (Westgate, 2001).

FIGURE 24-23 Saltatory baseline fetal heart rate showing rapidly recurring couplets of acceleration combined with deceleration.
Prolonged Deceleration

This pattern, which is shown in Figure 24-24, is defined as an isolated deceleration greater than 15 bpm lasting 2 minutes or longer but < 10 minutes from onset to return to baseline. Prolonged decelerations are difficult to interpret because they are seen in many different clinical situations. Some of the more common causes include cervical examination, uterine hyperactivity, cord entanglement, and maternal supine hypotension.

FIGURE 24-24 Prolonged fetal heart rate deceleration due to uterine hyperactivity. Approximately 3 minutes of the tracing are shown, but the fetal heart rate returned to normal after uterine hypertonus resolved. Vaginal delivery later ensued.

Epidural, spinal, or paracervical analgesia may induce prolonged deceleration of the fetal heart rate. For example, Eberle and coworkers (1998) reported that prolonged decelerations occurred in 4 percent of normal parturients given either epidural or intrathecal labor analgesia. Hill and associates (2003) observed prolonged deceleration in 1 percent of women given epidural analgesia during labor at Parkland Hospital. Other causes of prolonged deceleration include maternal hypoperfusion or hypoxia from any cause, placental abruption, umbilical cord knots or prolapse, maternal seizures including eclampsia and epilepsy, application of a fetal scalp electrode, impending birth, or even maternal Valsalva maneuver.

The placenta is very effective in resuscitating the fetus if the original insult does not recur immediately. Occasionally, such self-limited prolonged decelerations are followed by loss of beat-to-beat variability, baseline tachycardia, and even a period of late decelerations, all of which resolve as the fetus recovers. Freeman and colleagues (2003) emphasize rightfully that the fetus
may die during prolonged decelerations. Thus, management of prolonged decelerations can be extremely tenuous. Management of isolated prolonged decelerations is based on bedside clinical judgment, which inevitably will sometimes be imperfect given the unpredictability of these decelerations.

Fetal Heart Rate Patterns During Second-Stage Labor

Decelerations are virtually ubiquitous during the second stage. Melchior and Bernard (1985) reported that only 1.4 percent of more than 7000 deliveries lacked decelerations during second-stage labor. Both cord compression and fetal head compression have been implicated as causes of decelerations and baseline bradycardia during second-stage labor. The high incidence of such patterns minimized their potential significance during the early development and interpretation of electronic monitoring. For example, Boehm (1975) described profound, prolonged fetal heart rate deceleration in the 10 minutes preceding vaginal delivery of 18 healthy infants. However, Herbert and Boehm (1981) later reported another 18 pregnancies with similar prolonged second-stage decelerations. There was one stillbirth and one neonatal death. These experiences attest to the unpredictability of the fetal heart rate during second-stage labor.

Spong and associates (1998) analyzed the characteristics of second-stage variable fetal heart rate decelerations in 250 deliveries and found that as the total number of decelerations to < 70 bpm increased, the 5-minute Apgar score decreased. Put another way, the longer a fetus was exposed to variable decelerations, the lower the Apgar score was at 5 minutes.

Picquard and coworkers (1988) analyzed heart rate patterns during second-stage labor in 234 women in an attempt to identify specific patterns to diagnose fetal compromise. Loss of beat-to-beat variability and baseline fetal heart rate < 90 bpm were predictive of fetal acidemia. Krebs and associates (1981) also found that persistent or progressive baseline bradycardia and baseline tachycardia were associated with low Apgar scores. Gull and colleagues (1996) observed that abrupt fetal heart rate deceleration to < 100 bpm associated with loss of beat-to-beat variability for 4 minutes or longer was predictive of fetal acidemia. Thus, abnormal baseline heart rate—either bradycardia or tachycardia, absent beat-to-beat variability, or both—in the presence of second-stage decelerations, is associated with increased but not inevitable fetal compromise (Fig. 24-25).
FIGURE 24-25 Cord-compression fetal heart rate decelerations in second-stage labor associated with tachycardia and loss of variability. The umbilical cord arterial pH was 6.9.

 Admission Fetal Monitoring in Low-Risk Pregnancies

With this approach, women with low-risk pregnancies are monitored for a short time on admission for labor, and continuous monitoring is used only if fetal heart rate abnormalities are subsequently identified. Mires and coworkers (2001) randomly assigned 3752 low-risk women in spontaneous labor at admission either to auscultation of the fetal heart or to 20 minutes of electronic fetal monitoring. Use of admission electronic fetal monitoring did not improve infant outcome. Moreover, its use resulted in increased interventions, including operative delivery. Impey and associates (2003) performed a similar study in 8588 low-risk women and also found no improvement in infant outcome. More than half of the women enrolled in these studies, whether they received admission electronic monitoring or auscultation, eventually required continuous monitoring for diagnosed abnormalities in the fetal heart rate.

With the increasing rate of scheduled cesarean deliveries in the United States, clinicians and hospitals must decide whether fetal monitoring is required before the procedure in low-risk women. The American College of Obstetricians and Gynecologists (2010) has concluded that data are insufficient to determine the value of fetal monitoring under these circumstances.

Centralized Monitoring

Technological advances have made it possible to observe fetal heart rate monitors from a remote, centralized location. Such intrapartum monitoring equipment has become common in American labor and delivery units. The rationale behind centralized monitoring is that the ability to monitor several patients simultaneously would lead to better outcomes. What is the evidence that this rationale is correct? To our knowledge, only one study on centralized fetal monitoring has been
Anderson and colleagues (2011) measured the ability of 12 individuals to detect critical signals in fetal heart rate tracings on one, two, or four monitors. The results showed that detection accuracy declined as the number of displays increased.

### OTHER INTRAPARTUM ASSESSMENT TECHNIQUES

#### Fetal Scalp Blood Sampling

According to the American College of Obstetricians and Gynecologists (2009), measurements of the pH in capillary scalp blood may help to identify the fetus in serious distress. That said, it also emphasized that neither normal nor abnormal scalp pH results have been shown to be predictive of infant outcome. The College also indicated that the procedure is now used uncommonly and is not even available at some hospitals.

For completion, an illuminated endoscope is inserted through the dilated cervix after membrane rupture so as to press firmly against the fetal scalp (Fig. 24-26). The skin is wiped clean with a cotton swab and coated with a silicone gel to cause the blood to accumulate as discrete globules. An incision is made through the skin to a depth of 2 mm with a special blade on a long handle. As a drop of blood forms on the surface, it is immediately collected into a heparinized glass capillary tube. The pH of the blood is measured promptly.

**FIGURE 24-26** The technique of fetal scalp sampling using an amnioscope. The end of the endoscope is displaced from the fetal vertex approximately 2 cm to show the disposable blade against the fetal scalp before incision. (Adapted from Hamilton, 1974.)
The pH of fetal capillary scalp blood is usually lower than that of umbilical venous blood and approaches that of umbilical arterial blood. Zalar and Quilligan (1979) recommended a protocol to try to confirm fetal distress. If the pH is > 7.25, labor is observed, and if between 7.20 and 7.25, the pH measurement is repeated within 30 minutes. If the pH is < 7.20, another scalp blood sample is collected immediately, and the mother is taken to an operating room and prepared for surgery. Delivery is performed promptly if the low pH is confirmed. Otherwise, labor is allowed to continue, and scalp blood samples are repeated periodically.

The only benefits reported for scalp pH testing are fewer cesarean deliveries for fetal distress (Young, 1980b). Goodwin and coworkers (1994), however, in a study of 112,000 deliveries, showed a decrease in the scalp pH sampling rate. The rate dropped from approximately 1.8 percent in the mid-1980s to 0.03 percent by 1992 but with no increased delivery rate for fetal distress. They concluded that scalp pH sampling was unnecessary. Kruger and colleagues (1999) have advocated the use of fetal scalp blood lactate concentration as an adjunct to pH. Wiberg-Itzel and associates (2008) randomized 1496 fetuses to scalp blood pH analysis and 1496 to scalp blood lactate analysis. They found either to be equivalent in predicting fetal acidemia. The advantage of lactate measurement was that a smaller amount of blood was needed, which led to a lower procedural failure rate compared with scalp sampling for pH.

Scalp Stimulation

Clark and coworkers (1984) have suggested that scalp stimulation is an alternative to scalp blood sampling. This proposal was based on the observation that heart rate acceleration in response to pinching of the scalp with an Allis clamp just before obtaining blood was invariably associated with a normal pH. Conversely, failure to provoke acceleration was not uniformly predictive of fetal acidemia. Later, Elimian and associates (1997) reported that of 58 cases in which the fetal heart rate accelerated ≥ 10 bpm after 15 seconds of gentle digital stroking of the scalp, 100 percent had a scalp pH of ≥ 7.20. Without an acceleration, however, only 30 percent had a scalp pH < 7.20.

Vibroacoustic Stimulation

Fetal heart rate acceleration in response to vibroacoustic stimulation has been recommended as a substitute for scalp sampling (Edersheim, 1987). The technique uses an electronic artificial larynx placed approximately 1 cm from or directly onto the maternal abdomen (Chap. 17, p. 341). Response to vibroacoustic stimulation is considered normal if a fetal heart rate acceleration of at least 15 bpm for at least 15 seconds occurs within 15 seconds after the stimulation and with prolonged fetal movements (Sherer, 1994). Lin and colleagues (2001) prospectively studied vibroacoustic stimulation in 113 women in labor with either moderate to severe variable or late fetal heart rate decelerations. They concluded that this technique is an effective predictor of fetal acidosis in the setting of variable decelerations. The predictability for fetal acidosis, however, is limited in the setting of late decelerations. Other investigators have reported that although vibroacoustic stimulation in second-stage labor is associated with fetal heart rate reactivity, the quality of the response did not predict neonatal outcome or enhance labor management (Anyaegbunam, 1994).

Skupski and coworkers (2002) performed a metaanalysis of reports on intrapartum fetal stimulation tests published between 1966 and 2000. Four types of fetal stimulation were analyzed and included scalp puncture for pH testing, Allis clamp pinching of the fetal scalp, vibroacoustic...
stimulation, and digital stroking of the scalp. Results were similar for all four methods. These investigators concluded that intrapartum stimulation tests were useful to exclude fetal acidemia. They cautioned, however, that these tests are “less than perfect.”

**Fetal Pulse Oximetry**

Using technology similar to that of adult pulse oximetry, instrumentation has been developed that may allow assessment of fetal oxyhemoglobin saturation once membranes are ruptured. A unique padlike sensor such as shown in Figure 24-27 is inserted through the cervix and positioned against the fetal face, where it is held in place by the uterine wall. A transabdominal fetal pulse oximeter has also been described in a preliminary study (Vintzileos, 2005). As reviewed by Yam and coworkers (2000), the transcervical device has been used extensively by many investigators. It has been reported to reliably register fetal oxygen saturation in 70 to 95 percent of women throughout 50 to 88 percent of their labors. The lower limit for normal fetal oxygen saturation is generally considered to be 30 percent by investigators (Gorenberg, 2003; Stiller, 2002). As shown in Figure 24-28, however, fetal oxygen saturation normally varies greatly when measured in umbilical artery blood (Arikan, 2000). Bloom and associates (1999) reported that brief, transient fetal oxygen saturations below 30 percent were common during labor because such values were observed in 53 percent of fetuses with normal outcomes. Saturation values below 30 percent, however, when persistent for 2 minutes or longer, were associated with an increased risk of potential fetal compromise.

**FIGURE 24-27** Schematic diagram of fetal pulse oximeter sensor placement.
FIGURE 24-28 Frequency distribution of umbilical artery oxygen saturation values in 1281 vigorous newborn infants. Dotted line indicates normal distribution. (Redrawn from Arikan, 2000, with permission.)

Garite and colleagues (2000) randomly assigned 1010 women with term pregnancies and in whom predefined abnormal fetal heart rate patterns developed. Patients received either conventional fetal monitoring alone or fetal monitoring plus continuous fetal pulse oximetry. Cesarean delivery for fetal distress was performed when pulse oximetry values remained < 30 percent for the entire interval between two contractions or when the fetal heart rate patterns met predefined guidelines. The use of fetal pulse oximetry significantly reduced the cesarean delivery rate for nonreassuring fetal status from 10.2 to 4.5 percent. Alternatively, the cesarean delivery rate for dystocia increased significantly from 9 to 19 percent when pulse oximetry was used. There were no neonatal benefits or adverse effects associated with fetal pulse oximetry. Based on these observations, in 2000, the Obstetrics and Gynecology Devices Panel of the Medical Device Advisory Committee of the Food and Drug Administration (FDA) (2012) approved marketing of the Nellcor N-400 Fetal Oxygen Monitoring System.

Since then, another three randomized trials of fetal pulse oximetry have been reported. Of these, Klauser and colleagues (2005) randomly assigned 360 women with nonreassuring fetal heart rate patterns to standard fetal monitoring plus fetal pulse oximetry or to standard monitoring alone and found no benefits for oximetry. East and coworkers (2006) randomized 600 women with nonreassuring fetal heart rate patterns to standard monitoring either alone or with added fetal pulse oximetry. These investigators reported that addition of oximetry significantly reduced cesarean delivery rates for a nonreassuring fetal heart rate pattern. They further reported, however, that neonatal outcomes were not different between the study groups. Also, Bloom and associates (2006) reported the largest trial, which was performed by the Maternal-Fetal Units Network. A
total of 5341 women in labor at term underwent placement of the fetal oximetry sensor, but the information was randomly withheld from care providers. Unlike the earlier studies, participants were not required to have nonreassuring fetal heart rate patterns. Sensor application was generally successful and fetal oxygen saturation values were registered 75 percent of the time. Knowledge of fetal oxygen saturation did not change the cesarean delivery rates in the overall population or in the subgroup of 2168 women who had nonreassuring fetal heart rate patterns. Moreover, neonatal outcomes were not improved by knowledge of fetal oxygen saturation status. Because of these findings, in 2005, the manufacturer discontinued sale of the fetal oximeter system in the United States.

**Fetal Electrocardiography**

As fetal hypoxia worsens, there are changes in the T-wave and in the ST segment of the fetal ECG. Because of this, several investigators have assessed the value of analyzing these parameters as an adjunct to conventional fetal monitoring. The technique requires internal fetal heart monitoring and special equipment to process the fetal ECG. The rationale behind this technology is based on the observation that the mature fetus exposed to hypoxemia develops an elevated ST segment with a progressive rise in T-wave height that can be expressed as a T:QRS ratio (Fig. 24-29). It is postulated that increasing T:QRS ratios reflect fetal cardiac ability to adapt to hypoxia and appears before neurological damage. Worsening hypoxia results in an increasingly negative ST-segment deflection such that it appears as a biphasic waveform (Fig. 24-30). In 2005, the manufacturer—Neoventa Medical—received FDA (2012) approval for their ST analysis program—the STAN system.
There have been a few studies of ST-segment changes with fetal monitoring. Westgate and coworkers (1993) conducted a randomized trial of 2400 pregnancies. Infant outcomes were not improved compared with those in whom conventional fetal monitoring alone was used. There was, however, a reduction in the cesarean delivery rate for fetal distress. In another randomized trial of 4966 Swedish women, Amer-Wåhlin and colleagues (2001, 2007) found that the addition of ST-segment analysis to conventional fetal monitoring significantly reduced cesarean delivery rates for fetal distress and metabolic acidemia in umbilical artery blood. Subsequently, Doria and associates (2007) introduced STAN as a clinical practice in a London hospital and reported no changes in the incidence of operative delivery or neonatal encephalopathy. Most recently, Becker and colleagues (2012) performed a metaanalysis of five randomized trials comprising 15,352 patients and found that use of ST-segment analysis did not reduce the rates of cesarean delivery or fetal metabolic acidemia at birth.

It must be considered that ST-segment abnormalities might occur late in the course of fetal compromise. Neilson (2013) reviewed the Cochrane Database to assess fetal ECG analysis during labor. There were 16,295 women in which such monitoring was performed. He concluded that fetal ST-segment waveform analysis was perhaps useful in preventing fetal acidosis and neonatal encephalopathy when standard fetal heart rate monitoring suggested abnormal patterns. Although no randomized trials have yet been performed in the United States, the Maternal-Fetal Medicine Units Network has one in progress.

**Intrapartum Doppler Velocimetry**

Doppler analysis of the umbilical artery has been studied as another potential adjunct to conventional fetal monitoring. Further described in Chapter 10 (p. 219), abnormal Doppler waveforms may signify pathological umbilical-placental vessel resistance. From their review, Farrell and associates (1999) concluded that this technique was a poor predictor of adverse perinatal outcomes. They concluded that Doppler velocimetry had little if any role in fetal surveillance during labor.

**FETAL DISTRESS**
The terms *fetal distress* and *birth asphyxia* are too broad and vague to be applied with any precision to clinical situations (American College of Obstetricians and Gynecologists, 2005). Uncertainty regarding the diagnosis based on interpretation of fetal heart rate patterns has given rise to descriptions such as *reassuring* or *nonreassuring*. The term “reassuring” suggests a restoration of confidence by a particular pattern, whereas “nonreassuring” suggests inability to remove doubt. These patterns during labor are dynamic—they can rapidly change from reassuring to nonreassuring and vice versa. In this situation, obstetricians experience surges of both confidence and doubt. Put another way, most diagnoses of fetal distress using heart rate patterns occur when obstetricians lose confidence or cannot assuage doubts about fetal condition. *These assessments are subjective clinical judgments that are inevitably subject to imperfection and must be recognized as such.*

### Pathophysiology

Why is the diagnosis of fetal distress based on heart rate patterns so tenuous? One explanation is that these patterns are more a reflection of fetal physiology than of pathology. Physiological control of heart rate includes various interconnected mechanisms that depend on blood flow and oxygenation. Moreover, the activity of these control mechanisms is influenced by the preexisting state of fetal oxygenation, for example, as seen with chronic placental insufficiency. Importantly, the fetus is tethered by an umbilical cord, whereby blood flow is constantly in jeopardy. Moreover, normal labor is a process of increasing acidemia (Rogers, 1998). Thus, normal labor is a process of repeated fetal hypoxic events resulting inevitably in acidemia. Put another way, and assuming that “asphyxia” can be defined as hypoxia leading to acidemia, normal parturition is an asphyxiating event for the fetus.

### Diagnosis

Because of the above uncertainties, it follows that identification of “fetal distress” based on fetal heart rate patterns is imprecise and controversial. It is well known that experts in interpretation of these patterns often disagree with each other. In fact, Parer (1997), a strong advocate of electronic fetal heart rate monitoring and an organizer of the 1997 NICHD fetal monitoring workshop lightheartedly compared the experts in attendance to marine iguanas of the Galapagos Islands, to wit: “all on the same beach but facing different directions and spitting at one another constantly!”

Ayres-de-Campos and colleagues (1999) investigated interobserver agreement of fetal heart rate pattern interpretation and found that agreement—or conversely, disagreement—was related to whether the pattern was normal, suspicious, or pathological. Specifically, experts agreed on 62 percent of normal patterns, 42 percent of suspicious patterns, and only 25 percent of pathological patterns. Keith and coworkers (1995) asked each of 17 experts to review 50 tracings on two occasions, at least 1 month apart. Approximately 20 percent changed their own interpretations, and approximately 25 percent did not agree with the interpretations of their colleagues. And although Murphy and associates (2003) concluded that at least part of the interpretation problem is due to a lack of formalized education in American training programs, this is obviously only a small modifier. Put another way, how can the teacher enlighten the student if the teacher is uncertain?

### National Institutes of Health Workshops Three-Tier Classification System
The NICHD (1997) held a succession of workshops in 1995 and 1996 to develop standardized and unambiguous definitions of fetal heart rate (FHR) tracings and published recommendations for interpreting these patterns. In 2008, a second workshop was convened to reevaluate the 1997 recommendations and to clarify terminology (see Table 24-1)(Macones, 2008). A major result was the recommendation of a three-tier system for classification of FHR patterns (Table 24-2). The American College of Obstetricians and Gynecologists (2013b) subsequently recommended use of this tiered system.

| TABLE 24-2. Three-Tier Fetal Heart Rate Interpretation System |
Category I—Normal
Include all of the following:
- Baseline rate: 110–160 bpm
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

Category II—Indeterminate
Include all FHR tracings not categorized as Category I or III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples include any of the following:
- Baseline rate
- Bradycardia not accompanied by absent baseline variability
- Tachycardia
- Baseline FHR variability
  - Minimal baseline variability
  - Absent baseline variability not accompanied by recurrent decelerations
  - Marked baseline variability
- Accelerations
- Absence of induced accelerations after fetal stimulation
- Periodic or episodic decelerations
  - Recurrent variable decelerations accompanied by minimal or moderate baseline variability
  - Prolonged deceleration ≥ 2 min but < 10 min
  - Recurrent late decelerations with moderate baseline variability
  - Variable decelerations with other characteristics, such as slow return to baseline, “overshoots,” or “shoulders”

Category III—Abnormal
Include either:
- Absent baseline FHR variability and any of the following:
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
  - Sinusoidal pattern

bpm = beats per minute; FHR = fetal heart rate.
From Macones, 2008, with permission.
A few studies have been done to assess the three-tiered system. Jackson and coworkers (2011) studied 48,444 women in labor and found that category I (normal FHR) patterns were observed during labor in 99.5 percent of tracings. Category II (indeterminate FHR) patterns were found in 84.1 percent of tracings, and category III (abnormal FHR) patterns were seen in 0.1 percent (54 women). Most—84 percent of women—had a mix of categories during labor. Cahill and colleagues (2012) retrospectively studied the incidence of umbilical cord acidemia (pH ≤ 7.10) correlated with fetal heart rate characteristics during the 30 minutes preceding delivery. None of the three categories demonstrated a significant association with cord blood acidemia. The American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2014) concluded that a category I or II tracing with a 5-minute Apgar score > 7 or normal arterial blood acid-base values was not consistent with an acute hypoxic-ischemic event.

Sholapurkar (2012) also challenged the validity of the three-tier system because most abnormal fetal heart rate patterns fall into the indeterminate category II, that is, one for which no definite management recommendations can be made. It was further suggested that this resulted from most fetal heart rate decelerations being inappropriately classified as variable decelerations due to cord compression.

Parer and King (2010) compared the current situation in the United States with that of other countries in which a consensus on classification and management has been reached by a number of professional societies. Some of these include the Royal College of Obstetricians and Gynaecologists, the Society of Obstetricians and Gynaecologists of Canada, the Royal Australian and New Zealand College of Obstetricians and Gynaecologists, and the Japan Society of Obstetrics and Gynaecology. Parer and King (2010) further comment that the NICHD three-tier system is inadequate because category II—indeterminate FHR—consists of a “vast heterogenous mixture of patterns” that prevents development of a management strategy. Parer and Ikeda (2007) had previously proposed a color-coded five-tier system for both FHR interpretation and management.

There have been two reports comparing the five-tier and three-tier systems. Bannerman and associates (2011) found that the two systems were similar in fetal heart rate interpretations for tracings that were either very normal or very abnormal. Coletta and coworkers (2012) found that the five-tier system had better sensitivity than the three-tier system. It is apparent that, after 50 years of continuous electronic fetal heart rate monitoring use, there is not a consensus on interpretation and management recommendations for FHR patterns (Parer, 2011).

## Meconium in the Amnionic Fluid

Obstetrical teaching throughout the past century has included the concept that meconium passage is a potential warning of fetal asphyxia. In 1903, J. Whitridge Williams observed and attributed meconium passage to “relaxation of the sphincter ani muscle induced by faulty aeration of the (fetal) blood.” Even so, obstetricians have also long realized that the detection of meconium during labor is problematic in the prediction of fetal distress or asphyxia. In their review, Katz and Bowes (1992) emphasized the prognostic uncertainty of meconium by referring to the topic as a “murky subject.” Indeed, although 12 to 22 percent of labors are complicated by meconium, only a few are linked to infant mortality. In an investigation from Parkland Hospital, meconium was found to be a “low-risk” obstetrical hazard because the perinatal mortality rate attributable to meconium was 1 death per 1000 live births (Nathan, 1994).

Three theories have been suggested to explain fetal passage of meconium and in part may explain the tenuous connection between its detection and infant mortality. First, the pathological explanation proposes that fetuses pass meconium in response to hypoxia and that meconium...
therefore signals fetal compromise (Walker, 1953). Second, the physiological explanation is that in utero passage of meconium represents normal gastrointestinal tract maturation under neural control (Mathews, 1979). A final theory posits that meconium passage follows vagal stimulation from common but transient umbilical cord entrapment with resultant increased bowel peristalsis (Hon, 1961). Thus, meconium release may represent physiological processes.

Ramin and associates (1996) studied almost 8000 pregnancies with meconium-stained amniotic fluid delivered at Parkland Hospital. Meconium aspiration syndrome was significantly associated with fetal acidemia at birth. Other significant correlates of aspiration included cesarean delivery, forceps to expedite delivery, intrapartum heart rate abnormalities, depressed Apgar scores, and need for assisted ventilation at delivery. Analysis of the type of fetal acidemia based on umbilical blood gases suggested that the fetal compromise associated with meconium aspiration syndrome was an acute event. This is because most acidemic fetuses had abnormally increased $P_{CO_2}$ values rather than a pure metabolic acidemia.

Dawes and coworkers (1972) observed that such hypercarbia in fetal lambs induces gasping and resultant increased amnionic fluid inhalation. Jovanovic and Nguyen (1989) observed that meconium gasped into the fetal lungs caused aspiration syndrome only in asphyxiated animals. Ramin and colleagues (1996) hypothesized that the pathophysiology of meconium aspiration syndrome includes, but is not limited to, fetal hypercarbia, which stimulates fetal respiration leading to aspiration of meconium into the alveoli. Lung parenchymal injury is secondary to acidemia-induced alveolar cell damage. In this pathophysiological scenario, meconium in amnionic fluid is a fetal environmental hazard rather than a marker of preexistent compromise. This proposed pathophysiological sequence is not all-inclusive, because it does not account for approximately half of the cases of meconium aspiration syndrome in which the fetus was not acidemic at birth.

Thus, it was concluded that the high incidence of meconium observed in the amnionic fluid during labor often represents fetal passage of gastrointestinal contents in conjunction with normal physiological processes. Although normal, such meconium becomes an environmental hazard when fetal acidemia supervenes. Importantly, such acidemia occurs acutely, and therefore meconium aspiration is unpredictable and likely unpreventable. Moreover, Greenwood and colleagues (2003) showed that clear amnionic fluid was also a poor predictor. In a prospective study of 8394 women with clear amnionic fluid, they found that clear fluid was an unreliable sign of fetal well-being.

Growing evidence indicates that many infants with meconium aspiration syndrome have suffered chronic hypoxia before birth (Ghidini, 2001). Blackwell and associates (2001) found that 60 percent of infants diagnosed with meconium aspiration syndrome had umbilical artery blood pH $\geq 7.20$, implying that the syndrome was unrelated to the neonatal condition at delivery. Similarly, markers of chronic hypoxia, such as fetal erythropoietin levels and nucleated red blood cell counts in newborn infants, suggest that chronic hypoxia is involved in many meconium aspiration syndrome cases (Dollberg, 2001; Jazayeri, 2000).

In the recent past, routine obstetrical management of a newborn with meconium-stained amnionic fluid included intrapartum suctioning of the oropharynx and nasopharynx. Guidelines from the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, however, recommend that such infants no longer routinely receive intrapartum suctioning because it does not prevent meconium aspiration syndrome (Perlman, 2010). As discussed in Chapter 32 (p. 626), if the infant is depressed, the trachea is intubated, and meconium suctioned from beneath the glottis. If the newborn is vigorous, defined as having strong respiratory efforts, good muscle tone, and a heart rate $> 100$ bpm, then tracheal suction is not necessary and
Management Options

The principal management options for significantly variable fetal heart rate patterns consist of correcting any fetal insult, if possible. Measures suggested by the American College of Obstetricians and Gynecologists (2013b,c) are listed in Table 24-3. Moving the mother to the lateral position, correcting maternal hypotension caused by regional analgesia, and discontinuing oxytocin serve to improve uteroplacental perfusion. Examination is done to exclude prolapsed cord or impending delivery. Simpson and James (2005) assessed benefits of three maneuvers in 52 women with fetal oxygen saturation sensors already in place. They used intravenous hydration—500 to 1000 mL of lactated Ringer solution given over 20 minutes; lateral versus supine position; and using a nonrebreathing mask that administered supplemental oxygen at 10 L/min. Each of these maneuvers significantly increased fetal oxygen saturation levels, although the increments were small.

aSimultaneous evaluation of the suspected cause(s) is also an important step in management of abnormal FHR tracings.

bThe combination of multiple interventions simultaneously may be appropriate and potentially more effective than doing them individually or serially.

FHR = fetal heart rate.

**Tocolysis**

A single intravenous or subcutaneous injection of 0.25 mg of terbutaline sulfate given to relax the uterus has been described as a temporizing maneuver in the management of nonreassuring fetal
heart rate patterns during labor. The rationale is that inhibition of uterine contractions might improve fetal oxygenation, thus achieving in utero resuscitation. Cook and Spinnato (1994) described their experience during 10 years with terbutaline tocolysis for fetal resuscitation in 368 pregnancies. Such resuscitation improved fetal scalp blood pH values, although all fetuses underwent cesarean delivery. These investigators concluded that although the studies were small and rarely randomized, most reported favorable results with terbutaline tocolysis for nonreassuring patterns. Small intravenous doses of nitroglycerin—60 to 180 μg—also have been reported to be beneficial (Mercier, 1997). The American College of Obstetricians and Gynecologists (2013b) has concluded that there is insufficient evidence to recommend tocolysis for non-reassuring fetal heart rate patterns.

Amnioinfusion

Gabbe and coworkers (1976) showed in monkeys that removal of amnionic fluid produced variable decelerations and that replenishment of fluid with saline relieved the decelerations. Miyazaki and Taylor (1983) infused saline through an intrauterine pressure catheter in laboring women who had either variable decelerations or prolonged decelerations attributed to cord entrapment. Such therapy improved the heart rate pattern in half of the women studied. Later, Miyazaki and Nevarez (1985) randomly assigned 96 nulliparous women in labor with cord compression patterns and found that those who were treated with amnioinfusion required cesarean delivery for fetal distress less often.

Based on many of these early reports, transvaginal amnioinfusion has been extended into three clinical areas. These include: (1) treatment of variable or prolonged decelerations, (2) prophylaxis for women with oligohydramnios, as with prolonged ruptured membranes, and (3) attempts to dilute or wash out thick meconium (Chap. 33, p. 638).

Many different amnioinfusion protocols have been reported, but most include a 500- to 800-mL bolus of warmed normal saline followed by a continuous infusion of approximately 3 mL per minute (Owen, 1990; Pressman, 1996). In another study, Rinehart and colleagues (2000) randomly gave a 500-mL bolus of normal saline at room temperature alone or 500-mL bolus plus continuous infusion of 3 mL per minute. Their study included 65 women with variable decelerations, and the investigators found neither method to be superior. Wenstrom and associates (1995) surveyed use of amnioinfusion in teaching hospitals in the United States. The procedure was used in 96 percent of the 186 centers surveyed, and it was estimated that 3 to 4 percent of all women delivered at these centers received such infusion. Potential complications of amnioinfusion are summarized in Table 24-4.

| TABLE 24-4. Complications Associated with Amnioinfusion from a Survey of 186 Obstetrical Units |
Prophylactic Amnioinfusion for Variable Decelerations. Hofmeyr and Lawrie (2012) used the Cochrane Database to specifically analyze the effects of amnioinfusion in the management of fetal heart rate patterns associated with umbilical cord compression. Nineteen suitable studies were identified, most with fewer than 200 participants. It was concluded that amnioinfusion appeared to be useful in reducing the occurrence of variable decelerations, improving neonatal outcome, and reducing cesarean delivery rates. The American College of Obstetricians and Gynecologists (2013a) recommends consideration of amnioinfusion with persistent variable decelerations.

Prophylactic Amnioinfusion for Oligohydramnios. Amnioinfusion in women with oligohydramnios has been used prophylactically to avoid intrapartum fetal heart rate patterns from cord occlusion. Nageotte and coworkers (1991) found that this resulted in significantly decreased frequency and severity of variable decelerations in labor. However, the cesarean delivery rate or condition of term infants was not improved. In a randomized investigation, Macri and colleagues (1992) studied prophylactic amnioinfusion in 170 term and postterm pregnancies complicated by both thick meconium and oligohydramnios. Amnioinfusion significantly reduced cesarean delivery rates for fetal distress and meconium aspiration syndrome. In contrast, Ogundipe and associates (1994) randomly assigned 116 term pregnancies with an amniotic fluid index < 5 cm to receive prophylactic amnioinfusion or standard obstetrical care. There were no significant differences in overall cesarean delivery rates, delivery rates for fetal distress, or umbilical cord acid-base studies.

Ammioinfusion for Meconium-Stained Amnionic Fluid. Pierce and associates (2000) summarized the results of 13 prospective trials of intrapartum amnioinfusion in 1924 women with moderate to thick meconium-stained fluid. Infants born to women treated by amnioinfusion were significantly less likely to have meconium below the vocal cords and were less likely to develop meconium aspiration syndrome than infants born to women not undergoing amnioinfusion. The cesarean delivery rate was also lower in the amnioinfusion group. Similar results were reported by Rathore and coworkers (2002). In contrast, several investigators were not supportive of amnioinfusion for meconium staining. For example, Usta and associates (1995) reported that amnioinfusion was not feasible in half of women with moderate or thick meconium who were randomized to this treatment. These investigators were unable to demonstrate any improvement in neonatal outcomes.

Spong and coworkers (1994) also concluded that although prophylactic amnioinfusion did dilute meconium, it did not improve perinatal outcome. Last, Fraser and colleagues (2005) randomized amnioinfusion in 1998 women with thick meconium staining of the amniotic fluid in labor and found no benefits. Because of these findings, the American College of Obstetricians and Gynecologists (2012a, 2013c) does not recommend amnioinfusion to dilute meconium-stained amniotic fluid. According to Xu and coworkers (2007), in areas lacking continuous monitoring, amnioinfusion may be used to lower the incidence of meconium aspiration syndrome.

### Fetal Heart Rate Patterns and Brain Damage

Attempts to correlate fetal heart rate patterns with brain damage have been based primarily on studies of infants identified as a result of medicolegal actions. Phelan and Ahn (1994) reported that among 48 fetuses later found to be neurologically impaired, a persistent nonreactive fetal heart rate tracing was already present at the time of admission in 70 percent. They concluded that fetal neurological injury occurred predominately before arrival to the hospital. When they looked retrospectively at heart rate patterns in 209 brain-damaged infants, they concluded that there was not a single unique pattern associated with fetal neurological injury (Ahn, 1996). Graham and associates (2006) reviewed the world literature published between 1966 and 2006 on the effect of fetal heart rate monitoring to prevent perinatal brain injury and found no benefit.

### Experimental Evidence

Fetal heart rate patterns necessary for perinatal brain damage have been studied in experimental animals. Myers (1972) described the effects of complete and partial asphyxia in rhesus monkeys in studies of brain damage due to perinatal asphyxia. Complete asphyxia was produced by total occlusion of umbilical blood flow that led to prolonged deceleration (Fig. 24-31). Fetal arterial pH did not drop to 7.0 until approximately 8 minutes after complete cessation of oxygenation and umbilical flow. At least 10 minutes of such prolonged deceleration was required before there was evidence of brain damage in surviving fetuses.

![FIGURE 24-31 Prolonged deceleration in a rhesus monkey shown with blood pressure and](image-url)
biochemical changes during total occlusion of umbilical cord blood flow. (Adapted from Myers, 1972.)

Myers (1972) also produced partial asphyxia in rhesus monkeys by impeding maternal aortic blood flow. This resulted in late decelerations due to uterine and placental hypoperfusion. He observed that several hours of these late decelerations did not damage the fetal brain unless the pH fell below 7.0. Indeed, Adamsons and Myers (1977) reported subsequently that late decelerations were a marker of partial asphyxia long before brain damage occurred.

The most common fetal heart rate pattern during labor—due to umbilical cord occlusion—requires considerable time to significantly affect the fetus in experimental animals. Clapp and colleagues (1988) partially occluded the umbilical cord for 1 minute every 3 minutes in fetal sheep. Rocha and associates (2004) totally occluded the umbilical cord for 90 seconds every 30 minutes for 3 to 5 hours a day for 4 days without producing necrotic brain cell injury. Results from such studies suggest that the effects of umbilical cord entrapment depend on the degree of occlusion—partial versus total, the duration of individual occlusions, and the frequency of such occlusions.

**Human Evidence**

The contribution of intrapartum events to subsequent neurological handicaps has been greatly overestimated, as discussed in further detail in Chapter 33 (p. 638). It is clear that for brain damage to occur, the fetus must be exposed to much more than a brief period of hypoxia. Moreover, the hypoxia must cause profound, just barely sublethal metabolic acidemia. Because of this, the American College of Obstetricians and Gynecologists (2012b) recommends umbilical cord blood gases be obtained whenever there is cesarean delivery for fetal compromise, a low 5-minute Apgar score, severe fetal-growth restriction, an abnormal fetal heart rate tracing, maternal thyroid disease, or multifetal gestation (Chap. 32, p. 628). Fetal heart rate patterns consistent with these sublethal conditions are fortunately rare.

**Benefits of Electronic Fetal Heart Rate Monitoring**

There are several fallacious assumptions behind expectations of improved perinatal outcome with electronic monitoring. One assumption is that fetal distress is a slowly developing phenomenon and that electronic monitoring permits early detection of the compromised fetus. This assumption is illogical—that is, how can all fetuses die slowly? Another presumption is that all fetal damage develops in the hospital. Within the past 20 years, attention has been focused on the reality that most damaged fetuses suffered insults before arrival at labor units. The very term fetal monitor implies that this inanimate technology in some fashion “monitors.” The assumption is made that if a dead or damaged infant is delivered, the tracing strip must provide some clue, because this device was monitoring fetal condition. All of these assumptions led to great expectations and fostered the belief that all neonatal deaths or injuries were preventable.

By the end of the 1970s, questions regarding the efficacy, safety, and costs of electronic monitoring were being voiced from the Office of Technology Assessment, the United States Congress, and the Centers for Disease Control and Prevention. Banta and Thacker (2002) reviewed 25 years of the controversy on the benefits, or lack thereof, of electronic fetal monitoring. Using the Cochrane Database, Alfirevic and colleagues (2013) reviewed 13 randomized trials involving more than 37,000 women. They concluded that electronic fetal monitoring increased the rate of cesarean and operative vaginal deliveries but produced no
declines in rates of perinatal mortality, neonatal seizures, or cerebral palsy. Grimes and Peipert (2010) wrote a *Current Commentary* on electronic fetal monitoring in *Obstetrics & Gynecology*. They summarized that such monitoring, although it has been used in 85 percent of the almost 4 million annual births in the United States, has failed as a public health screening program. They noted that the positive predictive value of electronic fetal monitoring for fetal death in labor or cerebral palsy is near zero—meaning that “almost every positive test result is wrong.”

There have been two recent attempts to study the epidemiological effects of electronic fetal monitoring in the United States, each using national vital statistics of births linked to infant deaths. Chen and coworkers (2011) used 2004 data on 1,732,211 singleton live births, 89 percent of which underwent electronic fetal monitoring. They reported that monitoring increased operative delivery rates but decreased early neonatal mortality rates. This benefit was gestational age dependent, however, and the highest impact was seen in preterm fetuses. Most recently, Ananth and colleagues (2013) reported a similar but larger epidemiological study using United States birth certificate data linked with infant death certificate data. They studied 57,983,286 nonanomalous singleton livebirths born between 1990 and 2004. The temporal increase in fetal monitoring use between 1990 and 2004 was associated with a decline in neonatal mortality rates, especially in preterm gestations. In an accompanying editorial, Resnik (2013) cautioned that an epidemiological association between fetal monitoring and reduced neonatal death does not establish causation. He suggested that the limitations of the study by Ananth “should make the reader skeptical of the findings.” He opined that the electronic fetal monitoring debate “goes on … and on … and on.” And it does indeed.

### Parkland Hospital Experience: Selective versus Universal Monitoring

In July 1982, an investigation began at Parkland Hospital to ascertain whether all women in labor should undergo electronic monitoring (Leveno, 1986). In alternating months, universal electronic monitoring was rotated with selective heart rate monitoring, which was the prevailing practice. During the 3-year investigation, 17,410 labors were managed using universal electronic monitoring, and these outcomes were compared with a similar-sized cohort of women selectively monitored electronically. No significant differences were found in any perinatal outcomes. There was a small but significant increase in the cesarean delivery rate for fetal distress associated with universal monitoring. Thus, increased application of electronic monitoring at Parkland Hospital did not improve perinatal results, but it slightly increased the frequency of cesarean delivery for fetal distress.

### Current Recommendations

The methods most commonly used for intrapartum fetal heart rate monitoring include auscultation with a fetal stethoscope or a Doppler ultrasound device, or continuous electronic monitoring of the heart rate and uterine contractions. No scientific evidence has identified the most effective method, including the frequency or duration of fetal surveillance that ensures optimum results. Summarized in Table 24-5 are the recommendations of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012). Intermittent auscultation or continuous electronic monitoring is considered an acceptable method of intrapartum surveillance in both low- and high-risk pregnancies. The recommended interval between checking the heart rate, however, is longer in the uncomplicated pregnancy. When auscultation is used, it is recommended that it be...
performed after a contraction and for 60 seconds. It also is recommended that a 1-to-1 nurse-patient ratio be used if auscultation is employed. The position taken by the American College of Obstetricians and Gynecologists (2013b) in their Practice Bulletin, however, is somewhat different. While acknowledging that the available data do not show a clear benefit for the use of electronic monitoring over intermittent auscultation, the committee recommends limiting use of auscultation to low-risk pregnancies and further recommends recording the fetal heart rate every 15 minutes in active first stage labor and every 5 minutes in the second stage.

**INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY**

Analysis of electronically measured uterine activity permits some generalities concerning the relationship of certain contraction patterns to labor outcome. There is considerable normal variation, however, and caution must be exercised before judging true labor or its absence solely from a monitor tracing. Uterine muscle efficiency to effect delivery varies greatly. To use an analogy, 100-meter sprinters all have the same muscle groups yet cross the finish line at different times.

**Internal Uterine Pressure Monitoring**

Amnionic fluid pressure is measured between and during contractions by a fluid-filled plastic
catheter with its distal tip located above the presenting part (Fig. 24-32). The catheter is connected to a strain-gauge pressure sensor adjusted to the same level as the catheter tip in the uterus. The amplified electrical signal produced in the strain gauge by variation in pressure within the fluid system is recorded on a calibrated moving paper strip simultaneously with the fetal heart rate recording (see Fig. 24-6). Intrauterine pressure catheters are now available that have the pressure sensor in the catheter tip, which obviates the need for the fluid column.
FIGURE 24-32 Placement of an intrauterine pressure catheter to monitor contractions and their pressures. A. The white catheter, contained within the blue introducer, is inserted into the birth canal and placed along one side of the fetal head. B. The catheter is then gently advanced into the
uterus, and the introducer is withdrawn.

### External Monitoring

Uterine contractions can be measured by a displacement transducer in which the transducer button, or “plunger,” is held against the abdominal wall. As the uterus contracts, the button moves in proportion to the strength of the contraction. This movement is converted into a measurable electrical signal that indicates the *relative* intensity of the contraction. It has generally been accepted to not give an accurate measure of intensity. Bakker and associates (2010) performed a randomized trial comparing internal versus external monitoring of uterine contractions in 1456 women. The two methods were equivalent in terms of operative deliveries and neonatal outcomes.

### Patterns of Uterine Activity

Caldeyro-Barcia and Poseiro (1960), from Montevideo, Uruguay, were pioneers who have done much to elucidate the patterns of spontaneous uterine activity throughout pregnancy. Contractile waves of uterine activity were usually measured using intraamnionic pressure catheters. But early in their studies, as many as four simultaneous intramyometrial microballoons were also used to record uterine pressure. These investigators also introduced the concept of *Montevideo units* to define uterine activity (Chap. 23, p. 458). By this definition, uterine performance is the product of the intensity—increased uterine pressure above baseline tone—of a contraction in mm Hg multiplied by contraction frequency per 10 minutes. For example, three contractions in 10 minutes, each of 50 mm Hg intensity, would equal 150 Montevideo units.

During the first 30 weeks of pregnancy, uterine activity is comparatively quiescent. Contractions are seldom greater than 20 mm Hg, and these have been equated with those first described in 1872 by John Braxton Hicks. Uterine activity increases gradually after 30 weeks, and it is noteworthy that these *Braxton Hicks contractions* also increase in intensity and frequency. Further increases in uterine activity are typical of the last weeks of pregnancy, termed *prelabor*. During this phase, the cervix ripens (Chap. 21, p. 410).

According to Caldeyro-Barcia and Poseiro (1960), clinical labor usually commences when uterine activity reaches values between 80 and 120 Montevideo units. This translates into approximately three contractions of 40 mm Hg every 10 minutes. Importantly, there is no clear-cut division between prelabor and labor, but rather a gradual and progressive transition.

During first-stage labor, uterine contractions increase progressively in intensity from approximately 25 mm Hg at commencement of labor to 50 mm Hg at the end. At the same time, frequency increases from three to five contractions per 10 minutes, and uterine baseline tone from 8 to 12 mm Hg. Uterine activity further increases during second-stage labor, aided by maternal pushing. Indeed, contractions of 80 to 100 mm Hg are typical and occur as frequently as five to six per 10 minutes. Interestingly, the duration of uterine contractions—60 to 80 seconds—does not increase appreciably from early active labor through the second stage (Bakker, 2007; Pontonnier, 1975). Presumably, this duration constancy serves fetal respiratory gas exchange. During a uterine contraction, as the intrauterine pressure exceeds that of the intervillous space, respiratory gas exchange is halted. This leads to functional fetal “breath holding,” which has a 60- to 80-second limit that remains relatively constant.

Caldeyro-Barcia and Poseiro (1960) also observed empirically that uterine contractions are clinically palpable only after their intensity exceeds 10 mm Hg. Moreover, until the intensity of contractions reaches 40 mm Hg, the uterine wall can readily be depressed by the finger. At greater
intensity, the uterine wall then becomes so hard that it resists easy depression. Uterine contractions usually are not associated with pain until their intensity exceeds 15 mm Hg, presumably because this is the minimum pressure required for distending the lower uterine segment and cervix. It follows that Braxton Hicks contractions exceeding 15 mm Hg may be perceived as uncomfortable because distention of the uterus, cervix, and birth canal is generally thought to produce discomfort.

Hendricks (1968) observed that “the clinician makes great demands upon the uterus.” The uterus is expected to remain well relaxed during pregnancy, to contract effectively but intermittently during labor, and then to remain in a state of almost constant contraction for several hours postpartum. Figure 24-33 demonstrates an example of normal uterine activity during labor. Uterine activity progressively and gradually increases from prelabor through late labor. Interestingly, as shown in Figure 24-33, uterine contractions after birth are identical to those resulting in delivery of the infant. It is therefore not surprising that the uterus that performs poorly before delivery is also prone to atony and puerperal hemorrhage.

**FIGURE 24-33** Intrauterine pressure recorded through a single catheter. A. Prelabor. B. Early labor. C. Active labor. D. Late labor. E. Spontaneous activity ½ hour postpartum. F. Spontaneous
Origin and Propagation of Contractions

The uterus has not been studied extensively in terms of its nonhormonal physiological mechanisms of function. The normal contractile wave of labor originates near the uterine end of one of the fallopian tubes. Thus, these areas act as “pacemakers” (Fig. 24-34). The right pacemaker usually predominates over the left and starts most contractile waves. Contractions spread from the pacemaker area throughout the uterus at 2 cm/sec, depolarizing the whole organ within 15 seconds. This depolarization wave propagates downward toward the cervix. Intensity is greatest in the fundus, and it diminishes in the lower uterus. This phenomenon is thought to reflect reductions in myometrial thickness from the fundus to the cervix. Presumably, this descending gradient of pressure serves to direct fetal descent toward the cervix and to efface the cervix. Importantly, all parts of the uterus are synchronized and reach their peak pressure almost simultaneously, giving rise to the curvilinear waveform shown in Figure 24-34. Young and Zhang (2004) have shown that the initiation of each contraction is triggered by a tissue-level bioelectric event.
FIGURE 24-34 Schematic representation of the normal contractile wave of labor. Large uterus on the left shows the four points at which intramyometrial pressure was recorded with microballoons. Four corresponding pressure tracings are shown in relation to each other by shading on the small uteri at top. (Adapted from Caldeyro-Barcia, 1960.)

The pacemaker theory also serves to explain the varying intensity of adjacent coupled contractions shown in panels A and B of Figure 24-33. Such coupling was termed incoordination by Caldeyro-Barcia and Poseiro (1960). A contractile wave begins in one cornual-region pacemaker, but does not synchronously depolarize the entire uterus. As a result, another contraction begins in the contralateral pacemaker and produces the second contractile wave of the couplet. These small contractions alternating with larger ones appear to be typical of early labor. Indeed, labor may progress with such uterine activity, albeit at a slower pace. These authors also
observed that labor would progress slowly if regular contractions were hypotonic—that is, contractions with intensity less than 25 mm Hg or frequency less than 2 per 10 minutes.

Hauth and coworkers (1986) quantified uterine contraction pressures in 109 women at term who received oxytocin for labor induction or augmentation. Most of these women achieved 200 to 225 Montevideo units, and 40 percent had up to 300 units to effect delivery. The authors suggested that these levels of uterine activity should be sought before consideration of cesarean delivery for presumed dystocia.

### New Terminology for Uterine Contractions

This has been recommended by the American College of Obstetricians and Gynecologists (2013b) for the description and quantification of uterine contractions. Normal uterine activity is defined as five or fewer contractions in 10 minutes, averaged over a 30-minute window. Tachysystole was defined as more than five contractions in 10 minutes, averaged over 30 minutes. Tachysystole can be applied to spontaneous or induced labor (Chap. 26, p. 527). The term hyperstimulation was abandoned. Stewart and associates (2012) prospectively studied uterine tachysystole in 584 women undergoing labor induction with misoprostol at Parkland Hospital. There was no association of adverse infant outcomes with increasing number of contractions per 10 minutes or per 30 minutes. Six or more contractions in 10 minutes, however, were significantly associated with fetal heart rate decelerations.

### Complications of Electronic Fetal Monitoring

Electrodes for fetal heart rate evaluation and catheters for uterine contraction measurement are both associated with infrequent but potentially serious complications. Rarely, an intrauterine pressure catheter during placement may lacerate a fetal vessel in the placenta. Also with insertion, placental and possibly uterine perforation can cause hemorrhage, serious morbidity, and spurious recordings that have resulted in inappropriate management. Severe cord compression has been described from entanglement with the pressure catheter. Injury to the fetal scalp or breech by a heart rate electrode is rarely severe. However, application at some other site—such as the eye in face presentations—can be serious.

Both the fetus and the mother may be at increased risk of infection from internal monitoring (Faro, 1990). Scalp wounds from the electrode may become infected, and subsequent cranial osteomyelitis has been reported (Brook, 2005; Eggink, 2004; McGregor, 1989). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) have recommended that certain maternal infections, including human immunodeficiency virus (HIV), herpes simplex virus, and hepatitis B and C virus, are relative contraindications to internal fetal monitoring.

CHAPTER 25

Obstetrical Analgesia and Anesthesia

GENERAL PRINCIPLES

ANALGESIA AND SEDATION DURING LABOR

NERVE BLOCKS

PUENDAL BLOCK

SPINAL (SUBARACHNOID) BLOCK

EPIDURAL ANALGESIA

LOCAL INFILTRATION FOR CESAREAN DELIVERY

GENERAL ANESTHESIA

Obstetrical anesthesia presents unique challenges. Labor begins without warning, and anesthesia may be required within minutes of a full meal. Vomiting with aspiration of gastric contents is a constant threat. The usual physiological adaptations of pregnancy require special consideration, especially with disorders such as preeclampsia, placental abruption, or sepsis syndrome.

Of all anesthesia-related deaths in the United States from 1995 to 2005, 3.6 percent were in pregnant women (Li, 2009). Berg and colleagues (2010) analyzed deaths of women during or within 1 year of pregnancy in the United States from 1998 through 2005. They found that 54 of 4693—1.2 percent—such deaths were attributable to anesthesia complications. Hawkins and associates (2011) analyzed anesthesia-related maternal mortality in this country between 1979 and 2002. As shown in Table 25-1, anesthetic-related maternal mortality rates decreased nearly 60 percent during this time, and there currently is approximately one anesthetic death per million live births. About two thirds of deaths associated with general anesthesia were caused by intubation failure or induction problems during cesarean delivery. Deaths associated with regional analgesia were caused by high spinal or epidural blocks—26 percent; respiratory failure—19 percent; and drug reaction—19 percent. The improved case-fatality rate for general anesthesia was especially notable considering that such anesthesia is now used for the highest-risk patients and the most hurried emergencies, that is, decision-incision intervals < 15 minutes (Bloom, 2005).

| Table 25-1. Case-Fatality Rates and Rate Ratios of Anesthesia-Related Deaths During Cesarean Delivery by Type of Anesthesia in the United States, 1979–2002 |
Several factors have contributed to improved obstetrical anesthesia safety (Hawkins, 2011). The most significant is the increased use of regional analgesia. Increased availability of in-house anesthesia coverage almost certainly is another important reason. Despite these encouraging results suggesting the safety of general anesthesia, there are now reports of increasing complications with regional analgesia techniques.

**GENERAL PRINCIPLES**

**Obstetrical Anesthesia Services**

The American College of Obstetricians and Gynecologists (2008) reaffirmed its joint position with the American Society of Anesthesiologists that a woman’s request for labor pain relief is sufficient medical indication for its provision. Identification of any of the risk factors shown in Table 25-2 should prompt consultation with anesthesia personnel to permit a joint management plan. This plan should include strategies to minimize the need for emergency anesthesia in women for whom such anesthesia would be especially hazardous.

### TABLE 25-2. Maternal Factors That May Prompt Anesthetic Consultation

- Morbid obesity
- Severe edema or anatomical abnormalities of the face, neck, or spine, including trauma or surgery
- Abnormal dentition, small mandible, or difficulty opening the mouth
- Extremely short stature, short neck, or neck arthritis
Serious maternal medical problems, such as cardiac, pulmonary, or neurological disease
Bleeding disorders
Severe preeclampsia
Prior anesthetic complications
Obstetrical complications likely to lead to operative delivery—examples include placenta previa, preterm breech presentation, or higher-order multifetal gestation

Goals for optimizing obstetrical anesthesia services have been jointly established by the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2009) and include:

1. Availability of a licensed practitioner who is credentialed to administer an appropriate anesthetic whenever necessary and to maintain support of vital functions in an obstetrical emergency
2. Availability of anesthesia personnel to permit the start of a cesarean delivery within 30 minutes of the decision to perform the procedure
3. Anesthesia personnel immediately available to perform an emergency cesarean delivery during the active labor of a woman attempting vaginal birth after cesarean (Chap. 31, p. 615)
4. Appointment of a qualified anesthesiologist to be responsible for all anesthetics administered
5. Availability of a qualified physician with obstetrical privileges to perform operative vaginal or cesarean delivery during administration of anesthesia
6. Availability of equipment, facilities, and support personnel equal to that provided in the surgical suite
7. Immediate availability of personnel, other than the surgical team, to assume responsibility for resuscitation of a depressed newborn (Chap. 32, p. 625).

To meet these goals, 24-hour in-house anesthesia coverage is usually necessary. Providing such service in smaller facilities is more challenging—a problem underscored by the fact that approximately a third of all hospitals providing obstetrical care have fewer than 500 deliveries per year (American College of Obstetricians and Gynecologists, 2009).

Bell and coworkers (2000) calculated the financial burden that may be incurred to provide 24/7 obstetrical anesthesia coverage. Given the average indemnity and Medicaid reimbursement for labor epidural analgesia, they concluded that such coverage could not operate profitably at their tertiary referral institution. Compounding this burden, some third-party payers have denied reimbursement for epidural analgesia in the absence of a specific medical indication—an approach repudiated by the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2008).

Role of an Obstetrician
Every obstetrician should be proficient in local and pudendal analgesia that may be administered
in appropriately selected circumstances. In general, however, it is preferable for an anesthesiologist or anesthetist to provide pain relief so that the obstetrician can focus attention on the laboring woman and her fetus.

**Principles of Pain Relief**

In a scholarly review, Hawkins (2010) emphasized that labor pain is a highly individual response to variable stimuli that are uniquely received and interpreted (Fig. 25-1). These stimuli are modified by emotional, motivational, cognitive, social, and cultural circumstances. Labor pain caused by uterine contractions and cervical dilation is transmitted through visceral afferent sympathetic nerves entering the spinal cord from T10 through L1. Later in labor, perineal stretching transmits painful stimuli through the pudendal nerve and sacral nerves S2 through S4. Cortical responses to pain and anxiety during labor are complex and may be influenced by maternal expectations for childbirth, her age and preparation through education, the presence of emotional support, and other factors. Pain perception is heightened by fear and the need to move into various positions. A woman may be motivated to have a certain type of birthing experience, and these opinions will influence her judgment regarding pain management and other choices during labor and delivery.
Cortical responses to pain
- Are variable — depend on perception of pain, extent of fear and anxiety, age, and other factors

Physiological responses to pain
- Release of stress hormones (cortisol)
- Sympathetic nervous system response
- Increased oxygen consumption
- Hyperventilation
- Increased blood pressure
- Increased cardiac output
- Increased vascular resistance

Uterine contraction
- T10-L1

Perineal pain
- S2-S4

Delayed gastric emptying
Maternal physiological responses to labor pain may influence maternal and fetal well-being and labor progress. For example, hyperventilation may induce hypocarbia. An increased metabolic rate increases oxygen consumption. Increases in cardiac output and vascular resistance may increase maternal blood pressure. Pain, stress, and anxiety cause release of stress hormones such as cortisol and β-endorphins. The sympathetic nervous system response to pain leads to a marked increase in circulating catecholamines that can adversely affect uterine activity and uteroplacental blood flow. Effective analgesia attenuates or eliminates these responses.

**ANALGESIA AND SEDATION DURING LABOR**

If uterine contractions and cervical dilatation cause discomfort, pain relief with a narcotic such as meperidine (Demerol), plus one of the tranquilizer drugs such as promethazine (Phenergan), is usually appropriate. With a successful program of analgesia and sedation, the mother should rest quietly between contractions. In this circumstance, discomfort usually is felt at the acme of an effective uterine contraction. Appropriate drug selection and administration of the medications shown in Table 25-3 should safely accomplish these objectives.

**Parenteral Agents**

**Meperidine and Promethazine**

Meperidine, 50 to 100 mg, with promethazine, 25 mg, may be administered intramuscularly at intervals of 2 to 4 hours. A more rapid effect is achieved by giving meperidine intravenously in doses of 25 to 50 mg every 1 to 2 hours. Whereas analgesia is maximal 30 to 45 minutes after an
intramuscular injection, it develops almost immediately following intravenous administration. Meperidine readily crosses the placenta, and its half-life in the newborn is approximately 13 hours or longer (American College of Obstetricians and Gynecologists, 2013b). Its depressant effect in the fetus follows closely behind the peak maternal analgesic effect.

According to Bricker and Lavender (2002), meperidine is the most common opioid used worldwide for pain relief from labor. Tsui and associates (2004) found meperidine to be superior to placebo for pain relief in the first stage of labor. In a randomized investigation of epidural analgesia conducted at Parkland Hospital, patient-controlled intravenous analgesia with meperidine was found to be an inexpensive and reasonably effective method for labor analgesia (Sharma, 1997). Women randomized to self-administered analgesia were given 50-mg meperidine with 25-mg promethazine intravenously as an initial bolus. Thereafter, an infusion pump was set to deliver 15 mg of meperidine every 10 minutes as needed until delivery. Neonatal sedation, as measured by need for naloxone treatment in the delivery room, was identified in 3 percent of newborns.

**Butorphanol (Stadol)**

This synthetic narcotic, given in 1- to 2-mg doses, compares favorably with 40 to 60 mg of meperidine (Quilligan, 1980). Its major side effects are somnolence, dizziness, and dysphoria. Neonatal respiratory depression is reported to be less than with meperidine. Importantly, the two drugs are not given contiguously because butorphanol antagonizes the narcotic effects of meperidine. Hatjis and Meis (1986) described a transient sinusoidal fetal heart rate pattern following butorphanol administration but with no short-term maternal or neonatal adverse sequelae (Chap. 24, p. 482).

**Fentanyl**

This short-acting and potent synthetic opioid may be given in doses of 50 to 100 μg intravenously every hour. Its main disadvantage is a short duration of action, which requires frequent dosing or use of a patient-controlled intravenous pump. Moreover, Atkinson and coworkers (1994) reported that butorphanol provided better initial analgesia than fentanyl and was associated with fewer requests for additional medication or for epidural analgesia.

**Efficacy and Safety of Parenteral Agents**

Parenteral sedation is not without risks. Hawkins and colleagues (1997) reported that 4 of 129 maternal anesthetic-related deaths were from such sedation—one from aspiration, two from inadequate ventilation, and one from overdosage.

Narcotics used during labor may cause newborn respiratory depression. Naloxone is a narcotic antagonist capable of reversing respiratory depression induced by opioid narcotics. It acts by displacing the narcotic from specific receptors in the central nervous system. Withdrawal symptoms may be precipitated in recipients who are physically dependent on narcotics. For this reason, naloxone is contraindicated in a newborn of a narcotic-addicted mother (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). After adequate ventilation has been established, naloxone may be given to reverse respiratory depression in a newborn infant whose mother received narcotics (Chap. 32, p. 626).

**Nitrous Oxide**
A self-administered mixture of 50-percent nitrous oxide (N₂O) and oxygen may provide satisfactory analgesia during labor (Rosen, 2002a). Some preparations are premixed in a single cylinder (Entonox), and in others, a blender mixes the two gases from separate tanks (Nitronox). The gases are connected to a breathing circuit through a valve that opens only when the patient inspires. The use of intermittent nitrous oxide for labor pain has been reviewed by Rosen (2002a).

### NERVE BLOCKS

Various nerve blocks have been developed over the years to provide pain relief during labor and/or delivery. These include pudendal, paracervical, and neuraxial blocks such as spinal, epidural, and combined spinal-epidural techniques.

#### Anesthetic Agents

Some of the more commonly used nerve block anesthetics, along with their usual concentrations, doses, and durations of action, are summarized in Table 25-4. The dose of each agent varies widely and is dependent on the particular nerve block and physical status of the woman. The onset, duration, and quality of analgesia can be enhanced by increasing the dose. This can be done safely only by incrementally administering small-volume boluses of the agent and by carefully monitoring early warning signs of toxicity. Administration of these agents must be followed by appropriate monitoring for adverse reactions. Equipment and personnel to manage these reactions must be immediately available.

...
Most often, serious toxicity follows inadvertent intravenous injection. Systemic toxicity from local anesthetics typically manifests in the central nervous and cardiovascular systems. For this reason, when epidural analgesia is initiated, dilute epinephrine is sometimes added and given as a test dose. A sudden significant rise in the maternal heart rate or blood pressure immediately after administration suggests intravenous catheter placement. Local analgesic agents are manufactured in more than one concentration and ampule size, which increases the potential for dosing errors.

### Central Nervous System Toxicity

Early symptoms are those of *stimulation* but, as serum levels increase, *depression* follows. Symptoms may include light-headedness, dizziness, tinnitus, metallic taste, and numbness of the tongue and mouth. Patients may show bizarre behavior, slurred speech, muscle fasciculation and excitation, and ultimately, generalized convulsions, followed by loss of consciousness.

For management, the convulsions should be controlled, an airway established, and oxygen delivered. Succinylcholine abolishes the peripheral manifestations of the convulsions and allows tracheal intubation. Diazepam (Valium) can be used to inhibit convulsions. Magnesium sulfate,
administered according to the regimen for eclampsia, also controls convulsions (Chap. 40, p. 758). Abnormal fetal heart rate patterns such as late decelerations or persistent bradycardia may develop from maternal hypoxia and lactic acidosis induced by convulsions. With arrest of convulsions, administration of oxygen, and application of other supportive measures, the fetus usually recovers more quickly in utero than following immediate cesarean delivery. Moreover, the mother is better served if delivery is forestalled until the intensity of hypoxia and metabolic acidosis has diminished.

**Cardiovascular Toxicity**

These manifestations generally develop later than those from cerebral toxicity, and they may not develop at all because they are induced by higher serum drug levels. The notable exception is bupivacaine, which is associated with the development of neurotoxicity and cardiotoxicity at virtually identical levels (Mulroy, 2002). Because of this risk of systemic toxicity, use of 0.75-percent solution of bupivacaine for epidural injection has been proscribed by the Food and Drug Administration. Similar to neurotoxicity, cardiovascular toxicity is characterized first by stimulation and then by depression. Accordingly, there is hypertension and tachycardia, which soon is followed by hypotension, cardiac arrhythmias, and impaired uteroplacental perfusion.

Hypotension is managed initially by turning the woman onto either side to avoid aortocaval compression. A crystalloid solution is infused rapidly along with intravenously administered ephedrine. Emergency cesarean delivery is considered if maternal vital signs have not been restored within 5 minutes of cardiac arrest (Chap. 47, p. 956). As with convulsions, however, the fetus is likely to recover more quickly in utero once maternal cardiac output is reestablished.

---

**Pudendal Block**

Pain with vaginal delivery arises from stimuli from the lower genital tract. These are transmitted primarily through the pudendal nerve, the peripheral branches of which provide sensory innervation to the perineum, anus, vulva, and clitoris. The pudendal nerve passes beneath the posterior surface of the sacrospinous ligament just as the ligament attaches to the ischial spine. Sensory nerve fibers of the pudendal nerve are derived from ventral branches of the S₂ through S₄ nerves.

The pudendal nerve block is a relatively safe and simple method of providing analgesia for spontaneous delivery. As shown in Figure 25-2, a tubular introducer is used to sheath and guide a 15-cm 22-gauge needle into position over the pudendal nerve. The end of the introducer is placed against the vaginal mucosa just beneath the tip of the ischial spine. The introducer allows 1.0 to 1.5 cm of needle to protrude beyond its tip, and the needle is pushed beyond the introducer tip into the mucosa. A mucosal wheal is made with 1 mL of 1-percent lidocaine solution or an equivalent dose of another local anesthetic (see Table 25-3). To guard against intravascular infusion, aspiration is attempted before this and all subsequent injections. The needle is then advanced until it touches the sacrospinous ligament, which is infiltrated with 3 mL of lidocaine. The needle is advanced farther through the ligament. As it pierces the loose areolar tissue behind the ligament, the resistance of the plunger decreases. Another 3 mL of solution is injected into this region. Next, the needle is withdrawn into the introducer, which is moved to just above the ischial spine. The needle is inserted through the mucosa and 3 more mL is deposited. The procedure is then repeated on the other side.
FIGURE 25-2 Local infiltration of the pudendal nerve. Transvaginal technique showing the needle extended beyond the needle guard and passing through the sacrospinous ligament to reach the pudendal nerve.

Within 3 to 4 minutes of injection, the successful pudendal block will allow pinching of the lower vagina and posterior vulva bilaterally without pain. If delivery occurs before the pudendal block becomes effective and an episiotomy is indicated, then the fourchette, perineum, and adjacent vagina can be infiltrated with 5 to 10 mL of 1-percent lidocaine solution directly at the planned episiotomy site. By the time of repair, the pudendal block usually has become effective.

Pudendal block usually does not provide adequate analgesia when delivery requires extensive obstetrical manipulation. Moreover, such analgesia is usually inadequate for women in whom complete visualization of the cervix and upper vagina or manual exploration of the uterine cavity is indicated.

Infrequently, complications may follow this block. As previously described, intravascular injection of a local anesthetic agent may cause serious systemic toxicity. Hematoma formation from perforation of a blood vessel is most likely when there is a coagulopathy (Lee, 2004). Rarely, severe infection may originate at the injection site. The infection may spread posteriorly to the hip joint, into the gluteal musculature, or into the retropsoas space (Svancarek, 1977).

### Paracervical Block
This block usually provides satisfactory pain relief during first-stage labor. However, because the pudendal nerves are not blocked, additional analgesia is required for delivery. For paracervical blockade, usually lidocaine or chloroprocaine, 5 to 10 mL of a 1-percent solution, is injected into the cervix laterally at 3 and 9 o’clock. Because these anesthetics are relatively short acting, paracervical block may have to be repeated during labor. We do not use it at Parkland Hospital.

Fetal bradycardia is a worrisome complication that occurs in approximately 15 percent of paracervical blocks (Rosen, 2002b). Bradycardia usually develops within 10 minutes and may last up to 30 minutes. Doppler studies have shown an increase in the pulsatility index of the uterine arteries following paracervical blockade (Chap. 10, p. 219). These observations support the hypothesis of drug-induced arterial vasospasm as a cause of fetal bradycardia (Manninen, 2000). For these reasons, paracervical block should not be used in situations of potential fetal compromise.

Neuraxial Regional Blocks

Epidural, spinal, or combined spinal-epidural techniques were the more common methods used for relief of pain during labor and/or delivery in the United States in 2008 (Osterman, 2011b). Nearly two out of three mothers receive neuraxial anesthesia for relief of pain either during labor or during vaginal or cesarean delivery. Neuraxial techniques were more common in vaginal deliveries assisted by forceps—84 percent or vacuum extraction—77 percent than spontaneous vaginal deliveries—60 percent (Osterman, 2011a). Among first births, 68 percent of women delivered vaginally received neuraxial pain relief compared with 57 percent of women delivering their second or higher number child.

Epidural analgesia via a catheter as shown in Figure 25-3 is typically used for relief of labor pain, although it can also be used for anesthesia during operative vaginal and cesarean delivery. Spinal analgesia is typically given as a single intrathecal injection of a local anesthetic at the time of operative vaginal delivery or cesarean. Continuous spinal analgesia during labor via an indwelling spinal catheter is also under investigation. Combined spinal-epidural analgesia/anesthesia also illustrated in Figure 25-3 consists of a single intrathecal injection followed by a catheter placed into the epidural space for either patient- or provider-controlled infusion of a local anesthetic and/or an opioid such as fentanyl. The combined spinal–epidural technique has the advantages of immediate pain relief from the spinal injection coupled with a portal for continuous analgesia via the epidural catheter. Unlike the spinal injection, the relief provided by the epidural catheter takes approximately 30 minutes to become effective. Perhaps as many as a third of epidural catheter tips will migrate during labor, resulting in ineffective pain control should cesarean be necessary.
Spinal (Subarachnoid) Block

Introduction of a local anesthetic into the subarachnoid space to effect analgesia has long been used for delivery. Advantages include a short procedure time, rapid blockade onset, and high success rate. Because of the smaller subarachnoid space during pregnancy, likely the consequence of internal vertebral venous plexus engorgement, the same amount of anesthetic agent in the same volume of solution produces a much higher blockade in parturients than in nonpregnant women.

Vaginal Delivery

Low spinal block can be used for operative vaginal delivery. The level of analgesia should extend to the T10 dermatome, which corresponds to the level of the umbilicus. Blockade to this level provides excellent relief from the pain of uterine contractions (Fig. 25-4).
Several local anesthetic agents have been used for spinal analgesia (see Table 25-4). Addition of glucose to any of these agents creates a hyperbaric solution, which is heavier and denser than cerebrospinal fluid. A sitting position causes a hyperbaric solution to settle caudally, whereas a lateral position will have a greater effect on the dependent side. Lidocaine given in a hyperbaric solution produces excellent analgesia and has the advantage of a rapid onset and relatively short duration. Bupivacaine in an 8.25-percent dextrose solution provides satisfactory anesthesia to the lower vagina and the perineum for more than 1 hour. Neither is administered until the cervix is fully dilated, and all other criteria for safe forceps delivery have been fulfilled (Chap. 29, p. 575).

Preanalgesic intravenous hydration with 1 L of crystalloid solution will prevent or minimize hypotension in many cases.

Cesarean Delivery

A level of sensory blockade extending to the T₄ dermatome is desired for cesarean delivery (see Fig. 25-4). Depending on maternal size, 10 to 12 mg of bupivacaine in a hyperbaric solution or 50 to 75 mg of lidocaine hyperbaric solution are administered. The addition of 20 to 25 μg of fentanyl increases the rapidity of blockade onset and reduces shivering. The addition of 0.2 mg of morphine improves pain control during delivery and postoperatively.

Complications

Shown in Table 25-5 are some of the more common complications associated with neuraxial analgesia. Importantly, obese women have significantly impaired ventilation and thus close clinical monitoring is imperative (Vricella, 2011).

| TABLE 25-5. Complications of Regional Analgesia |
**Hypotension.** This common complication may develop soon after injection of the local anesthetic agent. It is the consequence of vasodilatation from sympathetic blockade and is compounded by obstructed venous return due to uterine compression of the great vessels. In the supine position, even in the absence of maternal hypotension measured in the brachial artery, placental blood flow may still be significantly reduced. Treatment includes uterine displacement by left lateral patient positioning, intravenous crystalloid hydration, and intravenous bolus injections of ephedrine or phenylephrine.

Ephedrine is a sympathomimetic drug that binds to alpha- and beta-receptors but also indirectly enhances norepinephrine release. It raises blood pressure by increasing heart rate and cardiac output and by variably elevating peripheral vascular resistance. In animal studies, ephedrine preserves uteroplacental blood flow during pregnancy compared with alpha<sub>1</sub>-receptor agonists. Accordingly, it is a preferred vasopressor for obstetrical use. Phenylephrine is a pure alpha agonist and raises blood pressure solely through vasoconstriction. A metaanalysis of seven randomized trials by Lee (2002a) suggests that the safety profiles of ephedrine and phenylephrine are comparable. Following their systematic review of 14 reports, Lee (2002b) questioned whether routine prophylactic ephedrine is needed for elective cesarean delivery. But although fetal

Acidemia has been reported with prophylactic ephedrine use, this was not observed with prophylactic phenylephrine use (Ngan Kee, 2004).

Hypotension is the more common blood pressure perturbation. However, paradoxically, hypertension from ergonovine or methylergonovine injections following delivery is more common in women who have received a spinal or epidural block.

High Spinal Blockade. Most often, complete spinal blockade follows administration of an excessive dose of local anesthetic. This is certainly not always the case, because accidental total spinal block has even occurred following an epidural test dose. With complete spinal blockade, hypotension and apnea promptly develop and must be immediately treated to prevent cardiac arrest. In the undelivered woman: (1) the uterus is immediately displaced laterally to minimize aortocaval compression, (2) effective ventilation is established, preferably with tracheal intubation, and (3) intravenous fluids and ephedrine are given to correct hypotension.

Postdural Puncture Headache. Leakage of cerebrospinal fluid (CSF) from the meningeal puncture site can lead to postdural puncture or “spinal headache.” Presumably, when the woman sits or stands, the diminished CSF volume creates traction on pain-sensitive central nervous system structures.

Rates of this complication can be reduced by using a small-gauge spinal needle and avoiding multiple punctures. In a prospective, randomized study of five different spinal needles, Vallejo and associates (2000) concluded that Sprotte and Whitacre needles had the lowest risks of postdural puncture headaches. Sprigge and Harper (2008) reported that the incidence of postdural puncture headache was 1 percent in more than 5000 women undergoing spinal analgesia. Postdural puncture headaches are much less frequent with epidural blockade because the dura is not intentionally punctured. The incidence of inadvertent dural puncture with epidural analgesia approximates 0.2 percent (Introna, 2012; Katircioglu, 2008). There is no good evidence that placing a woman absolutely flat on her back for several hours is effective in preventing headache. Vigorous hydration may be of value, but compelling evidence to support its use is also lacking.

If a headache develops, the administration of caffeine, a cerebral vasoconstrictor, has been shown in randomized studies to afford temporary relief (Camann, 1990). With severe headache, an epidural blood patch is most effective. Ten to 20 mL of autologous blood are obtained aseptically by venipuncture into a tube without anticoagulant. This blood is then injected into the epidural space at the site of dural puncture. Further CSF leakage is halted by either mass effect or coagulation. Relief is immediate, and complications are uncommon. In a randomized trial of 64 women, Scavone and coworkers (2004) found that prophylactic blood patch did not decrease either the incidence of postdural puncture headache or the need for a subsequent therapeutic blood patch.

If a headache does not have the pathognomonic postural characteristics or persists despite treatment with a blood patch, other diagnoses should be considered. For example, Chisholm and Campbell (2001) described a case of superior sagittal sinus thrombosis that manifested as a postural headache. Chan and Paech (2004) have described persistent CSF leak in three women Smarkusky and colleagues (2006) described pneumocephalus, which caused immediate cephalgia. Finally, intracranial and intraspinal subarachnoid hematomas have developed after spinal analgesia (Dawley, 2009; Liu, 2008).

Convulsions. In rare instances, postdural puncture cephalgia is associated with temporary blindness and convulsions. Shearer and associates (1995) described eight such cases associated
with 19,000 regional analgesic procedures done at Parkland Hospital. It is presumed that these too are caused by CSF hypotension. Immediate treatment of seizures and blood patch was usually effective in these cases.

**Bladder Dysfunction.** With spinal analgesia, bladder sensation is likely to be obtunded and bladder emptying impaired for several hours after delivery. As a consequence, bladder distention is a frequent postpartum complication, especially if appreciable volumes of intravenous fluid are given. Millet (2012) randomized 146 women with neuraxial analgesia to either intermittent or continuous bladder catheterizations and found that the intermittent method was associated with significantly higher rates of bacteriuria.

**Arachnoiditis and Meningitis.** Local anesthetics are no longer preserved in alcohol, formalin, or other toxic solutes, and disposable equipment is used by most. These practices, coupled with aseptic technique, have made meningitis and arachnoiditis rare but have not eliminated them (Centers for Disease Control and Prevention, 2010).

**Contraindications to Spinal Analgesia**

Shown in Table 25-6 are the absolute contraindications to regional analgesia according to the American College of Obstetricians and Gynecologists (2013b). Obstetrical complications that are associated with maternal hypovolemia and hypotension—for example, severe hemorrhage—are contraindications to spinal blockade. The additive cardiovascular effects of spinal blockade in the presence of acute blood loss in nonpregnant patients were documented by Kennedy and coworkers (1968).

Disorders of coagulation and defective hemostasis also preclude spinal analgesia use. Although there are no randomized studies to guide the management of anticoagulation at the time of delivery, consensus opinion suggests that women given subcutaneous unfractionated heparin or low-molecular-weight heparin should be instructed to stop therapy when labor begins (Krivak, 2007). Subarachnoid puncture is also contraindicated if there is cellulitis at the needle entry site. Neurological disorders are considered by many to be a contraindication, if for no other reason than that exacerbation of the neurological disease might be attributed without cause to the anesthetic agent. Other maternal conditions, such as significant aortic stenosis or pulmonary hypertension, are also relative contraindications to spinal analgesia (Chap. 49, p. 983).

As with significant hemorrhage, severe preeclampsia is another complication in which markedly decreased blood pressure can be predicted when neuraxial analgesia is used. Wallace
and associates (1995) randomly assigned 80 women with severe preeclampsia undergoing cesarean delivery at Parkland Hospital to receive general anesthesia or either epidural or combined spinal-epidural analgesia. There were no differences in maternal or neonatal outcomes. Still, 30 percent of women given epidural analgesia and 22 percent of those given spinal-epidural blockade developed hypotension—the average reduction in mean arterial pressure was between 15 and 25 percent.

### Epidural Analgesia

Relief of labor and childbirth pain, including cesarean delivery, can be accomplished by injection of a local anesthetic agent into the epidural or peridural space (see Fig. 25-3). This potential space contains areolar tissue, fat, lymphatics, and the internal vertebral venous plexus. This plexus becomes engorged during pregnancy such that the volume of the epidural space is appreciably reduced. Entry for obstetrical analgesia is usually through a lumbar intervertebral space. Although only one injection may be given, usually an indwelling catheter is placed for subsequent agent administration or continuous infusion. Infusions use a volumetric pump controlled either by the patient or by a caregiver. The American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2008) believe that under appropriate physician supervision, labor and delivery nursing personnel who have been specifically trained in the management of epidural infusions should be able to adjust dosage and also discontinue infusions.

### Continuous Lumbar Epidural Block

Complete analgesia for the pain of labor and vaginal delivery necessitates a block from the T₁₀ to the S₅ dermatomes (Figs. 25-1 and 25-4). For cesarean delivery, a block extending from the T₄ to the S₁ dermatomes is desired. The effective spread of anesthetic depends upon the catheter tip location; the dose, concentration, and volume of anesthetic agent used; and whether the mother is head-down, horizontal, or head-up (Setayesh, 2001). Individual variations in anatomy or presence of synechiae may preclude a completely satisfactory block. Finally, the catheter tip may migrate from its original location during labor.

**Technique.** One example of the sequential steps and techniques for performance of epidural analgesia is detailed in Table 25-7. Before injection of the local anesthetic therapeutic dose, a test dose is given. The woman is observed for features of toxicity from intravascular injection and for signs of spinal blockade from subarachnoid injection. If these are absent, only then is a full dose given. Analgesia is maintained by intermittent boluses of similar volume, or small volumes of the drug are delivered continuously by infusion pump (Halpern, 2009). The addition of small doses of a short-acting narcotic—fentanyl or sufentanil—has been shown to improve analgesic efficacy while avoiding motor blockade (Chestnut, 1988). As with spinal blockade, it is imperative that close monitoring, including the level of analgesia, be performed by trained personnel. Appropriate resuscitation equipment and drugs must be available during administration of epidural analgesia.

**TABLE 25-7. Technique for Labor Epidural Analgesia**

Informed consent is obtained, and the obstetrician consulted

Monitoring includes the following:

- Blood pressure every 1 to 2 minutes for 15 minutes after giving a bolus of local
anesthetic
Continuous maternal heart rate monitoring during analgesia induction
Continuous fetal heart rate monitoring
Continual verbal communication
Hydration with 500 to 1000 mL of lactated Ringer solution
The woman assumes a lateral decubitus or sitting position
The epidural space is identified with a loss-of-resistance technique
The epidural catheter is threaded 3 to 5 cm into the epidural space
A test dose of 3 mL of 1.5% lidocaine with 1:200,000 epinephrine or 3 mL of 0.25%
bupivacaine with 1:200,000 epinephrine is injected after careful aspiration to avert
intravascular injection and after a uterine contraction. This minimizes the chance of confusing
tachycardia that results from labor pain with that of tachycardia from intravenous injection of
the test dose
If the test dose is negative, one or two 5-mL doses of 0.25% bupivacaine are injected to achieve
a sensory T₁₀ level
After 15 to 20 minutes, the block is assessed using loss of sensation to cold or pinprick. If no
block is evident, the catheter is replaced. If the block is asymmetrical, the epidural catheter is
withdrawn 0.5 to 1.0 cm and an additional 3 to 5 mL of 0.25% bupivacaine is injected. If the
block remains inadequate, the catheter is replaced
The woman is positioned in the lateral or semilateral position to avoid aortocaval compression
Subsequently, maternal blood pressure is recorded every 5 to 15 minutes. The fetal heart rate is
monitored continuously
The level of analgesia and intensity of motor blockade are assessed at least hourly

From Glosten, 1999, with permission.

Complications

**Total Spinal Blockade.** As shown in Table 25-5, there are certain problems inherent in epidural
analgesia use. Dural puncture with inadvertent subarachnoid injection may cause total spinal
blockade. Sprigge and Harper (2008) cited an incidence of 0.91 percent recognized accidental
dural punctures at the time of epidural analgesia in more than 18,000 women. Personnel and
facilities must be immediately available to manage this complication as described on page 504.

**Ineffective Analgesia.** Using currently popular continuous epidural infusion regimens such as
0.125-percent bupivacaine with 2-mg/mL fentanyl, 90 percent of women rate their pain relief as
good to excellent (Sharma, 1997). Alternatively, a few women find epidural analgesia to be
inadequate for labor. In a study of almost 2000 parturients, Hess and associates (2001) found that
approximately 12 percent complained of three or more episodes of pain or pressure. Risk factors
for such breakthrough pain included nulliparity, heavier fetal weights, and epidural catheter
placement at an earlier cervical dilatation. Dresner and colleagues (2006) reported that epidural
analgesia was more likely to fail as body mass index increased. If epidural analgesia is allowed to
dissipate before another injection of anesthetic drug, subsequent pain relief may be delayed,
incomplete, or both.

In some women, epidural analgesia is not sufficient for cesarean delivery. For example, in a
Maternal Fetal Medicine Units (MFMU) Network study, 4 percent of women initially given epidural analgesia required a general anesthetic for cesarean delivery (Bloom, 2005). Also at times, perineal analgesia for delivery is difficult to obtain, especially with the lumbar epidural technique. When this situation is encountered, pudendal block or systemic analgesia or rarely general anesthesia may be added.

**Hypotension.** Sympathetic blockade from epidurally injected analgesic agents may cause hypotension and decreased cardiac output. According to Miller and coworkers (2013), hypotension is more common—20 percent—in women with an admission pulse pressure < 45 mm Hg compared with 6 percent in those whose pulse pressure is > 45 mm Hg. In normal pregnant women, hypotension induced by epidural analgesia usually can be prevented by rapid infusion of 500 to 1000 mL of crystalloid solution as described for spinal analgesia. Danilenko-Dixon and associates (1996) showed that maintaining a lateral position compared with the supine position minimized hypotension. Despite these precautions, hypotension is the most frequent side effect and is severe enough to require treatment in a third of women (Sharma, 1997).

**Central Nervous Stimulation.** Convulsions are an uncommon but serious complication, the immediate management of which was described previously (p. 507). Also cited was the case described by Smarkusky and coworkers (2006) of acute onset of intrapartum headache due to a postdural pneumocephalus.

**Maternal Fever.** Fusi and colleagues (1989) observed that the mean temperature increased in laboring women given epidural analgesia. Subsequently, several randomized and retrospective cohort studies have confirmed that some women develop intrapartum fever following this procedure. Many studies are limited by inability to control for other risk factors, such as labor length, duration of ruptured membranes, and number of vaginal examinations. With this in mind, the frequency of intrapartum fever associated with epidural analgesia was found by Lieberman and O’Donoghue (2002) to be 10 to 15 percent above the baseline rate.

The two general theories concerning the etiology of maternal hyperthermia are *maternal-fetal infection* or *dysregulation of body temperature*. Dashe and coworkers (1999) studied placental histopathology in laboring women given epidural analgesia and identified intrapartum fever only when there was placent alinflammation. This suggests that fever is due to infection. The other proposed mechanisms include alteration of the hypothalamic thermoregulatory set point, impairment of peripheral thermoreceptor input to the central nervous system with selective blockage of warm stimuli, or imbalance between heat production and heat loss. Sharma (2014) randomized 400 nulliparas with labor epidural analgesia to receive cefoxitin 2 g prophylactically versus placebo. It was hypothesized that epidural-related fever was due to infection and that prophylactic antimicrobial use should significantly reduce the rate of fever. Approximately equal proportions—about 40 percent—of women developed fever ≥ 38°C during labor. This result suggested that infection was unlikely to be the cause of fever associated with epidural analgesia during labor. Whatever the mechanism, women with persistent fever are usually treated with antimicrobials for presumed chorioamnionitis.

**Back Pain.** An association between epidural analgesia and back pain has been reported by some but not all. In a prospective cohort study, Butler and Fuller (1998) reported that back pain after delivery was common with epidural analgesia, however, persistent pain was uncommon. Based on their systematic review, Lieberman and O’Donoghue (2002) concluded that available data do not support an association between epidural analgesia and development of de novo, long-term...
Miscellaneous Complications. A spinal or epidural hematoma is a rare complication of an epidural catheter (Grant, 2007). Epidural abscesses are equally rare (Darouiche, 2006). Uncommonly, the plastic epidural catheter is sheared off (Noblett, 2007).

Effect on Labor
Most studies, including the combined five randomized trials from Parkland Hospital shown in Table 25-8, report that epidural analgesia prolongs labor and increases the use of oxytocin stimulation. Alexander and associates (2002) examined the effects of epidural analgesia on the Friedman (1955) labor curve described in Chapter 22 (p. 445). There were 459 nulliparas randomly assigned to patient-controlled epidural analgesia or patient-controlled intravenous meperidine. Compared with original Friedman criteria, epidural analgesia prolonged the active phase of labor by 1 hour. As further shown in Table 25-8, epidural analgesia also increased the need for operative vaginal delivery because of prolonged second-stage labor, but importantly, without adverse neonatal effects (Chestnut, 1999). This association between epidural analgesia and prolonged second-stage labor as well as operative vaginal delivery has been attributed to local-anesthetic induced motor blockade and resultant impaired maternal expulsive efforts. Craig and colleagues (2014) randomized 310 nulliparous women with labor epidural analgesia to bupivacaine plus fentanyl or fentanyl alone during second-stage labor. Epidural bupivacaine analgesia did cause motor blockade during the second stage, however, the duration of the second stage was not increased. Neither obstetrical nor neonatal outcomes were different between the two study groups. Patient satisfaction was high, irrespective of the method.

| TABLE 25-8. Selected Labor Events in 2703 Nulliparous Women Randomized to Epidural Analgesia or Intravenous Meperidine Analgesia |
Fetal Heart Rate. Hill and associates (2003) examined the effects of epidural analgesia with 0.25-percent bupivacaine on fetal heart rate patterns. Compared with intravenous meperidine, no deleterious effects were identified. Reduced beat-to-beat variability and fewer accelerations were more common in fetuses whose mothers received meperidine (Chap. 24, p. 479). Based on their systematic review, Reynolds and coworkers (2002) reported that epidural analgesia was associated with improved neonatal acid-base status compared with meperidine.

Cesarean Delivery Rates. A contentious issue in the past was whether epidural analgesia increased the risk for cesarean delivery. Evidence that it did was from the era when dense blocks of local anesthetic agents were used that impaired motor function and therefore likely did contribute to increased rates of cesarean delivery. As techniques were refined, however, many investigators believed that epidural administration of dilute anesthetic solutions did not increase cesarean delivery rates. Some observational studies have suggested a decreased risk for cesarean delivery with oxytocin induction (Hants, 2013).

Several studies conducted at Parkland Hospital were designed to answer this and related questions. From 1995 to 2002, a total of 2703 nulliparas at term and in spontaneous labor were enrolled in five trials to evaluate epidural analgesia techniques compared with methods of intravenous meperidine administration. The results from these are summarized in Figure 25-5 and show that epidural analgesia does not significantly increase cesarean delivery rates.

$^a$Data are presented as n (%) or mean ± SD.

$^b$First stage = initiation of analgesia to complete cervical dilatation.

Adapted from Sharma, 2004.
Yancey and colleagues (1999) described the effects of an on-demand labor epidural analgesia service at Tripler Army Hospital in Hawaii. This followed a policy change in military medical centers. As a result, the incidence of labor epidural analgesia increased from 1 percent before the policy to 60 percent within 2 years. The primary cesarean delivery rate was 13.4 percent before and 13.2 percent after this dramatic change. In a follow-up study, Yancey and coworkers (2001) reported that fetal malpresentations at vaginal delivery were not more common after epidural usage increased. The only significant difference that they found was an increased duration of second-stage labor of approximately 25 minutes (Zhang, 2001).

Based on these randomized studies and a metaanalysis of 14 such trials, Sharma and Levenc (2003) and Leighton and Halpern (2002) concluded that epidural analgesia is not associated with an increased cesarean delivery rate.

**Timing of Epidural Placement**

In several retrospective studies, epidural placement in early labor was linked to an increased risk
of cesarean delivery (Lieberman, 1996; Rogers, 1999; Seyb, 1999). These observations prompted at least five randomized trials, which showed that timing of epidural placement has no effect on the risk of cesarean birth, forceps delivery, or fetal malposition (Chestnut, 1994a,b; Luxman, 1998; Ohel, 2006; Wong, 2005, 2009). Thus, withholding epidural placement until some arbitrary cervical dilation has been attained is unsupportable and serves only to deny women maximal labor pain relief. The American College of Obstetricians and Gynecologists (2013b) recommends that the decision for epidural analgesia should be made individually with each patient and that women should not be required to reach 4 to 5 cm cervical dilation before receiving epidural analgesia.

Safety

The relative safety of epidural analgesia is reflected by the extraordinary experiences reported by Crawford (1985) from the Birmingham Maternity Hospital in England. From 1968 through 1985 more than 26,000 women were given epidural analgesia for labor, and there were no maternal deaths. The nine potentially life-threatening complications followed either inadvertent intravenous or intrathecal injection of lidocaine, bupivacaine, or both. Similarly, according to the Confidential Enquiries into Maternal Deaths in the United Kingdom between 2003 and 2005, there were few anesthesia-related deaths associated with epidural use (Lewis, 2007).

There were no anesthesia-related maternal deaths among nearly 20,000 women who received epidural analgesia in the MFMU Network study cited earlier (Bloom, 2005). And finally, Ruppen and associates (2006) reviewed data from 27 studies involving 1.4 million pregnant women who received epidural analgesia. They calculated risks of 1:145,000 for deep epidural infection, 1:168,000 for epidural hematoma, and 1:240,000 for persistent neurological injury.

Contraindications

As with spinal analgesia, contraindications to epidural analgesia include actual or anticipated serious maternal hemorrhage, infection at or near the puncture site, and suspicion of neurological disease (see Table 25-6).

Thrombocytopenia. Although low platelet counts are intuitively worrisome, the level at which epidural bleeding might develop is unknown according to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007). Epidural hematomas are rare, and incidence of nerve damage from a hematoma is estimated to be 1 in 150,000 (Grant, 2007). The American College of Obstetricians and Gynecologists (2013b) has concluded that women with a platelet count of 50,000 to 100,000/μL may be candidates for regional analgesia.

Anticoagulation. Women receiving anticoagulation therapy who are given regional analgesia are at increased risk for spinal cord hematoma and compression (Chap. 52, p. 1039). The American College of Obstetricians and Gynecologists (2013b) has concluded the following:

1. Women receiving unfractionated heparin therapy should be able to receive regional analgesia if they have a normal activated partial thromboplastin time (aPTT)
2. Women receiving prophylactic doses of unfractionated heparin or low-dose aspirin are not at increased risk and can be offered regional analgesia
3. For women receiving once-daily low-dose low-molecular-weight heparin, regional analgesia should not be placed until 12 hours after the last injection
4. Low-molecular-weight heparin should be withheld for at least 2 hours after epidural catheter removal
5. The safety of regional analgesia in women receiving twice-daily low-molecular-weight heparin has not been studied sufficiently. It is not known whether delaying regional analgesia for 24 hours after the last injection is adequate.

**Severe Preeclampsia-Eclampsia.** Potential concerns with epidural analgesia in those with severe preeclampsia include hypotension as well as hypertension from pressor agents given to correct hypotension. Additionally, there is the potential for pulmonary edema following infusion of large volumes of crystalloid. These are outweighed by disadvantages of general anesthesia. Tracheal intubation may be difficult because of upper airway edema. Moreover, general anesthesia can lead to severe, sudden hypertension that can cause pulmonary or cerebral edema or intracranial hemorrhage.

With improved techniques for infusion of dilute local anesthetics into the epidural space, most obstetricians and obstetrical anesthesiologists have come to favor epidural blockade for labor and delivery in women with severe preeclampsia. There seems to be no argument that epidural analgesia for women with severe preeclampsia-eclampsia can be safely used when trained anesthesiologists and obstetricians are responsible for the woman and her fetus. In a study from Parkland Hospital, Lucas and colleagues (2001) randomly assigned 738 women with hypertension to epidural analgesia or patient-controlled intravenous analgesia during labor. A standardized protocol for prehydration, incremental epidural administration, and ephedrine use was employed. They concluded that labor epidural analgesia was safe in women with hypertensive disorders.

Women with severe preeclampsia have remarkably diminished intravascular volume compared with normal pregnancy (Zeeman, 2009). Conversely, total body water is increased because of the capillary leak caused by endothelial cell activation (Chap. 40, p. 734). This imbalance is manifested as pathological peripheral edema, proteinuria, ascites, and total lung water. For all of these reasons, aggressive volume replacement increases the risk for pulmonary edema, especially in the first 72 hours postpartum. In one study, Hogg and associates (1999) reported that 3.5 percent of women with severe preeclampsia developed pulmonary edema when preloaded without a protocol limitation to volume. Importantly, this risk can be reduced or obviated with judicious prehydration—usually with 500 to 1000 mL of crystalloid solution. Specifically, in the study by Lucas and colleagues (2001) cited earlier, there were no instances of pulmonary edema among the women in whom the crystalloid preload was limited to 500 mL. Moreover, vasodilation produced by epidural blockade is less abrupt if the analgesia level is achieved slowly with dilute solutions of local anesthetic agents. This allows maintenance of blood pressure while simultaneously avoiding infusion of large crystalloid volumes.

With vigorous intravenous crystalloid therapy, there is also concern about development of cerebral edema (Chap. 40, p. 745). Finally, Heller and coworkers (1983) demonstrated that most cases of pharyngolaryngeal edema were related to aggressive volume therapy.

**Epidural Opiate Analgesia**

Injection of opiates into the epidural space to relieve pain from labor has become popular. Their mechanism of action derives from interaction with specific receptors in the dorsal horn and dorsal roots. Opiates alone usually will not provide adequate analgesia, and they most often are given with a local anesthetic agent such as bupivacaine. The major advantages of using such a combination are the rapid onset of pain relief, a decrease in shivering, and less dense motor blockade. Side effects are common and include pruritus and urinary retention. Naloxone, given intravenously, will abolish these symptoms without affecting the analgesic action.
Combined Spinal–Epidural Techniques

The combination of spinal and epidural techniques has increased in popularity and may provide rapid and effective analgesia for labor and for cesarean delivery. An introducer needle is first placed in the epidural space. A small-gauge spinal needle is then introduced through the epidural needle into the subarachnoid space—this is called the needle-through-needle technique (see Figure 25-3). A single bolus of an opioid, sometimes in combination with a local anesthetic, is injected into the subarachnoid space. The spinal needle is withdrawn, and an epidural catheter is then placed through the introducer needle. A subarachnoid opioid bolus results in the rapid onset of profound pain relief with virtually no motor blockade. The epidural catheter permits repeated analgesia dosing. Miro (2008) compared epidural analgesia with combined spinal-epidural analgesia for labor in 6497 women and found the overall outcomes and complications to be similar for the two techniques. In a randomized comparison, however, Abrão and colleagues (2009) reported that combined spinal-epidural analgesia was associated with a greater incidence of fetal heart rate abnormalities related to uterine hypertonus than was epidural analgesia alone. Beamon and coworkers (2014) reported similar results.

Continuous Spinal Analgesia During Labor

There is emerging interest in continuous spinal analgesia for relief of labor pain. This neuraxial technique was first used more than 60 years ago (Hinebaugh, 1944). Frequent severe postdural puncture headaches led to its abandonment. With redesigned needles and catheters, Arkoosh (2008) subsequently randomized 429 women to either continuous spinal or conventional epidural analgesia during labor. There were no differences in complications between these two neuraxial techniques. However, the technique remains investigational.

Local Infiltration for Cesarean Delivery

A local block is occasionally useful to augment an inadequate or “patchy” regional block that was given emergently. Rarely, local infiltration may be needed to perform an emergency cesarean delivery to save the life of a fetus in the absence of anesthesia support. Young (2012) reviewed regional analgesia techniques used for cesarean delivery that provide analgesia to the parietal peritoneum as well as skin and muscles of the anterior abdominal wall.

In one technique, the skin is infiltrated along the proposed incision, and the subcutaneous, muscle, and rectus sheath layers are injected as the abdomen is opened. A dilute solution of lidocaine—30 mL of 2-percent with 1:200,000 epinephrine diluted with 60 mL of normal saline—is prepared, and a total of 100 to 120 mL is infiltrated. Injection of large volumes into the fatty layers, which are relatively devoid of nerve supply, is avoided to limit the total dose of local anesthetic needed.

A second technique involves a field block of the major branches supplying the abdominal wall, to include the 10th, 11th, and 12th intercostal nerves and the ilioinguinal and genitofemoral nerves. As shown in Figure 25-6, the former group of nerves is located at a point midway between the costal margin and iliac crest in the midaxillary line. The latter group is found at the level of the external inguinal ring. Only one skin puncture is made at each of the four sites (right and left sides). At the intercostal block site, the needle is directed medially, and injection is carried down to the transversalis fascia, avoiding injection of the subcutaneous fat. Approximately 5 to 8 mL of 0.5-percent lidocaine is injected. The procedure is repeated at a 45-degree angle cephalad and caudad.
to this line. The other side is then injected. At the ilioinguinal and genitofemoral sites, the injection is started at a site 2 to 3 cm lateral from the pubic tubercle at a 45-degree angle. Finally, the skin overlying the planned incision is injected.

**FIGURE 25-6** Local anesthetic block for cesarean delivery. The first injection site is halfway between the costal margin and iliac crest in the midaxillary line to block the 10th, 11th, and 12th intercostal nerves. A second injection at the external inguinal ring blocks branches of the genitofemoral and ilioinguinal nerves. These sites are infiltrated bilaterally. A final site is along the line of proposed skin incision.

**GENERAL ANESTHESIA**

Trained personnel and specialized equipment—including fiberoptic intubation—are mandatory for the safe use of general anesthesia. This is because a common cause of death cited for general anesthesia is failed intubation. This occurs in approximately 1 of every 250 general anesthetics
administered to pregnant women—a tenfold higher rate than in nonpregnant patients (Hawkins, 2011; Quinn, 2013). The American College of Obstetricians and Gynecologists (2013b) has concluded that this relative increase in morbidity and mortality rates suggests that neuraxial analgesia is the preferred method of pain control and should be used unless contraindicated (see Table 25-6). Indeed, in two reports from the MFMU Network, 93 percent of more than 54,000 cesarean deliveries were performed using neuraxial analgesia (Bloom, 2005; Brookfield, 2013). Butwick and coworkers (2014) cited a higher incidence of general anesthesia use among non-white women.

**Patient Preparation**

Before anesthesia induction, several steps should be taken to help minimize the complication risks. These include antacid use, lateral uterine displacement, and preoxygenation.

Antacid administration shortly before anesthesia induction has probably decreased mortality rates from general anesthesia more than any other single practice. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) recommends timely administration of a nonparticulate antacid, an H$_2$-receptor antagonist, or metoclopramide. For many years, we have recommended administration of 30 mL of Bicitra—sodium citrate with citric acid—a few minutes before anesthesia induction by either general or major neuraxial block. If more than 1 hour has passed after the first dose was given and anesthesia has not yet been induced, then a second dose is given.

Lateral uterine displacement is also provided as the uterus may compress the inferior vena cava and aorta when the mother is supine. With uterine displacement, the duration of general anesthesia has less effect on neonatal condition than if the woman remains supine (Crawford, 1972).

Last, because functional reserve lung capacity is reduced, the pregnant woman becomes hypoxemic more rapidly during periods of apnea than do nonpregnant patients. Obesity exacerbates this tendency (McClelland, 2009). To minimize hypoxia between the time of muscle relaxant injection and intubation, it is important first to replace nitrogen in the lungs with oxygen. This preoxygenation is accomplished by administering 100-percent oxygen via face mask for 2 to 3 minutes before anesthesia induction. In an emergency, four vital capacity breaths of 100-percent oxygen via a tight breathing circuit will provide similar benefit (Norris, 1985).

**Induction of Anesthesia**

Thiopental given intravenously was widely used and offered easy and rapid induction, prompt recovery, and minimal risk of vomiting. Unfortunately, this thiobarbiturate is no longer available in the United States because the sole European manufacturer stopped production on the basis that the drug was also being used for capital punishment (American Society of Anesthesiologists, 2011). It was deemed “an unfortunate irony that many more lives will be lost or put in jeopardy as a result of not having thiopental available for its legitimate medical use.” Drugs now being used in lieu of thiopental include propofol or etomidate. Propofol has the undesirable side effect of hypotension.

Ketamine also may be used to render a patient unconscious. Doses of 1 mg/kg induce general anesthesia. Alternatively, given intravenously in low doses of 0.2 to 0.3 mg/kg, ketamine may be used to produce analgesia and sedation just before vaginal delivery. Ketamine may also prove useful in women with acute hemorrhage because it is not associated with hypotension. Conversely, it usually causes a rise in blood pressure, and thus it generally should be avoided in women who are already hypertensive. Unpleasant delirium and hallucinations are commonly induced by this
Intubation

Immediately after a patient is rendered unconscious, a muscle relaxant is given to aid intubation. Succinylcholine, a rapid-onset and short-acting agent, frequently is used. Cricoid pressure—the Sellick maneuver—is applied by a trained assistant to occlude the esophagus from the onset of induction until intubation is completed. Before the operation begins, proper placement of the endotracheal tube must be confirmed.

Failed Intubation

Although uncommon, failed intubation is a major cause of anesthesia-related maternal mortality. A history of prior difficult intubation and a careful anatomical assessment of the neck and the maxillofacial, pharyngeal, and laryngeal structures may help predict intubation complications. Even in cases in which the initial airway assessment was unremarkable, edema may develop intrapartum and present considerable challenges. Morbid obesity is also a major risk factor for failed or difficult intubation. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) stresses the importance of appropriate preoperative preparation. This includes the immediate availability of specialized equipment such as different-shaped laryngoscopes, laryngeal mask airways, fiberoptic bronchoscope, and transtracheal ventilation set, as well as liberal use of awake oral intubation techniques.

Management. An important principle is to start the operative procedure only after it has been ascertained that tracheal intubation has been successful and that adequate ventilation can be accomplished. Even with an abnormal fetal heart rate pattern, cesarean delivery initiation will only serve to complicate matters if there is difficult or failed intubation. Frequently, the woman must be allowed to awaken and a different technique used, such as an awake intubation or regional analgesia.

Following failed intubation, the woman is ventilated by mask and cricoid pressure is applied to reduce the aspiration risk. Surgery may proceed with mask ventilation, or the woman may be allowed to awaken. In those cases in which the woman has been paralyzed and in which ventilation cannot be reestablished by insertion of an oral airway, by laryngeal mask airway, or by use of a fiberoptic laryngoscope to intubate the trachea, then a life-threatening emergency exists. To restore ventilation, percutaneous or even open cricothyrotomy is performed, and jet ventilation begun. Failed intubation drills have been recommended to optimize response to such an emergency.

Gas Anesthetics

Once the endotracheal tube is secured, a 50:50 mixture of nitrous oxide and oxygen is administered to provide analgesia. Usually, a volatile halogenated agent is added to provide amnesia and additional analgesia. The mechanisms of action of inhaled anesthetics have been reviewed by Campagna and associates (2003).

The most commonly used volatile anesthetics in the United States include isoflurane and two of its derivatives, desflurane and sevoflurane. They are usually added in low concentrations to the nitrous oxide-oxygen mixture to provide amnesia. They are potent, nonexplosive agents that produce remarkable uterine relaxation when given in high concentrations. These are used when
relaxation is a requisite, such as for internal podalic version of the second twin, breech decomposition, and replacement of the acutely inverted uterus.

**Extubation**

The endotracheal tube may be safely removed only if the woman is conscious to a degree that enables her to follow commands and is capable of maintaining oxygen saturation with spontaneous respiration. Consideration should be given to emptying the stomach via a nasogastric tube before extubation. As induction has become safer, extubation may now be more perilous. Of 15 anesthesia-related deaths of pregnant women from 1985 to 2003 in Michigan, none occurred during induction, whereas five resulted from hypoventilation or airway obstruction during emergence, extubation, or recovery (Mhyre, 2007).

**Aspiration**

Massive gastric acidic inhalation may cause pulmonary insufficiency from aspiration pneumonitis. Such pneumonitis has in the past been the most common cause of anesthetic deaths in obstetrics and therefore deserves special attention. To minimize this risk, antacids should be given routinely, intubation should be accompanied by cricoid pressure, and regional analgesia should be employed when possible.

**Fasting**

According to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) and the American College of Obstetricians and Gynecologists (2013a), there are insufficient data regarding fasting times for clear liquids and the risk of pulmonary aspiration during labor. Recommendations are that modest amounts of clear liquids such as water, clear tea, black coffee, carbonated beverages, and pulp-free fruit juices be allowed in uncomplicated laboring women. Obvious solid foods should be avoided. A fasting period of 6 to 8 hours, depending on the type of food ingested, is recommended for uncomplicated parturients undergoing elective cesarean delivery or puerperal tubal ligation.

O’Sullivan (2009) randomized 2426 low-risk nulliparas to consume either water and ice chips alone or small amounts of bread, biscuits, vegetables, fruits, yogurt, soup, and fruit juice. Approximately 30 percent of women in each arm of the study underwent cesarean delivery. No cases of aspiration occurred during the study, although approximately a third of women in each study arm vomited during labor or delivery. Epidural analgesia during labor was used in this study, although the authors did not report the type of anesthesia used for cesarean deliveries. Presumably neuraxial analgesia was used for cesarean deliveries, and this greatly minimized the pulmonary aspiration risk associated with general anesthesia. Given the low prevalence of aspiration, this trial, albeit large, was not powered to measure whether feeding during labor was safe. Our policy at Parkland Hospital is to prohibit oral intake during labor and delivery.

**Pathophysiology**

In 1952, Teabeaut demonstrated experimentally that if the pH of aspirated fluid was below 2.5, severe chemical pneumonitis developed. It was later demonstrated that the gastric juice pH of nearly half of women tested intrapartum was < 2.5 (Taylor, 1966). The right mainstem bronchus usually offers the simplest pathway for aspirated material to reach the lung parenchyma, and therefore, the right lower lobe is most often involved. In severe cases, there is bilateral
widespread involvement.

The woman who aspirates may develop evidence of respiratory distress immediately or several hours after aspiration, depending in part on the material aspirated and the severity of the response. Aspiration of a large amount of solid material causes obvious airway obstruction signs. Smaller particles without acidic liquid may lead to patchy atelectasis and later to bronchopneumonia.

When highly acidic liquid is inspired, decreased oxygen saturation along with tachypnea, bronchospasm, rhonchi, rales, atelectasis, cyanosis, tachycardia, and hypotension are likely to develop. At the injury sites, there is pulmonary capillary leakage and exudation of protein-rich fluid containing numerous erythrocytes into the lung interstitium and alveoli. This causes decreased pulmonary compliance, shunting of blood, and severe hypoxemia. Radiographic changes may not appear immediately, and these may be variable, although the right lung most often is affected. Therefore, chest radiographs alone should not be used to exclude aspiration.

Treatment
The methods recommended for treatment of aspiration have changed appreciably in recent years, indicating that previous therapy was not very successful. Suspicion of aspiration of gastric contents demands close monitoring for evidence of pulmonary damage. Respiratory rate and oxygen saturation as measured by pulse oximetry are the most sensitive and earliest indicators of injury.

Inhaled fluid should be immediately and thoroughly wiped from the mouth and removed from the pharynx and trachea by suction. Saline lavage may further disseminate the acid throughout the lung and is not recommended. If large particulate matter is inspired, bronchoscopy may be indicated to relieve airway obstruction. There is no convincing clinical or experimental evidence that corticosteroid therapy or prophylactic antimicrobial administration is beneficial (Marik, 2001). If clinical evidence of infection develops, however, then vigorous treatment is given. If acute respiratory distress syndrome develops, mechanical ventilation with positive end-expiratory pressure may prove lifesaving (Chap. 47, p. 944).

Induction implies stimulation of contractions before the spontaneous onset of labor, with or without ruptured membranes. When the cervix is closed and uneffaced, labor induction will often commence with cervical ripening, a process that generally employs prostaglandins to soften and open the cervix.
